The vector sum of the two voltages can be found by drawing the parallelogram shown in Fig. 12B. (A parallelogram is a four-sided figure, the opposite sides of which are parallel. Squares and rectangles are parallelograms in which all of the angles are 90°, or right angles.) To form this parallelogram, line BC is drawn parallel to vector OA, and line AC is drawn parallel to vector OB. Vector OC, the diagonal from point O to the point where the broken lines intersect, is the vector sum or "resultant" of the two voltages.

The angle between vectors OA and OB does not have to be a right angle (90°). For example, Fig. 12C shows two voltages that are considerably less than 90° out-of-phase. Whatever the angle may be, the vector sum can be found in the same way. Construct a parallelogram by drawing a line BC parallel to vector OA, and a line AC parallel to OB. The diagonal OC is the resultant.

If you compare the length of OC in Fig. 12C with the length of OC in Fig. 12B, you will find that they are different, even though the lengths of OB and OA are the same in both figures. This is

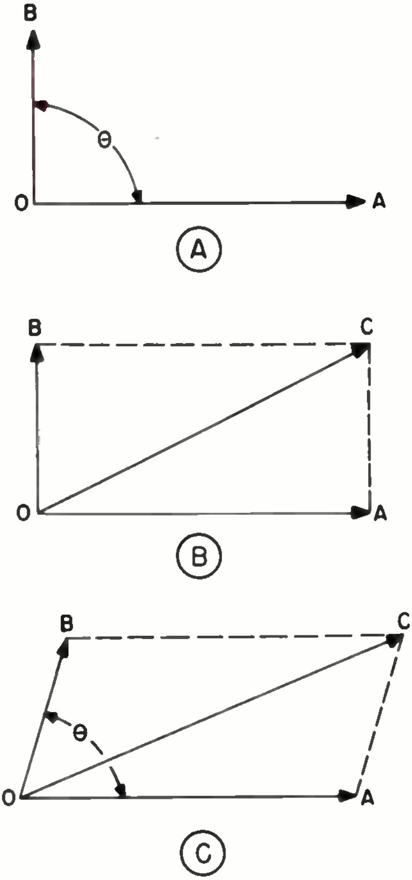

Fig. 12. How vectors are combined.

because the phase angle (θ) or relationship is not the same in both cases. Therefore, as you can see, the vector addition takes both amplitude and phase into account.

There is a form of vector shorthand that you should know about. It is illustrated in Fig. 13. A, C, and E show the standard method of completing the parallelograms. However, since the length of line AC is exactly that of line OB, there is really no need to draw OB -- we can draw AC instead, and thus find the resultant without having to construct the entire parallelogram.

B, D, and F of Fig. 13 show this short-cut method of finding the resultant. As you can see, all you need to do is to draw AC the same length and at the same angle that OB would be if it were drawn, and then draw in OC.

Whether you use the standard or the short-cut method of vector addition, you must make sure that the length of each vector corresponds to the amplitude of the voltage or current it represents, and that the phase angle is correct.

This brief explanation by no means covers the subject fully, but it covers the basic facts you need to know about vectors to work with the fundamental ac circuits used in the following experiments.

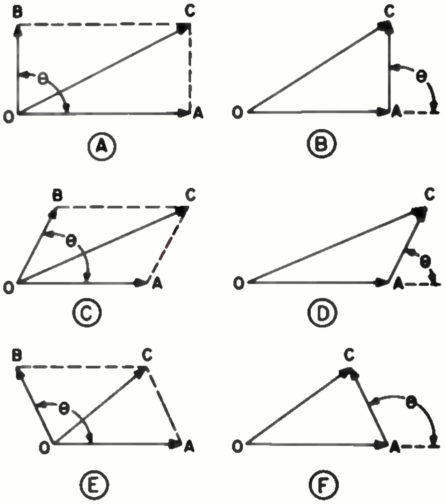

Fig. 13. A comparison between the "shorthand" method of adding two vectors by completing a triangle, and the conventional method of adding by completing a parallelogram. The result is the same in both cases.

EXPERIMENT 26

Purpose: To show that in an ac circuit containing only resistance, the sum of the individual voltage drops equals the source voltage with the greatest voltage being across the highest resistance; and

To show that in an ac circuit containing a capacitor and a resistor in series, the vector sum of the individual voltage drops equals the source voltage.

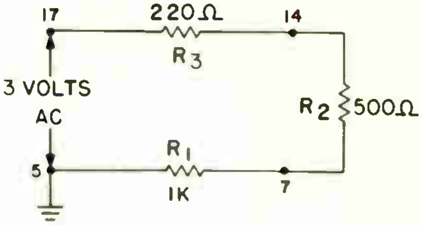

Fig. 26-1. Schematic of circuit for Steps 1,2,3.

Introductory Discussion: In carrying out the following experiment, you will first set up a circuit with three resistors connected in series, apply a specified ac voltage across the series circuit, and measure the ac voltage drop across each of the resistors. The sum of the individual voltage drops should equal the source voltage, because the voltages across the resistors are all in phase with each other.

Next, you will build a circuit with a capacitor in series with a resistor, apply an ac voltage across the combination, and measure the voltage drop across each component. The voltage drop across the capacitor lags behind the current through the capacitor by approximately 90°, but the current through the resistor is in phase with the capacitor current.

Therefore, the voltage across the capacitor is 90° out-of-phase with the voltage across the resistor. You will draw a vector

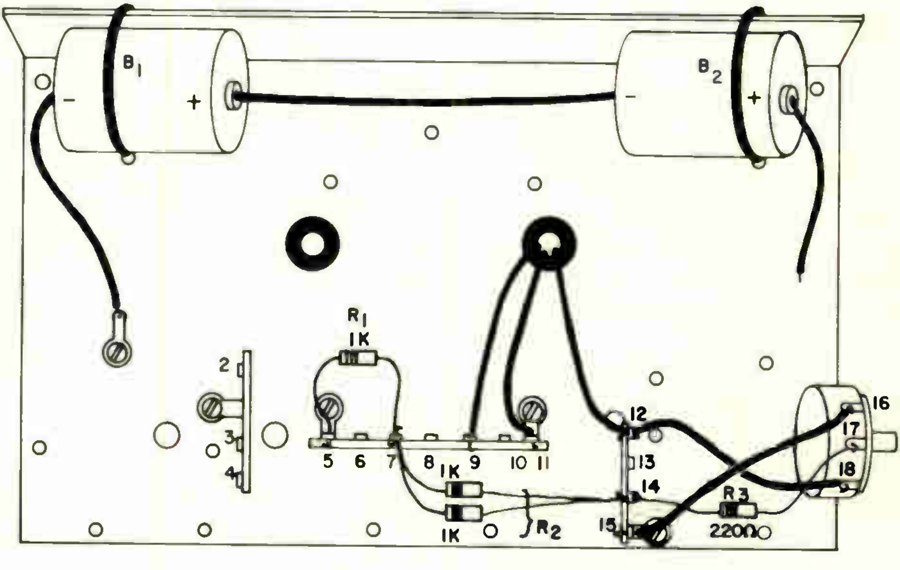

Fig. 26-2. Pictorial of circuit in Fig. 26-1.

diagram to show that the sum of the resistor voltage and the capacitor voltage is equal to the source voltage when the phase difference is taken into account.

Experimental Procedure: For this experiment, you need your experimental chassis, tvom and the following:

3 1K-ohm resistors
1 220-ohm resistor
1 18K-ohm resistor
1 .1-mfd capacitor
2 .25-mfd capacitors

You are to set up the simple series circuit shown in Fig. 26-1 across the ac voltage divider. A pictorial diagram is shown in Fig. 26-2.

Connect a 1K-ohm resistor from terminal 5 to terminal 7. Solder terminal 5. Now connect two 1000-ohm resistors in parallel from terminal 7 to terminal 14. Solder terminal 7. Connect the 220-ohm resistor from terminal 14 to terminal 17 on the potentiometer. Solder both terminals.

Connect the tvom ground clip to the chassis, plug in the power cord, touch the probe to terminal 17 and adjust the potentiometer to produce a voltage of exactly 3 volts ac. Remember to make an approximate adjustment on the 12V range first, and then switch to the 3V range.

Step 1. To measure the ac voltage drop across the 1K-ohm resistor R_1.

Leave the ground lead of the tvom clipped to the chassis and touch the probe to terminal 7. Read the meter carefully, then enter your reading on the first line of Fig. 26-3.

STEP	MEASUREMENT	YOUR VALUE
1	VOLTAGE ACROSS 1K	1.75
2	VOLTAGE ACROSS 500Ω	.83
3	VOLTAGE ACROSS 220Ω	.36
	TOTAL	2.94

Fig. 26-3. Results of Experiment 26.

Step 2. To measure the ac voltage across the 500-ohm resistance R_2.

Transfer the ground lead of the tvom to terminal 7. Touch the probe to terminal 14. Read the voltage, and record your reading on line 2 of Fig. 26-3.

Step 3. To measure the voltage across the 220-ohm resistor R_3.

Move the tvom ground clip to terminal 14. Touch the probe to terminal 17 of the potentiometer. Read the voltage, and enter your reading on line 3 of Fig. 26-3.

Unplug the line cord and remove all of the resistors. Wire the circuit shown in Fig. 26-4. Connect the 18K-ohm resistor from terminal 17 of the potentiometer to terminal 14. Connect the .1-mfd capaci-

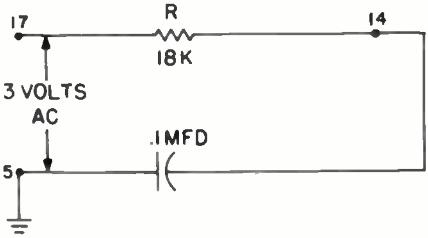

Fig. 26-4. Schematic diagram of the circuit used in Steps 4 and 5.

tor from terminal 14 to terminal 5. Solder all three connections.

Set your meter to the 12V range. Connect the ground clip of the tvom to the chassis, apply power to the voltage divider, and touch the probe to terminal 17. Adjust the potentiometer so that exactly 3 volts ac is applied to the test circuit.

Remember, the potentiometer that controls the supply voltage must be reset every time you change the parts used in an experimental setup. Each combination of parts draws a different current through the potentiometer and thus causes a different voltage drop across it, resulting in a different output from the voltage divider. Since we want to compare the results, we must set the divider voltage to the right value in each case. Also remember to switch your tvom to the 12V range when you start to adjust the potentiometer, and switch to a lower range only after you are sure it is safe to do so.

Step 4. To measure the ac voltage drop across the 18K-ohm resistor.

Connect the tvom negative lead to terminal 14. Touch the probe to the other lead of the resistor at terminal 17. Read the voltage and enter your reading in Fig. 26-5 as the voltage across the resistor for Step 4.

STEP NO.	NATURE OF MEASUREMENT	YOUR READING
4	VOLTAGE ACROSS 18K RESISTOR	1.6V
5	VOLTAGE ACROSS .1 MFD CAPACITOR	2.5V
	TOTAL	4.1V
	VECTOR TOTAL	2.968V

Fig. 26-5. Results of Steps 4 and 5.

Step 5. To measure the ac voltage across the .1-mfd capacitor.

Transfer the black test clip to the chassis. Touch the probe to terminal 14. Measure the voltage, and enter your reading in Fig. 26-5 as the voltage across the capacitor for Step 5. Unplug the power cord.

Discussion: The sum of the voltages you measured in Steps 1, 2 and 3 should be approximately equal to the source voltage. It will probably vary somewhat because of parts tolerances. However, add the voltages you have recorded for Steps 1, 2 and 3, and record your total in Fig. 26-3.

Next, add the voltages you measured in Steps 4 and 5, and record the sum on the line marked "Total" in Fig. 26-5. The sum of the voltages you measured across the capacitor and the resistor in Steps 4 and 5 should be greater than the source voltage, because the two voltage drops are not in phase. In fact, they are 90° out-of-phase. Therefore, we must add these voltages vectorially.

In drawing a vector diagram, we must have some starting point. In working with a series circuit, the current vector is used as a reference because current is common to all parts of a series circuit. The usual procedure is to draw the current vector first as a reference vector. In other words, the other vectors are drawn to show their relationship to the current vector. However, we have an 18K-ohm resistor in the circuit in Fig. 26-4, and the voltage across a resistor is always in phase with the current. Therefore, we can first draw the vector representing the voltage across the resistor and show the relationship of the other voltages to this vector.

As an example, let us suppose that we measured 1.75 volts across the resistor and 2.35 volts across the capacitor. We start the vector diagram by drawing a vector to represent the voltage across the 18K-ohm resistor. To do so, we draw a line OA as shown in Fig. 26-6, with the amount of voltage drawn according to some convenient scale. If we use a scale of 1 volt per inch to draw the vector, line OA will be 1-3/4 inches long.

Fig. 26-6. OA represents the voltage drop across the resistor.

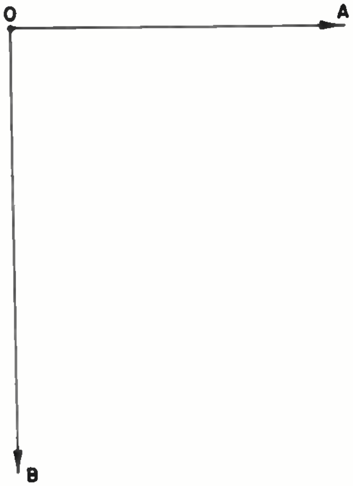

Fig. 26-7. OB represents the voltage drop across the capacitor.

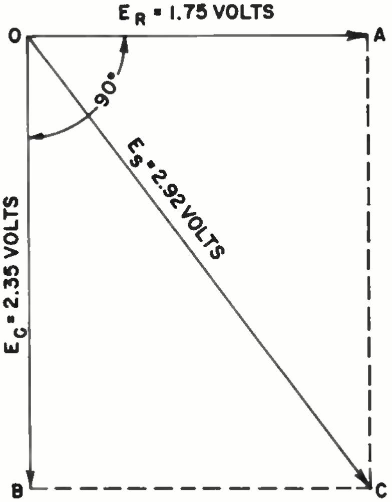

Fig. 26-8. Vector diagram of the sum of the voltage drops across the resistor and capacitor.

The voltage drop across the capacitor lags 90° behind the current, and hence lags 90° behind the resistor voltage drop also. Therefore, we draw the capacitor voltage vector straight downward from the origin O as line OB in Fig. 26-7, using the same scale to determine its length. If we measured 2.35 volts across the capacitor, this line will be a little over 2-5/16 inches long.

Now we complete the parallelogram by drawing line BC parallel to OA and line AC parallel to line OB. Next we draw the diagonal OC, as in Fig. 26-8, to represent the vector sum of the capacitor and resistor voltages. To find out how many volts OC represents, we measure its length and compare it with the voltage per-inch scale we used in drawing OA and OB. If you used a scale of one volt per inch, you should find that the length of OC is close to three inches.

The resultant could also be computed

mathematically by the process commonly used to solve right triangles. If you know how to solve this type of problem, using the Pythagorean Theorem, you can determine the vector sum in this way. If you are not familiar with this type of operation do not worry about it; use the graphical method.

Instructions for Statement No. 26: You have learned that the reactance of a capacitor decreases as its capacitance increases. If the capacitance is large enough, the current in a circuit can be almost as large as it would be if no capacitor were there.

We can, therefore, have a peculiar situation in a circuit that contains a large capacitor in series with the resistor. Even though the voltage drop across the capacitor may be appreciable, the fact that the voltage drops across the capacitor and the resistor are out-of-phase may mean that the voltage across the resistor is just about what it would be if the capacitor were out of the circuit.

To show this, connect the two .25-mfd capacitors in parallel with the .1-mfd capacitor as shown in Fig. 26-9. The total capacitance in the circuit is now .6-mfd.

Apply power to the voltage divider, and adjust the potentiometer until exactly 3 volts is applied between terminal 17 and the chassis. Measure the voltage drops across the 18K-ohm resistor and the .6-mfd capacity, and make notes of both. 7.4V 2.92

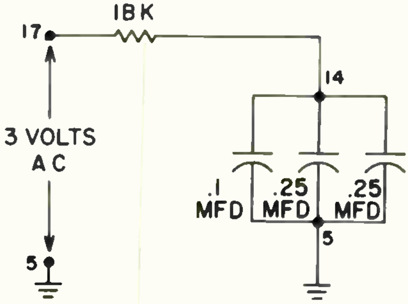

Fig. 26-9. Circuit for Statement 26.

Compare the resistor voltage you obtained in this Statement experiment with the one you found in Step 4. Bearing in mind that the voltage across the resistor is proportional to the current flowing in the circuit, determine what effect increasing the capacitance has had on the current. Finally, compare the voltage drop across the resistor with your source voltage of 3 volts. Complete the Statement below and on the Report Sheet.

Disconnect the power cord and turn off the tvom. Unsolder and remove the three capacitors and the resistor from the chassis, and lay them aside for future experiments.

Statement No. 26: When I used a capacity of .6-mfd instead of .1-mfd, I found that the current through the circuit:

[✓ *(1)*] *increased.*
(2) decreased.
(3) remained the same.

I found the resistor voltage to be:

(1) much higher than
(2) much lower than
[✓ *(3)*] *almost equal to*

the source voltage.

MOUNTING THE CHOKE COIL

Before going on to the next experiment, you must mount the choke coil on

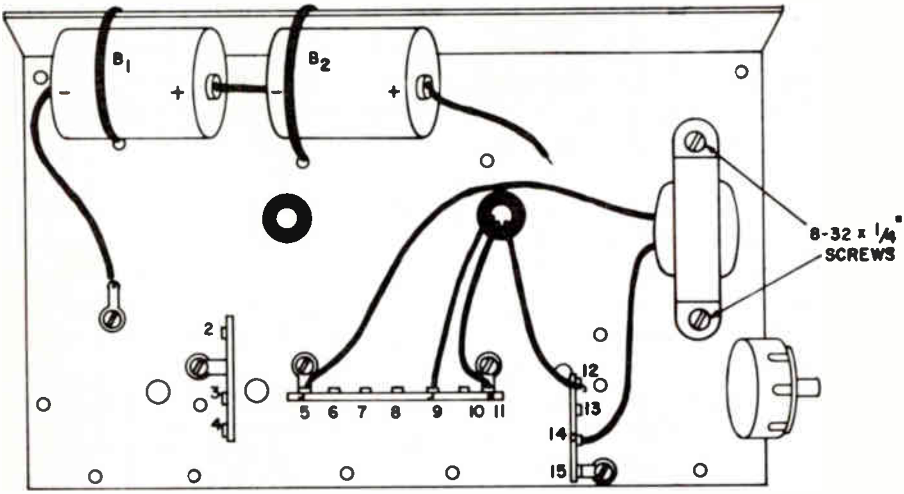

Fig. 14. The choke mounted on the experimental chassis.

the chassis. You will have to move one of the flashlight cells to make room.

You will need the following:

1 Choke coil (C026)
2 1/4" X 8-32 screws
2 8-32 hex nuts
2 No. 8 lockwashers

Move flashlight cell B_2 from the right side of your chassis to the left as shown in Fig. 14. Shorten the wire connecting the two cells together if you wish. To secure the cell to the chassis, you can run a length of hookup wire or string through hole F in the chassis between the unused rubber grommet and the bend in the chassis.

Position the choke on top of the chassis exactly as shown in Fig. 14. Pass 1/4" X 8-32 screws down through the holes in the mounting feet of the choke and through holes M and N in the chassis. Attach with No. 8 lockwashers and 8-32 hex nuts and tighten.

Connect and solder one choke lead to terminal 5. Connect and solder the other choke lead to terminal 14.

EXPERIMENT 27

Purpose: To show that the opposition offered by a coil to the flow of an alternating current is many times its opposition to the flow of a direct current.

Introductory Discussion: Coils are usually wound of copper wire, which, when stretched out, is practically as good a conductor for low frequency ac as it is for dc. Winding the wire in the form of a coil makes no change in its dc resistance, but it does cause a great increase in its inductance, thereby increasing its inductive reactance and its impedance. The opposition that the coil offers to ac, therefore, is much greater than its opposition to dc.

You have studied these properties in your lessons. We shall consider only the opposition of the coil to ac as compared to its opposition to dc in this experiment, but we suggest that you review these lessons to refresh your memory concerning the impedance, reactance, and inductance of coils and the application of Ohm's Law to them.

You will first determine the current through an iron-core choke coil when it is connected in series with a resistance of 1000 ohms to a 3-volt dc source. Next, you will apply 3 volts ac to the circuit, and determine the current. Finally, you will compare the two currents. Your results will show that the alternating current is much less than the direct current.

Experimental Procedure: You will need the experimental chassis, the tvom and the following:

2 1K-ohm resistors

Wire the circuit shown in Fig. 27-1.

The symbol **L** is used on schematic diagrams to represent a coil or an inductance. The parallel lines beside it indicate that the coil has an iron core.

Solder one lead of a 1K-ohm resistor to terminal 14. Connect the other resistor lead to terminal 13. Solder the free end of the positive battery lead to terminal 13.

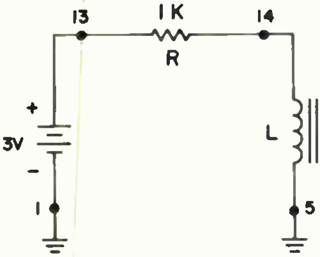

Fig. 27-1. Schematic for Step 1.

Step 1. To measure the dc voltage drop across the 1K-ohm resistor.

First, prepare your tvom for dc measurements on the 3V range. Fasten the ground clip to terminal 14 and touch the probe to terminal 13. Read the meter, and record your reading in Fig. 27-2.

STEP NO.	NATURE OF MEASUREMENT	YOUR VALUE IN VOLTS
1	DC VOLTS ACROSS R	1.75
3	AC VOLTS ACROSS R	.5V

Fig. 27-2. Results of Steps 1 and 3.

Since the resistance is 1000 ohms, the voltage across the resistor in volts will be equal to the current in milliamperes through the resistor. This was demonstrated in an earlier experiment.

Now, disconnect the test leads from the resistor, and unsolder the positive battery lead.

Step 2. To apply an ac voltage equivalent to the dc voltage used in Step 1 to the circuit.

Set up the circuit shown in Fig. 27-3. Unsolder the lead of the 1K-ohm resistor from terminal 13 and solder it to terminal 17 on the potentiometer. Switch the function switch in your tvom to ac. Connect the ground lead to the chassis, apply power to the voltage divider, touch the probe to terminal 17, and adjust the potentiometer to produce a voltage of exactly 3 volts.

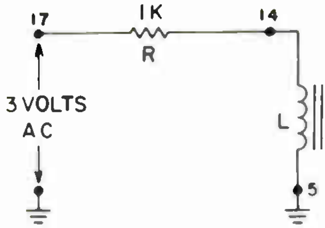

Fig. 27-3. Schematic of the circuit used in Step 2 and Step 3.

Step 3. To measure the ac voltage across the 1K-ohm resistor.

Move the ground clip to terminal 14, and touch the probe to terminal 17. Read the meter carefully on the 3V scale. Record your reading in Fig. 27-2, and unplug the voltage divider.

Discussion. The voltage you measured across the 1K-ohm resistor when a dc voltage was applied in Step 1 should have been considerably greater than the ac voltage drop you measured in Step 3, thus proving that the circuit current was less. Since the only difference between the circuits used for these two steps is the nature of the source voltage, we can say that the opposition offered by a coil is much greater for ac than for dc.

The opposition that your coil offers to alternating current is known as its impedance and is measured in ohms. There are several ways in which it can be determined. One quick method, which does not involve complex equipment and yet is reasonably accurate, is to connect the coil in series with a resistor, apply an ac voltage of known frequency, and measure the voltage drops across the resistor and the coil. Since the voltage drop across each part is proportional to the opposition offered by that part, we can set up the following equation:

$$\frac{E_L}{E_R} = \frac{Z}{R}$$

where E_L is the voltage across the coil, E_R is the voltage across the resistor, R is the resistance of the resistor, and Z is the impedance of the coil. This can be simplified by writing the equation in this form:

$$Z = \frac{E_L \times R}{E_R}$$

For your report on this experiment, you will find the approximate impedance of the coil by using this method. The impedance of the coil establishes the amount of current through the coil at the time of the measurement.

Instructions for Statement No. 27: Use the circuit shown in Fig. 27-3, but reduce the resistance of R to 500 ohms. This can be done by connecting another 1K-ohm resistor in parallel with the one now in series with the choke coil. When you have soldered the resistor in place, connect the tvom to the output of the voltage divider, and apply power. Adjust the potentiometer until a voltage of exactly 3 volts is applied to the coil and resistor.

Measure the ac voltage across the 500-ohm resistance; then measure the voltage across the coil. Use the 3V range for both measurements. Make a note of the readings you get, and unplug the ac power cord. .32V 2.734

To find the approximate impedance of your coil, use the formula

$$Z = \frac{E_L \times R}{E_R}$$

Multiply the voltage across the coil by 500 (the resistance of the resistor). Then divide the result by the voltage across the 500-ohm resistor. The result you get is the approximate impedance of the coil in ohms.

4.5K Ω Make a note of the value you obtained for the impedance of the coil, and then determine the dc resistance of the coil. You can use the ohmmeter section of your tvom to measure the dc resistance, but you must disconnect one lead of the coil in order to do this. Unsolder the choke coil lead from terminal 5, and connect the ground clip to one choke lead and the probe to the other lead. Reconnect the choke lead to terminal 5. Now, compare the impedance of the coil with the dc resistance, and answer the Statement.

300Ω

Statement No. 27: When I compared the dc resistance of the choke coil with its impedance, I found that the resistance was:

[✓ *(1) less than*]
(2) approximately equal to
(3) greater than

the impedance of the coil.

EXPERIMENT 28

Purpose: to show that the voltage drop across a coil is less than 90° out-of-phase with the current flowing through it because the coil has appreciable ac resistance; and

To show that we can find the phase angle by using vectors.

Introductory Discussion: In a previous experiment, you proved that the vector sum of the voltage across a capacitor and a resistor in series is equal to the source voltage, if the drop across the capacitor is considered to be 90° out-of-phase with the resistor voltage.

In any good solid-dielectric capacitor, the ac resistance is so small that it can be ignored. Therefore, we can say that the impedance of such a capacitor is equal to its reactance. Thus, the voltage across the capacitor is 90° out-of-phase with the current through it and 90° out-of-phase with the voltage across any resistor in series with it.

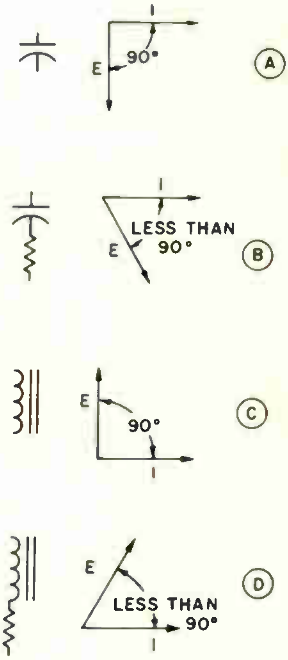

Fig. 28-1. The general phase relationship between the terminal voltage and the current when we have: (A) a pure capacitance; (B) a capacitance plus series resistance; (C) a pure inductance; (D) an inductance plus a series resistance.

However, always remember that the ac voltage we measure across any device is the voltage across the total opposition or impedance of that device. Fig. 28-1 shows the relationships. At A we have shown a device that contains only a capacitor. The phase relationship between the circuit current and the voltage across the terminals of the device is shown at the right; the voltage lags 90° behind the current because the impedance is made up solely of the reactance of the capacitor. If there is any appreciable resistance in the device, however, as shown at B, the phase angle is less than 90°. This device may be an electrolytic capacitor, since an electrolytic does have appreciable internal resistance.

If the impedance of a coil were made up of the coil reactance only, as at C, the coil voltage would *lead* the current by 90°. However, there is probably no coil that has so little resistance that it will act as a pure inductance. Every coil has some ac resistance, and it is always greater than the dc resistance because of skin effect, dielectric losses, and, in iron-core coils, core losses. The skin effect is the tendency of alternating currents to flow only along the surface of the wire rather than throughout its entire cross-section. At higher frequencies, these effects become much more noticeable. Thus, rf coils, which usually have low dc resistances, may have fairly high ac resistances.

The choke coil you will use in these experiments has a dc resistance of at least 400 ohms. Of course, its ac resistance is considerably higher. Unfortunately, there is no direct and simple method of finding its ac resistance; an ohmmeter will measure only the dc resistance.

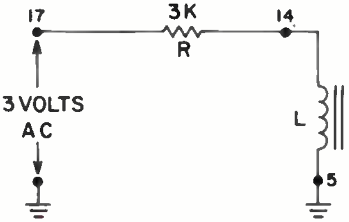

Fig. 28-2. Schematic of circuit used in Step 2.

To take this ac resistance into account, we treat the coil as though it were made up of a pure inductance in series with a resistance as in Fig. 28-1D. We can see what its total impedance is made up of with the aid of a vector diagram. The method we will use in this experiment is often called the 3-voltage vector method of finding the ac resistance and the inductive reactance of coils.

Experimental Procedure: For this experiment, you need the experimental chassis, tvom and the following:

1 3K-ohm resistor, 5%
2 .25-mfd capacitors

Set up the circuit shown in Fig. 28-2. To do this, unsolder and remove the two 1K-ohm resistors used in the last experiment and solder the 3K-ohm resistor in their place between terminals 14 and 17.

Connect the ground clip of the tvom to the chassis. Set the function switch to ac and apply power to your chassis. Touch the probe to terminal 17 and adjust the potentiometer until the voltage is exactly 3 volts, measured on the 3V range.

Step 1. To measure the ac voltage across the 3K-ohm resistor.

STEP NO.	NATURE OF MEASUREMENT	YOUR VALUE IN VOLTS	NRI VALUE IN VOLTS
1	VOLTAGE ACROSS R	1,56	1.5
2	VOLTAGE ACROSS L	2.36	2.25

Fig. 28-3. Results of Steps 1 and 2.

Connect the ground lead from the tvom to terminal 14. Apply power and touch the probe to the other end of the resistor at terminal 17. Read the voltage on the 3V ac scale. Record your reading for Step 1 in Fig. 28-3 as the voltage across R.

Step 2. To measure the ac voltage across the coil.

Clip the ground lead to the chassis and touch the probe to terminal 14. Read the voltage, and enter your reading in Fig. 28-3 as the voltage across L. Unplug the power cord.

Discussion: We are now going to show how the measurements you just made can be used to show that the phase angle between the voltage and current in the coil is less than 90°, and to compute the inductance and ac resistance of a coil. To illustrate our explanation, we will work out these characteristics for the coil on which we made measurements at NRI. In this experiment, you are to determine that the phase angle in your coil is less than 90°, but you do not have to compute the inductance and ac resistance unless you want to do so.

The NRI results for Steps 1 and 2 are given in Fig. 28-3. Yours will not necessarily be the same. If we consider the voltage drop across the coil to be exactly 90° out-of-phase with the voltage drop across the resistor, as it would be in a pure inductance, and add these values vectorially as in Fig. 28-4, our resultant is only 2.7 volts. Since this value is less than the source voltage of 3 volts, the voltage across the coil must not actually be 90° ahead of the resistor voltage. The reason is that the coil has considerable resistance. Using your readings, draw a vector diagram like that in Fig. 28-4 to show that the phase angle in your coil has to be less than 90°.

We don't know what the angle should be, and we can't calculate it without using rather complex mathematics. We can, however, use vectors to solve the problem. The method of doing so is shown in Fig. 28-5. Let's see how to use it.

We already know the three voltages for our vector diagram. What we do not know is the angle between them. To plot the angles, we start by using the voltage we measured across the series resistance

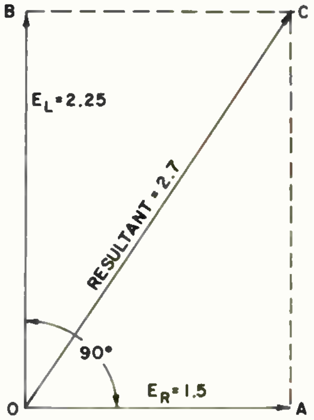

Fig. 28-4. The resultant, which is the vector sum of the voltages across the resistance and inductance, does NOT equal the source voltage.

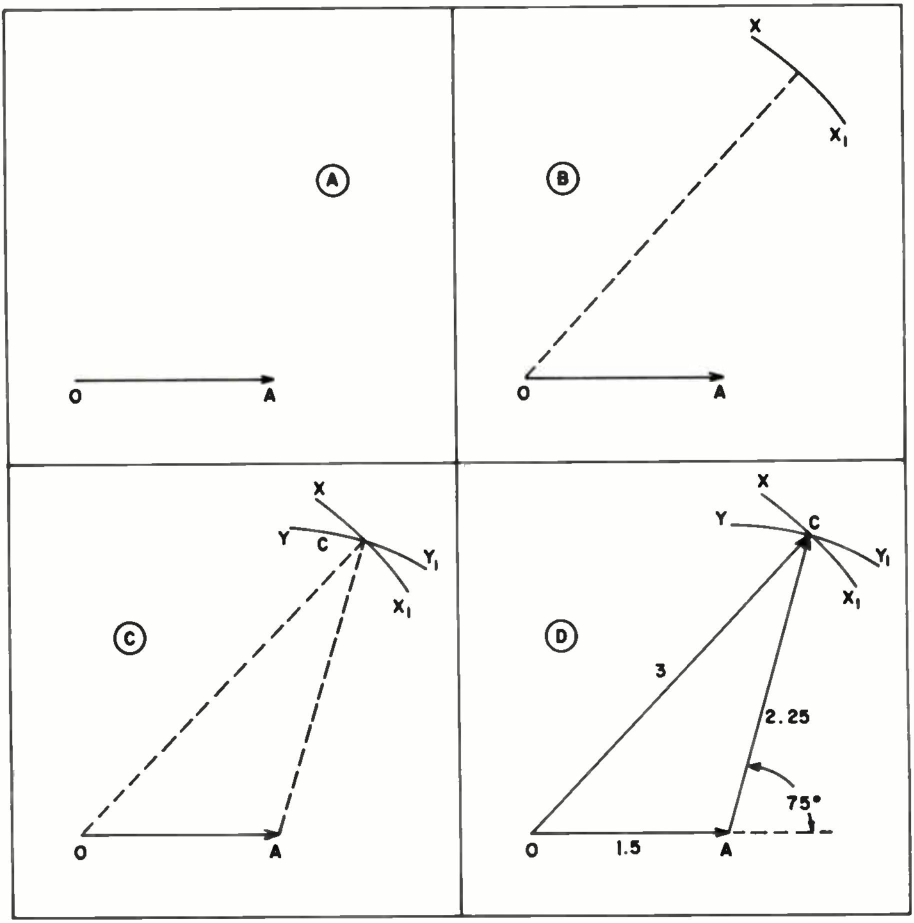

Fig. 28-5. How to use the three-voltage vector method of determining the voltage drop across the ac resistance of the coil, and the vector method of finding the voltage drop across the reactive component of the coil.

as a reference vector because it is in phase with the circuit current.

Using the figures shown in Fig. 28-3 for the coil we measured here at NRI, we plot a line, OA, to represent 1.5 volts. (The diagrams in Fig. 28-5 are *not* drawn to a scale of 1 inch equals 1 volt because of space limitations.) Now, draw your line OA to represent the voltage you measured across the 3K-ohm resistor. Use a scale of 1 inch equals 1 volt.

Using this same scale, we know that the resultant, which we have called OC in our previous vector diagrams, will be 3 inches long; it is our source voltage. It will start at point O. So the next thing we do is to use an ordinary drafting compass to draw an arc, using point O as the center, with a radius of 3 inches. This arc is called X-X_1 in Fig. 28-5B. Point C will fall somewhere on this arc.

As you learned earlier, line AC will be the same length and at the same angle as the other voltage vector, which we called OB in previous diagrams. In this case it is the voltage across the coil, which is 2.25 volts. Therefore, we draw another arc. This time the radius is 2.25 inches, and we use point A as the center. This is called Y-Y_1 in Fig. 28-5C. The point where these two arcs cross is point C. By drawing in lines OC and AC, as shown in Fig. 28-5D, we can find the phase angle between the coil voltage and the resistor voltage. In this vector diagram, the sides of the angle are made up of the line AC and the dashed line. This was explained previously in reference to Fig. 13D. For this particular coil, the angle is 75°. Since the resistor voltage and the circuit current are in phase, we know that the coil voltage is 75° ahead of the coil current.

You need not measure the angle; the important point to see is the phase angle between the current and voltage is less than 90° because the coil is not a pure inductance. This is as far as you need go in your calculations. However, we will show you how additional information can be obtained from these results.

So far, we have a vector diagram in which the sum of the voltage drops across the impedance of the coil and across the series resistance is equal to the source voltage. By using this information, we can find the voltage drops across the reactance and the ac resistance of the coil. From these, we can find the inductance and the ac resistance.

We can consider that the voltage across the coil impedance is the vector sum of two voltages 90° out-of-phase -- one across a pure inductance and one across a resistance.

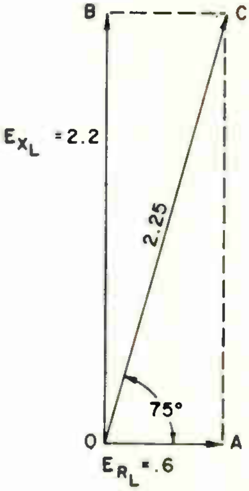

Fig. 28-6. How we find the voltage drop across the reactance and the ac resistance of the coil.

Therefore, we can draw another vector diagram using the coil voltage (line AC in Fig. 28-5D) as the resultant, as shown in Fig. 28-6. In this diagram we call this line OC. We know that it is 75° from the reference vector, and that the voltage across the coil resistance (E_{R_L}) is 90° out-of-phase with the voltage across the coil reactance (E_{X_L}). Therefore, we can draw these voltage vectors at right angles to each other.

So far, we know the angle of the two voltage vectors, but not their length. To find the length, we draw a line down from point C to form a right angle with the horizontal line, to give us point A. Then, we draw another line across from point C to form a right angle with the vertical line, to give us point B. By measuring the length of these vectors, we can find the voltage they represent. For this particular coil, the voltage across the coil resistance (E_{R_L}) equals .6 volt, and the voltage across the coil reactance (E_{X_L}) equals 2.2 volts.

To find the reactance of the coil, we divided E_{X_L} by the current. To find the current, we go back to the voltage across the 3000-ohm series resistance, which we recorded in Fig. 28-3. Our value was 1.5. Dividing this by 3, we get .0005 amperes as the circuit current. Now, dividing E_{X_L} by the current, we have 2.2 divided by .0005, which give us 4400 ohms as the inductive reactance (X_L) of the coil.

To find the inductance, we use the formula:

$$L = \frac{X_L}{2\pi f}$$

where 2π is 6.28 and f is 60, the frequency of the power line voltage. Substituting our values, we have:

$$L = \frac{4400}{6.28 \times 60} = \frac{4400}{376.8} = 11.7 \text{ henrys}$$

We can find the ac resistance of the coil by measuring the length of line OA and dividing this voltage value by the value of the circuit current. The length of line OA is .6 inches, which represents .6 volt. The ac resistance of the NRI coil works out to be .6 ÷ .0005 = 1200 ohms. Notice how much higher the ac resistance is than the dc resistance. The dc resistance of the coil we used was only 400 ohms.

You can determine the inductance and ac resistance of your coil if you wish to do so, but this is not necessary. However, be sure you understand that the ac resistance of a coil is much higher than the dc resistance, and also that the phase angle between the current and voltage in a coil is less than 90° because of the ac resistance of the coil.

Instructions for Statement No. 28: For this statement, you are to find out what happens to the circuit current when a capacitor is placed in parallel with the choke coil in a circuit like that shown in Fig. 28-7. Connecting a capacitor between the terminals of the choke coil provides another path, parallel to the one through the choke coil. Therefore, it would appear that the current through the resistor should increase.

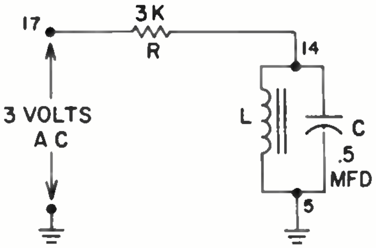

Fig. 28-7. Schematic of circuit used for Statement 28.

With the chassis connected as in Fig. 28-2, plug in the voltage divider, and adjust the potentiometer to get exactly 3 volts at the output between terminal 17 and ground. Measure the voltage across the 3K-ohm resistance and make a note of your reading in the margin of this page. 1.6V

Unplug the chassis, and set up the circuit shown in Fig. 28-7. Connect the two .25-mfd capacitors in parallel from terminal 5 to terminal 14. The two capacitors have a total capacitance of .5 mfd. Apply ac power and adjust the input to 3 volts. Note that the capacitors are in parallel with the choke coil. Now, mea- .31V sure the voltage across the resistor again. Compare this reading with your previous reading and answer the Statement below and on the Report Sheet.

Unplug the voltage divider; then unsolder and remove the two .25-mfd capacitors. Leave the 3K-ohm resistor connected to terminals 14 and 17.

Statement No. 28: When I connected the capacitors in parallel with the choke coil, I found that the circuit current, as indicated by the resistor voltages, was:

(1) the same as
(2) higher than
[✓ *(3)*] *lower than*

it was before the capacitors were connected.

EXPERIMENT 29

Purpose: to show that when a coil and a capacitor are connected in series across a source of ac voltage, the reactance of one tends to cancel that of the other, thus causing the circuit current to increase.

Introductory Discussion: The measurements you have made so far in your ac experiments have shown only that coils and capacitors offer a definite amount of opposition to the flow of alternating currents, and that the voltage across a coil or capacitor is out-of-phase with the current flowing through the device.

We know that the voltage across the inductive reactance of a coil leads the current through the coil by 90°, and that the voltage across a capacitor lags 90° behind the current through the capacitor. Therefore, when a coil and a capacitor are connected in series so that the current flowing through one also flows through the other, the voltages across the capacitor and the inductive reactance of the coil are 180° out-of-phase. As a result, the two voltages tend to cancel each other and the net voltage across the combination of the coil and the capacitor is the difference between them.

If the voltage across the capacitor is greater than the voltage across the coil, the net reactance will be capacitive and the combination will act like a capacitor. On the other hand, if the voltage across the coil is greater, the net reactance will be inductive, and the combination will act like a coil. However, if the two voltages are equal, there will be no reactance -- the only opposition to the circuit current will consist of the ac resistance of the coil and whatever other resistance there may be in the circuit. This condition is known as resonance.

In this experiment, you will first connect a capacitor in series with a resistor and determine the opposition (impedance) the capacitor offers to the flow of ac. You will then place your choke coil in series with the capacitor and the resistor and note the effect on the circuit current. If the current increases, you know that the coil must have reduced the impedance of the circuit. This is evidence that the coil has partly cancelled the opposition of the capacitor to the flow of current.

The amount of cancellation effect any given coil has depends on the capacitance value used with it. This can be shown either mathematically or experimentally. For the experimental approach, we will connect various capacitance values in series with a given coil and measure the voltage drops across the coil and capacitor. When the voltage across the reactive component of the coil equals the voltage across the capacitor, the circuit is at resonance. You will also see that at resonance the voltage across the capacitor and the voltage across the coil may actually exceed the source voltage.

Experimental Procedure: In addition to the ac voltage source, with the 3K-ohm resistance connected to it and your tvom, you will need:

- 2 .25-mfd capacitors
- 1 .1-mfd capacitor

The 3K-ohm resistor should still be connected to terminal 17 of the ac voltage source. Therefore, to form the series circuit shown in Fig. 29-1, unsolder the choke lead from terminal 14 and connect a .25-mfd capacitor from terminal 14 to terminal 5. Solder both connections. Connect the tvom test leads to terminal 17 and the chassis. Apply power to the circuit, and adjust the potentiometer to produce an output of exactly 5 volts. Use the 12-volt range of your tvom.

Step 1. To measure the ac voltage drops across the 3K-ohm resistor and the capacitor.

Connect the ground clip to terminal 14, and touch the probe to terminal 17 of the potentiometer. Enter your reading in Fig. 29-2. Then touch the probe to terminal 5 to measure the voltage across the capacitor, and again enter your reading in the proper space in Fig. 29-2. Unplug the power cord.

Step 2. To determine the effect of adding a coil to the series circuit.

Rewire your circuit as shown in Fig. 29-3. Move the capacitor lead from terminal 14 to terminal 6. Reconnect the free choke lead to terminal 14 and move the other choke lead from terminal 5 to terminal 6.

Fig. 29-4. Record the values found in Step 2.

When you have the circuit set up, apply power to the voltage divider, and adjust the potentiometer for a voltage of exactly 5 volts between terminal 17 and ground.

Connect the ground clip of your tvom to the junction of the resistor and the choke at terminal 14. Touch the probe to terminal 17 of the potentiometer, and measure the voltage drop across the 3K-ohm resistor. Record this reading in the first space in Fig. 29-4. Now, touch the probe to the junction of the choke and capacitor at terminal 6 and measure the voltage across the choke coil. Record your reading in Fig. 29-4.

To measure the voltage drop across the capacitor, move the ground lead of your tvom to the chassis, and touch the probe to terminal 6. Record your reading in Fig. 29-4. (Your readings may not be exactly the same as ours.)

To see if the current has increased, compare the voltage across the resistor in Fig. 29-2 with the reading you recorded in Fig. 29-4. Also, notice the voltages you have recorded for the capacitor and coil in Fig. 29-4.

Step 3. To show the effect on circuit conditions when different values of capacitance are used in combination with the coil.

Use the same circuit shown in Fig. 29-3, but change the value of the capacitor according to the values listed in the first column in Fig. 29-5. Take the measurements exactly as you did in Step 2. However, each time you connect a different value of capacitor in the circuit, make sure you connect the tvom leads from terminal 17 to ground, and set the ac source for a voltage of exactly 5 volts.

Connect a .1-mfd capacitor into the circuit and take the necessary voltage measurements. Record the values. You already have the voltage values for a .25-mfd capacitor in the circuit. Enter the values you recorded in Fig. 29-4 in the proper spaces in Fig. 29-5. You can form a .35-mfd capacitor by connecting a

.25-mfd capacitor in parallel with the .1-mfd capacitor. In a similar way, make up a .5-mfd by putting the two .25-mfd capacitors in parallel, and a .6-mfd by using the two .25-mfd capacitors and the .1-mfd capacitor in parallel. Measure the voltage across the coil, the voltage across the capacitor, and the voltage across the 3K-ohm resistance for each value of capacitance. Record your reading in Fig. 29-5.

When you have completed the readings needed for Fig. 29-5, unplug the voltage divider and unsolder and remove the capacitors and the resistors from the circuit.

Discussion: To show that the voltage drops across the coil and capacitor must in some way oppose or cancel each other, let us use the NRI values in Fig. 29-4 to draw the vector diagram in Fig. 29-6. We must take one additional measurement, however. This is the drop across the coil and the resistor. From this vector, we can determine the phase relationships, the resultant voltage differences in the circuit; and from these voltages, compute the total circuit reactance. You are not required to draw the vector or compute the reactances in this experiment. However, you may do so if you wish.

We can get a great deal of information from the vector diagram in Fig. 29-6. For example, the angle formed by lines BC and BD tells us that the voltage across a coil leads the voltage across the resistor (line OB, which is used here as the reference) by less than 90°. The line, CD, tells us that there is a voltage drop of 3.07 volts across the coil reactance (E_{X_L}), and the short line BD indicates that the voltage drop across the ac resistance of the coil is 1.45 volts.

Line DE is the voltage drop across the reactance of the capacitor (E_{X_C}). We learned in Experiment 27 that the voltage drop across a capacitor is 90° out-of-phase with the source voltage in the circuit. Thus, line DE is drawn straight downward from point D. The length of this line corresponds to 6.5 volts -- the voltage drop across the capacitor.

We now have the voltage drop across the inductive reactance (line CD) and the voltage drop across the capacitive re-

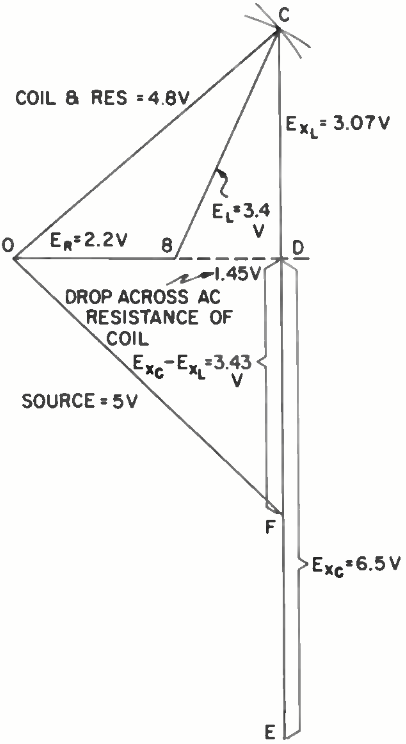

Fig. 29-6. Complete vector diagram of voltage relationship in a circuit consisting of a capacitor, a coil, and resistance connected across a source of ac voltage.

actance (line DE). As you learned in Step 2 of this experiment, these reactances oppose each other, and the net reactance or opposition to the current flow is the difference between the two voltage drops. This is shown in the diagram in Fig. 29-6. Beginning at point E, we subtract 3.07 volts, the length of line CD, from line ED. This leaves a total of 3.43 volts (line DF) as the net drop across the circuit reactance. We can prove that the length of line DF is actually the voltage drop across the net reactance by measuring the line from point F to point O. This is 5 volts -- the voltage of the source.

With this information, we can compute the circuit reactances and see that adding the coil *does* reduce the total reactance in the circuit. To compute the reactance, we divide the voltage drop across the reactance by the amount of current in the circuit, or R = E/I. The current, of course, is equal to the voltage drop across the 3000-ohm series resistor (2.2 volts) divided by 3000, or I = E/R. This works out to be approximately .0007 ampere.

Using the reactance formula, we find that the reactance of the capacitor alone is approximately 10,400 ohms. But when we compute the net reactance in the series circuit, as indicated by line DF in Fig. 29-6, we find that it is approximately 4900 ohms. (We compute the reactance by dividing the net voltage, 3.43 volts, by the circuit current, .0007 amperes.) From this we can see why the voltage drop across the components increased when we put the coil in the circuit. The voltage drops across the coil and capacitor actually opposed each other to produce a lower net reactance in the circuit, which caused an increase in the circuit current. This was indicated by the increase in the voltage drops across the circuit components.

In Step 3, you varied the capacitance value in the series circuit, and from your results that you recorded in Fig. 29-5, you should notice that the voltage drops across the components increased as you increased the value of the capacitance. You may notice that with one value of capacitance, the voltage drops reach their highest values. The fact that the higher voltage drops exist in the circuit shows that the circuit reactance must have become very low. This point is the resonance point for the coil-capacitor combination.

As you increased the capacitance further, you probably noticed that the voltage drops began to decrease. It is not necessary for you actually to reach resonance in this experiment. It is important only that you understand that the voltage drops across the coil-capacitor combination in a series circuit increase as the circuit capacitance is increased.

The resonant point of the series-resonant circuit can be shown graphically as in Fig. 29-7. Notice from the graph

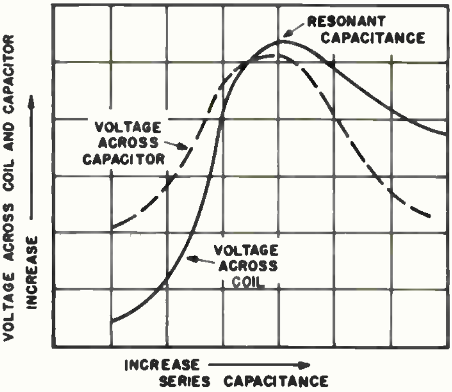

Fig. 29-7. Resonance in a series-resonant circuit.

that the voltage drops across the coil and capacitor increase with an increase in capacitance until a value is reached where both curves reach a maximum. This is the resonant point in the circuit. As the capacitor value is increased further, the voltage drops decrease, as indicated by the curves.

Instructions for Statement No. 29: You need not take any additional readings. Just examine the voltage readings you took across the capacitor in Fig. 29-5, and answer the Statement.

EXPERIMENT 30

Purpose: To show that shunting a capacitor across an inductance in an ac circuit will cause the line current to decrease; and

To show that when the reactance of the coil equals the reactance of the capacitor, the line current becomes a minimum, indicating that the combination has a high impedance.

Introductory Discussion: As you demonstrated in the preceding experiment, the principal characteristic of a series-resonant circuit is that at resonance it acts like a low resistance. This, of course, produces a high current through the circuit and a high voltage drop across the coil and capacitor. There are many circuit applications, however, in which the opposite effect is desirable. One of many practical examples of this is a wave trap designed to filter out undesired frequencies at the input of a radio or television receiver.

As you learned in your lessons, a parallel-resonant circuit at resonance acts like a high resistance. You will prove this by measuring the current in a circuit in which you will connect various capacitors in parallel with the coil.

The current in this circuit must divide between the two components. Part of the current will flow through the capacitor and the remainder through the coil. The circuit acts like a high resistance because the currents of the two branches are 180° out-of-phase. (This is just the opposite of the conditions in a series-resonant circuit, in which the voltages are 180° out-of-phase.) The net circuit current, which is the difference between the currents in the two branches of the parallel circuit, is, therefore, relatively small. In fact, it is just large enough to make up for the losses in the parallel-resonant circuit. As in a series-resonant circuit, these losses are due primarily to the ac resistance of the coil.

If you had an instrument sensitive enough, you could measure the current through the coil as various capacitors were connected across it. As you approached resonance, you would find that there was an increase in the current flowing in the parallel circuit, which would be accompanied by a corresponding decrease in the current in the rest of the circuit. With the equipment we have at hand, however, you can measure only the current flowing through the entire circuit with any degree of accuracy. Therefore, we shall assume that the impedance of the parallel-connected coil and capacitor is at its maximum when the circuit current is at its minimum.

Experimental Procedure: You need the experimental chassis, tvom and the following:

- 2 .25-mfd capacitors
- 1 .1-mfd capacitor
- 1 1K-ohm resistor
- 1 18K-ohm resistor

Construct the circuit shown in Fig. 30-1. Replace the 3000-ohm resistor with a 1000-ohm resistor. Then, unsolder the choke lead from terminal 6 and solder it to terminal 5.

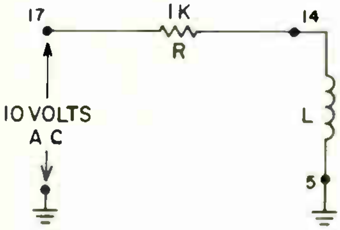

Fig. 30-1. Schematic of the circuit for Step 1.

Apply power to the circuit, and adjust it to produce a voltage of exactly 10 volts across the output of the ac voltage divider between terminal 17 and the chassis.

Step 1. To find the current through the coil and the resistor.

Measure the voltage drop across the 1K-ohm resistor by connecting the ground clip of the tvom to terminal 17 and the probe to terminal 14. Since the resistance is 1K-ohms (± 10%), the current (in milliamperes) through it is the same as the voltage across it in volts.

For example, our measurement for this step was 1.6 volts. Dividing this by 1000 to get the current in amperes gives a value of .0016, which is 1.6 milliamperes -- numerically the same as the voltage value. Record your voltage reading on the first line of Fig. 30-3. (It may not be the same as ours.) Unplug the line cord.

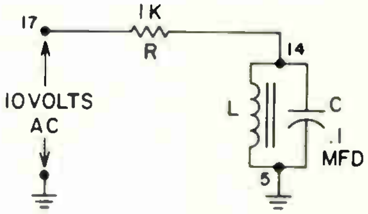

Fig. 30-2. The circuit for Step 2.

Step 2. To show that the circuit current decreases when a capacitor is connected across the choke coil.

Solder a .1-mfd capacitor across the terminals of the choke coil to form the circuit shown in Fig. 30-2, adjust the voltage between terminal 17 and ground to exactly 10 volts, and again measure the voltage drop across the 1K-ohm resistor.

	.60	.35	.5

Fig. 30-3. Record results for Steps 1, 2, and 3.

Enter your voltage reading on the second line of Fig. 30-3.

Step 3. To show how the circuit current varies as different values of capacitance are connected across the coil.

Replace the .1-mfd capacitor in turn with each capacitance listed for Step 3 in Fig. 30-3. (These values of capacitance are the same as those you used in the previous experiment, and are formed the same way.) Each time the capacitance is changed, be sure to readjust the input voltage to exactly 10 volts, and then measure the voltage drop across the resistor. You need not measure the voltage drops across the coil and capacitor in this step. Enter your readings in Fig. 30-3.

When you have finished making the measurements, unplug the power cord.

Discussion: As in the previous experiment, you may not be able to actually go through resonance with the coil-capacitor combination. This is unimportant because from your readings in Fig. 30-3 you can see that as the capacitance increases, the circuit current decreases. From the typical values in Fig. 30-3, you can see that we reached resonance with a .5-mfd capacitor.

In a parallel-resonant circuit, then, the circuit is at resonance when the circuit current is at a minimum, as shown by the curve in Fig. 30-4. Compare this curve with the one shown in Fig. 29-7. From these you should be able to see the difference between the two resonant circuits.

Instructions for Statement No. 30: We have mentioned several times that a solid-dielectric capacitor normally has very little ac resistance. For your report on this experiment, you will place a given amount of resistance in series with the capacitor in the parallel-resonant circuit and see what happens to the circuit current.

Set up the circuit shown in Fig. 30-5,

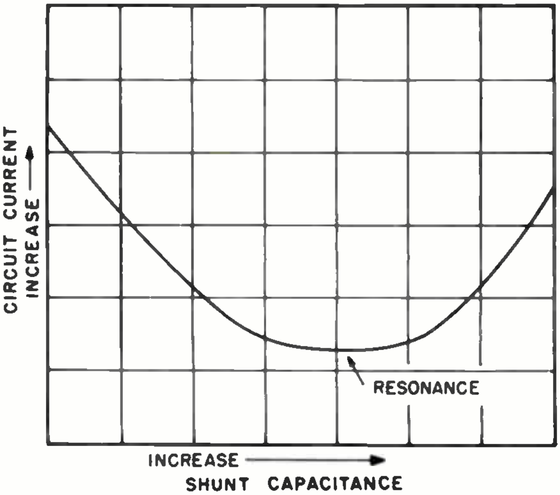

Fig. 30-4. Resonance in a parallel-resonant circuit.

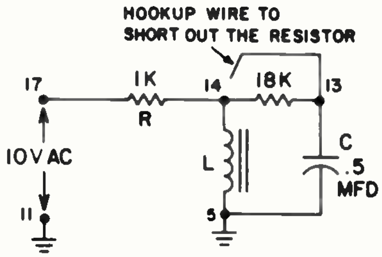

Fig. 30-5. Schematic of the circuit used in your experiment.

using .5-mfd for capacitor C. You should still have a .1-mfd and two .25-mfd capacitors connected between terminals 5 and 14. Remove the .1-mfd capacitor. You now have .5 mfd in parallel with the coil. Disconnect the leads of the two .25-mfd capacitors from terminal 14 and connect them to terminal 13. Leave the other leads of the capacitor combination connected to terminal 5. Then, connect an 18K-ohm resistor between terminals 13 and 14. You should still have a 1000-ohm resistor connected from terminal 14 to terminal 17.

Prepare a 4 or 5" length of hookup wire and solder one end to terminal 13. Arrange the other end of the piece of wire so that you can conveniently touch it to terminal 14 when you are instructed to do so. Solder all connections.

When you have the circuit set up, connect the tvom ground clip to the chassis and clip the probe to potentiometer terminal 17. Adjust the voltage to exactly 10 volts. Next, move the tvom ground clip to terminal 14 and the probe to terminal 17 and touch the short length of hookup wire that you soldered to terminal 13 to terminal 14. Measure the voltage across the 1K-ohm resistor, and make a note of the reading.

.2 V

Disconnect the hookup wire from terminal 14 and note whether the voltage across the 1K-ohm resistor increases, decreases, or remains unchanged. When you have found out what happens, unplug the power cord. Now complete the Statement below and on the Report Sheet.

Unsolder the resistors and the capacitors from the terminals, and lay them aside for future experiments.

Statement No. 30: When I removed the short, placing an 18K-ohm resistor in series with a capacitor, the circuit current:

(1) remained unchanged.
[✓ *(2) increased.*]
(3) decreased.

LOOKING AHEAD

Now that you have completed the experiments that demonstrate the fundamental properties of resistors, coils, and capacitors in ac and in dc circuits, you are ready to combine these components into more complex circuits. In your next group of experiments, you will demonstrate how power supplies work. A knowledge of power supply operation is important to you because power supplies are used to provide dc voltages in radio and television receivers. You will carry out experiments using solid state rectifiers as well as vacuum tube rectifiers.

After you have entered all your answers on the Report Sheet, send it to NRI for grading. While you are waiting for the next kit to arrive and the Report Sheet to be returned to you, gather all the parts you have left over from this kit and the previous kits, and put them in a safe place. The parts left over are shown in Table I.

After you have received a passing grade on your Report Sheet, you can unsolder and disconnect the choke, leads, and the connections to the potentiometer. Remove the flashlight cells, the potentiometer and the potentiometer mounting bracket. Remove the excess solder from the terminals and the parts.

HOW DO YOU FEEL?

A theory has been advanced (and to a large extent scientifically proven) that people feel good and feel bad in cycles.

Psychologists say that for a certain number of days you will be "sitting on top of the world." Then for a longer period of time you will feel about average. Then for a while you may be depressed – "in the dumps" -- have the "blues."

Then the cycle starts over again. It is claimed you can keep a record of the way you feel, and predict accurately about when you will be feeling grand -- or when you will be depressed. Be this as it may, we DO know that no matter how black things look at times, conditions always seem to improve. It's a very, very true saying that "every cloud has a silver lining." Perhaps this old saying is really based on the scientific theory I mentioned above.

And since you and I both know that we are bound to "snap out" of periods of depression, let's resolve never to make important decisions while feeling "low".

Don't fuss with a friend -- don't quit a good job – don't give up a worthwhile ambition just because you are in a "depressed cycle." Tomorrow, or next week you'll feel better!

INSTRUCTIONS FOR PERFORMING EXPERIMENTS 31 THROUGH 40

This part of your training program covers power supplies, tube fundamentals and transistor fundamentals. The experiments in this training kit are especially important because the knowledge and experience you gain will be of great value in your practical work.

You will study power supplies in some detail in this kit. You will build and investigate several types of rectifier circuits, filter networks, voltage regulators, and voltage doublers. Such broad coverage will enable you to understand nearly all of the power supply configurations currently in use and will give you self-confidence in your service work.

Following the work on power supplies, you will perform experiments on tube fundamentals and transistor fundamentals. You can see the importance of this when you realize that a tube or transistor is used in the vast majority of circuits which amplify, oscillate or perform any other active function. In addition to learning how these devices work, you will prepare yourself for work with amplifier, oscillator, mixer and other circuits which you will study in the following training kits.

HOW TO AVOID ELECTRICAL SHOCKS

As you get further along in your Practical Training Course, it becomes more and more important to take precautions to avoid electrical shocks.

One side of almost every power line is grounded. When you stand on the earth, you are at the same potential as everything else in contact with the earth, including the grounded side of the power line. So if you touch the other side of the power line, your body will complete the circuit to ground. If you are insulated from the earth, you can touch the other side of a power line and not get shocked. However, you should not touch a water pipe, a radiator, or a concrete floor at the same time, because they are at ground potential with respect to the high side of the line.

In ac-dc receivers, which operate on either ac or dc power line voltages, the ungrounded side of the power line connects to the receiver circuits, and in some cases directly to the chassis. Here an external ground must not be fastened to the chassis. Unless polarized plugs and receptacles are used the power cord plug may be inserted into the wall outlet so that the chassis is connected to the high side of the power line. A ground wire connected to the chassis, therefore, would short-circuit the power line and cause a house fuse to blow.

You can determine whether or not the chassis is at ground potential by measuring the ac voltage between a known grounded object and the chassis. If you read ac line voltage, remove the line plug, turn it over and measure the voltage again. It should be zero, which means that you can touch the chassis without being shocked.

A power line is not the only source of

electrical shocks. The B supply in a receiver may be even more dangerous, since in ac sets there may be several hundred volts between B+ and the chassis. You must observe the same precautions in working with the B supply as you do when working with a power line.

Make your work space safe. If you have provisions for an antenna and ground at your bench, the ground should be where you will not accidentally touch it. If water pipes are nearby, cover them with insulating shields so you cannot accidentally hold on to one while working with a chassis. If the floor is concrete, provide a platform of dry boards, without nails going through the boards to the concrete. For a stool with metal legs put an insulating caster under each leg.

Do not be afraid of electricity, but respect it. Beginners almost never get shocked. Only when you grow overconfident and disobey safety rules is there a real danger of your being shocked. Keep alive your respect for electricity and its effects, and you will have nothing to worry about.

CONTENTS OF THIS KIT

The contents of this kit are pictured in Fig. 1 and are listed below it. Check the parts you received against this list to be sure you have all of them. Do not discard any of these parts, or the parts from previous kits unless instructed to do so or until you have finished your NRI course; you will use the parts again in later experiments.

IMPORTANT: If any part of this kit is missing, look for a substitute part or special instruction sheet. If any part is obviously defective or has been damaged in shipment, return it immediately to NRI as directed on the packing slip accompanying this kit.

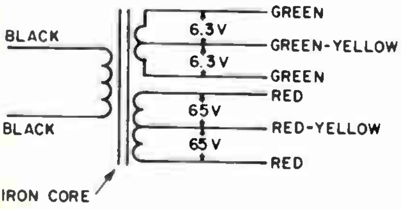

Fig. 2. Schematic symbol for power transformer.

THE POWER TRANSFORMER

The power transformer which you received in Kit 3 may be called a "combination" transformer, because it furnishes both high and low ac voltages from a given ac line voltage. The symbol used to represent this transformer in schematic diagrams is shown in Fig. 2.

As the diagram shows, there are three separate windings on this transformer. The primary winding, which is wound for 117-volt, 60-Hz ac power, is terminated in the two black leads. Under no circumstances should you connect the primary of this transformer to a dc power line or to an ac power line having a frequency of 25 or 40 Hz. The low voltage winding is the one with green leads. It is center-tapped with a green/yellow lead. Each section, between either of the green leads and the center tap, supplies about 6.3 volts; the voltage between the two green leads is approximately 12.6 volts.

The third winding, having the leads colored red, is also center-tapped. This winding, which is commonly called the high voltage secondary winding, supplies the high voltage needed for the plates of the vacuum tubes. It is designed to have a no-load output of about 130 volts between the red leads. Variations in line voltage may make the actual no-load output of your transformer anywhere between 100 and 140 volts. The center tap is brought out to the red/yellow lead.

THE VACUUM TUBE

You received a type 12BA6 vacuum tube in this kit. This is a miniature type pentode and its schematic symbol is shown in Fig. 3A. The labels G_1, G_2 and G_3 represent the control grid, screen grid and suppressor grid; K is the cathode; P is the plate; and H is the heater or filament.

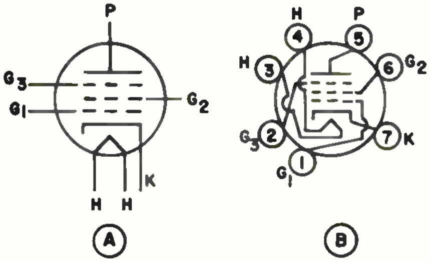

Fig. 3. (A) Schematic symbol and (B) basing diagram for a 12BA6 tube.

The 12BA6 fits a standard 7-pin tube socket, such as the socket you installed on your etched circuit board. The filament requires approximately 12.6V and the filament current is .3 amp.

Fig. 3B is a basing diagram of the 12BA6 tube. It shows the pin connections to the tube elements. The pins are numbered in a clockwise direction, counting from the open space when viewed from the bottom.

THE TRANSISTOR

You also received a power transistor in this kit. It is a germanium type PNP transistor in a TO3 case. The transistor has three elements: base, emitter and collector. The base and emitter have pin connections while the collector terminal is the transistor case. The schematic symbol for the transistor is shown in Fig. 4A and the elements are identified in Fig. 4B.

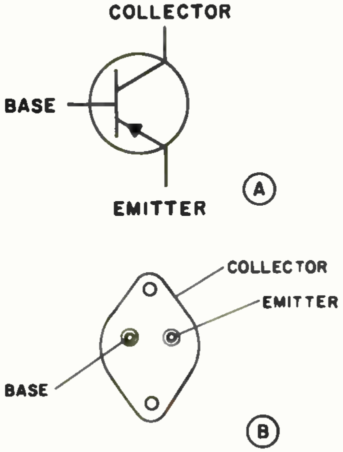

Fig. 4. (A) Schematic symbol and (B) basing of a PNP transistor with lead identification.

This transistor is designed to provide little amplification. However, it can pass high current. It will be mounted in such a manner that the chassis will serve as a heat sink and prevent the transistor from overheating.

SILICON DIODES

You received two solid-state silicon diodes (NRI part No. SR14) in this kit. We will call them high voltage or HV diodes to distinguish them from the diodes you received in Kit 1. These HV diodes can withstand up to 400 peak volts across their terminals. These HV diodes are commonly called "top hats" because of their appearance. The actual diodes are tiny pellets of silicon inside the plastic and metal package.

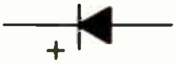

Fig. 5. The schematic symbol for a solid state diode.

Fig. 5 shows the schematic symbol for a solid-state diode. The diode has two elements – an anode represented by the arrow, and a cathode which is represented by the bar. The leads are usually identified by a + sign near the cathode lead or by a schematic symbol printed on the body of the diode. The cathode of the HV "top hat" diode is the lead that connects to the "brim" end of the case. Notice that this lead *connects directly to the metal case!* The anode lead comes from the top of the "top hat."

Preliminary Assembly

Before performing the experiments in this kit, you will have to make several changes in your experimental chassis. Most of the parts you will need are shown in Fig. 1. The others were included in the earlier kits.

PREPARING AND INSTALLING THE CHASSIS RAILS

You will need the following parts:

2	Chassis rails
1	3/8" rubber grommet
1	5/16" rubber grommet
1	3-lug terminal strip
1	2-lug terminal strip
9	3/8" X 6-32 screws
9	6-32 hex nuts
10	No. 6 lockwashers
1	500K-ohm potentiometer with On-Off switch

Make sure the power cord is unplugged. Unsolder and disconnect the leads of the power cord from the black leads of the power transformer. Also, unsolder the green lead from the 4-lug terminal strip.

Observe the two chassis rails which you received in this kit and the rail already attached to your chassis. Notice that the three are identical. Position one chassis rail as shown in Fig. 6, so that the two 3/8" holes are on the right, and the top and bottom lips of the rails are toward you. You will then have the inside of the rail facing you.

Install a 3/8" rubber grommet in the hole nearest the right end of the chassis rail. Squeeze the grommet into an oblong shape and push it into the hole so that the rubber completely lines the hole in the chassis.

Mount the 3-lug terminal strip on the inside of the same chassis rail. Position the terminal strip exactly as shown in Fig. 6. Pass a 6-32 screw through the rail from the outside. Place the foot of the terminal strip and a No. 6 lockwasher over the screw. Attach a hex nut and tighten the screw.

Pass the end of the power cord up through the grommet in the chassis rail. Tie an overhand knot in the cord approximately 2 inches from the end of the wire. Lay this chassis rail aside. Position the second rail as shown in Fig. 7.

Slip a control lockwasher over the shaft and bushing of the potentiometer and mount the potentiometer in the 3/8"

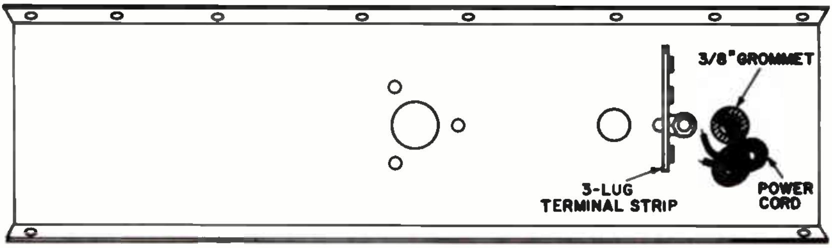

Fig. 6. The parts installed on the left chassis rail.

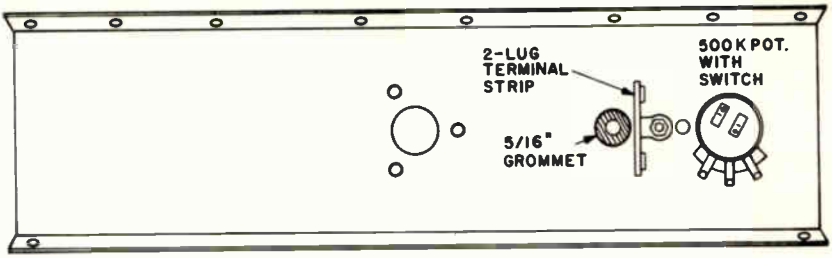

Fig. 7. Parts mounted on the front chassis rail.

hole nearest the end of the rail. Attach a control nut. Rotate the potentiometer so that the three terminals are in the positions shown in Fig. 7 and tighten the nut.

Install a 5/16" rubber grommet in the other 3/8" hole as shown in Fig. 7. This grommet will fit loosely in the hole. Mount the 2-lug terminal strip on the inside of your chassis rail near the rubber grommet. Position the terminal strip as shown in Fig. 7, and attach it securely, using a 6-32 screw, lockwasher and nut.

Next, you will fasten the chassis rails to the chassis plate. Remove the chassis rail from the front of the chassis plate. Set aside the 4-lug terminal strip. Using the same screws and nuts, mount this as the right chassis rail as shown in Fig. 8. Note that the lips are turned inward toward the center of the chassis plate and the rail extends beyond its front.

Fasten the chassis rail with the power cord and a 3-lug terminal strip to the left side of the chassis plate, as shown in Fig.

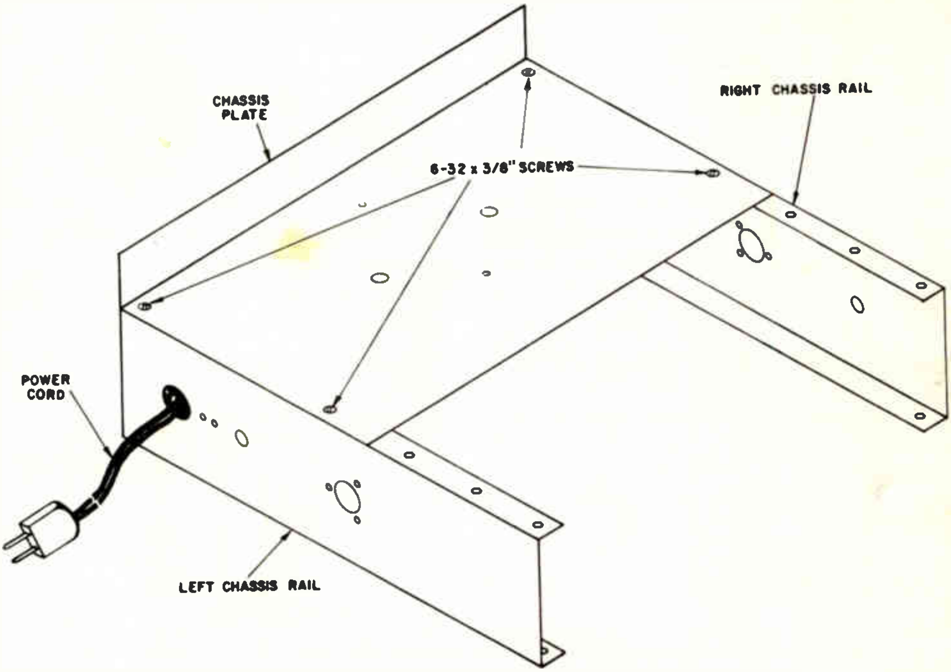

Fig. 8. Mounting the side rails on the chassis plate.

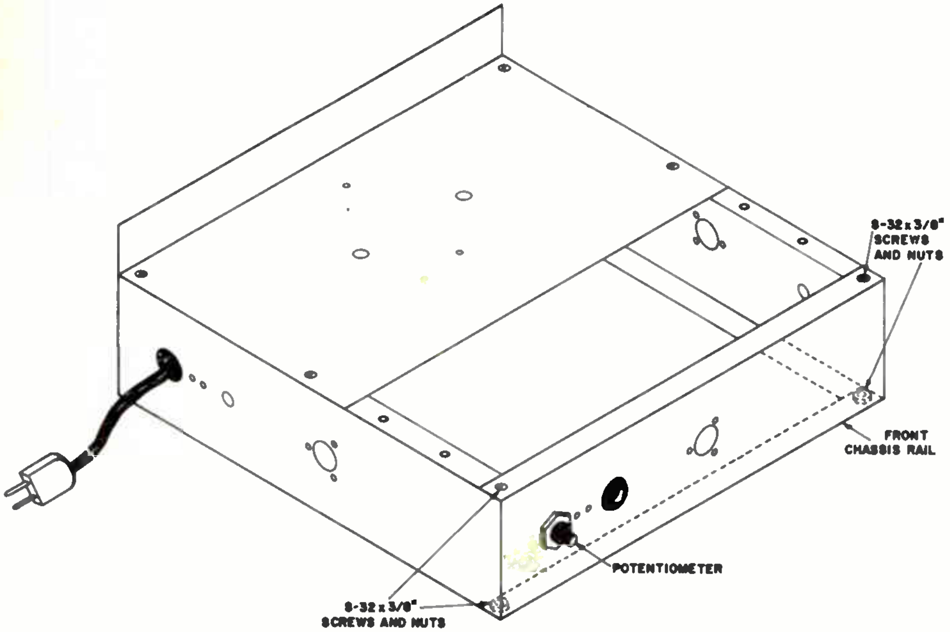

Fig. 9. Mounting the front rail on the chassis.

8. Secure with two 6-32 screws, No. 6 lockwashers and 6-32 hex nuts.

Next fasten the chassis rail with the potentiometer to the left and right side rails, to form a box as shown in Fig. 9. Notice that the top lip of the front rail fits *over* the top lips of the left and right side rails. Secure the front rail to the side rails with four 6-32 screws, No. 6 lockwashers and 6-32 hex nuts. Pass a screw through the top and bottom lip of both rails at each corner.

MOUNTING THE PARTS ON THE CHASSIS

Now, you will make changes on the chassis plate. You will need the following:

1	Power transistor
1	Transistor socket
1	7-lug terminal strip
1	3/8" X 6-32 screw
2	1/2" X 6-32 screws
1	Control knob
3	No. 6 lockwashers
3	6-32 hex nuts
2	Insulated shoulder washers
1	Transistor insulator

Remove the 3-lug terminal strip and solder lug from the left side of the chassis plate. Save the parts.

Mount the 7-lug terminal strip at holes F and I as shown in Fig. 10. Secure with the 6-32 screws and nuts just removed from the chassis. Reinstall the 4-lug terminal strip at hole U, as shown in Fig. 10. Use a 6-32 screw, No. 6 lockwasher and 6-32 hex nut.

Next, you will install the power transistor. The transistor mounts under the chassis at the location shown in Fig. 10. The transistor socket attaches to the pins which will project through holes C and C_3 in the chassis.

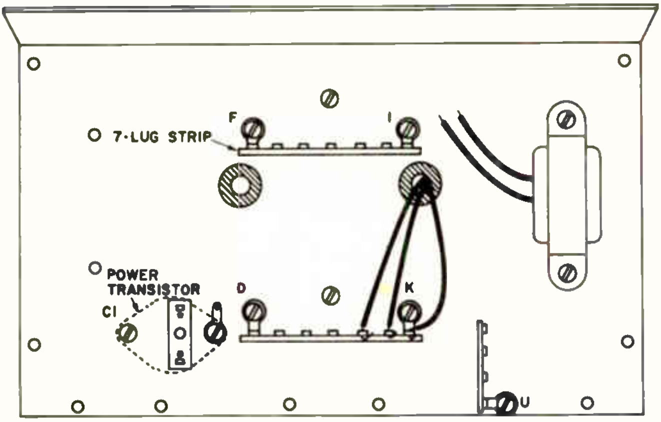

Fig. 10. Mounting the parts on the chassis.

Fig. 11 is an exploded view showing how to mount the transistor. Place the thin insulator over the transistor terminals. Place the solder lug and fiber shoulder washer over one of the two 1/2" X 6-32 screws. Slip a shoulder washer only over the other screw. Place the screw with the solder lug in transistor mounting hole C2 in the chassis and push the other screw through hole C1 so that the shoulder washers insulate the screws and the solder lug from the chassis.

Mount the transistor as shown in Figs. 10 and 11. Position the solder lug as shown in Fig. 10. Attach No. 6 lockwashers and 6-32 hex nuts and tighten the nuts just enough to compress the lockwashers.

Slip the transistor socket over the pins of the transistor. Install the control knob on the potentiometer shaft by lining up the flatted part of the shaft with the flat of the knob. Push the knob onto the shaft firmly.

WIRING THE CHASSIS

You now have a number of terminal strips and other parts mounted on the chassis plate and chassis rails. The simple terminal number system used in the earlier training kits would be a little awkward to use now that we have so many terminals. We will therefore change to a more flexible system.

If you have marked the terminal numbers on your chassis plate or a piece of tape with your crayon, you should now

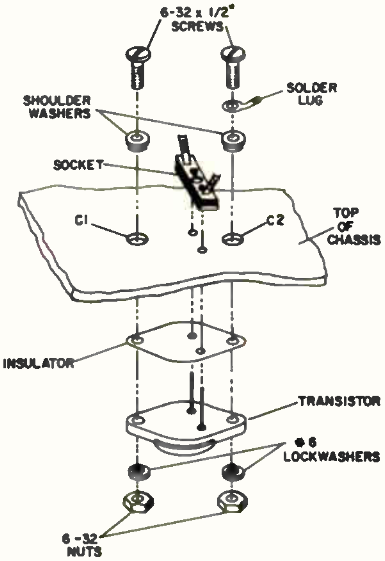

Fig. 11. Mounting the transistor on the chassis.

remove the markings. An ordinary pencil eraser or a soft cloth and a little liquid detergent will help you.

We will identify the terminals on the chassis by giving each terminal strip a letter designation. Each terminal will be completely identified by a letter and a number. Fig. 12 shows the terminals identified using this method. Notice, for example, the terminals on Strip A are called A1, A2, A3, etc., and those on Strip B are called B1, B2, B3, etc.

You will now connect the power transformer leads, the power cord and the on-off switch. Some of these connections are permanent. When instructed to make a permanent connection, remove about 1/4" of insulation from the end of the wire, bend a hook, slip the hook through the hole in the terminal and squeeze it closed with your longnose pliers.

Use only temporary connections on top of the chassis. The wiring is shown in Fig. 13.

Remove the tape from the red and red/yellow power transformer leads. Push the ends of these three leads of the power transformer up through the grommet in hole E of the chassis.

Connect one red lead to terminal B1 and solder the connection.

Connect the red/yellow transformer lead to terminal B2. Do not solder.

Connect the other red transformer lead to terminal B3.

You should have a green transformer lead connected to terminal B7 and the green/yellow lead connected to terminal B5. Move the green/yellow lead to B6 and connect the other green lead to B5 as shown in Fig. 13.

Connect the leads of the choke coil to terminals A6 and A7.

You will now perform the under-chassis wiring. Refer to Figs. 14A and B as you make the following connections. Each of these connections is to be permanent unless otherwise indicated.

Remove 1/4" of insulation from each end of the two 10" lengths of hookup wire. Twist the wires together to form a twisted pair.

At one end, connect one lead of the twisted pair to terminal D1 and connect the other lead to D2. Do not solder.

At the other end of the twisted pair connect one lead to terminal 4 of the on-off switch on the back of the potentiometer and connect the other lead to terminal 5 of the on-off switch. Solder

both connections and route the twisted pair along the side of the chassis rail.

Connect one black lead of the power transformer to terminal D1. Solder.

Connect the other black power transformer lead to D3. Do not solder.

Connect one lead of the power cord to D2. Solder.

Connect the other lead of the power cord to D3 and solder.

This completes your preliminary assembly and wiring. Check your work against the diagrams in Figs. 13 and 14 to see that you have done your work correctly.

At this point, your chassis is essentially complete. The space left between the chassis plate and the front rail is reserved for the circuit boards which you will mount and use in your experiments.

Instructions For Performing The Experiments

Here are some general instructions that you are to follow in performing all of the experiments in this kit and in future ones.

1. Follow these steps for each experiment:

(a) Read the entire experiment, paying particular attention to the discussion.

(b) Perform each step of the experiment, and record your results.

(c) Study the discussion carefully; then analyze your results.

(d) Answer the Statement in the manual and on the Report Sheet.

2. If, when you read through an experiment, you think you won't have enough time to finish it, spend one work period doing any preliminary construction and wiring work. Leave the actual measurements, circuit changes, etc., until you have time to do them all at once.

3. If you do not get acceptable results from any experiment, stop right there and find the trouble before going any further. Do the very best you can to solve the problem yourself, because doing so helps you to develop the troubleshooting techniques you'll need later on. Check over the wiring instructions, test every connection, and test each part if effect-to-cause reasoning fails to lead you to the trouble. Be sure to check the circuit against the schematic. If all these procedures fail, write to us on the special Kit Consultation Blank provided, and tell us which experiment and step you're working on. Give us a complete description of the symptoms that indicate trouble, and list the results of your tests. Go ahead with your regular lessons while waiting for our answer.

4. One object of these practical experiments is to develop your ability to wire a circuit with only a schematic diagram as your guide, just as an experienced serviceman does. Begin now to think in terms of tube and circuit elements rather than specific terminal numbers. For example, instead of thinking of the 100,000-ohm resistor as being between terminals B1 and B3, think of it as being across the high-voltage winding of the power transformer. This will soon teach you to visualize circuits so that you can work from a schematic diagram with ease. Because we want to encourage you to develop this ability, there will be few pictorial sketches in this manual.

5. As in the previous kit, we have omitted the color code listing for the resistors. If you have not yet learned the color code, we urge you to do so immediately. Knowing the code thoroughly is a big time saver in your assembly work, and it helps reduce errors in wiring. If you are in doubt as to the value of a particular resistor, or if you forget the color code, look it up in the chart in your first kit.

6. From now on, we shall not indicate what tools you need to wire circuits. You know that you have to use hookup wire, pliers, screwdrivers, etc. If there is any soldering or unsoldering to be done, you know that you will have to heat your soldering iron and must use rosin-core solder. Therefore, in any experiment in

which you are to make circuit changes, get out the tools you will need, and heat your soldering iron before beginning the assembly or disassembly of that experiment.

EXPERIMENT 31

Purpose: To show that a coil can develop a counter emf and to show that a transformer can be used to step voltage up or down while providing dc isolation.

Introductory Discussion: Coils are among the most widely used electronic components. It is therefore, desirable for you to learn how coils work and how they are used.

The most important characteristic of a coil is inductance. Inductance is the property that causes a magnetic field to be produced around a wire or coil through which current is flowing and causes a voltage to be induced in a wire or coil placed in a varying magnetic field.

Coils may be used separately, where inductance is required, or two or more coils may be wound on the same core to form a transformer. In most cases, transformers are used to inductively transfer signals or ac power from one circuit to another while providing isolation. The voltage may be "stepped" up or down, depending upon the ratio of the turns of the windings and how the transformer windings are connected.

Coils and transformers can be designed to operate at any desired frequency. In this experiment, you will use your power transformer and choke coil which are designed for use in 60-Hz power line applications.

We will use a neon lamp to indicate the presence of voltage in these steps. The tvom is unsuitable for several of these steps because the voltage will rise and fall before the meter has time to respond. The lamp, which you will use, will light when approximately 65 volts is applied to it. Thus, you will know that you have at least that voltage whenever the lamp lights. The brilliance of the glow depends upon the voltage applied to the lamp. Thus it will glow more brightly with 100 volts applied than with 65 volts applied.

Experimental Procedure: For this experiment, you will use the experimental chassis with the choke and the power transformer mounted on it and the following parts:

1 1.5 volt flashlight cell
1 Neon lamp

Make sure the chassis is unplugged from the ac receptacle.

Construct the circuit shown in the schematic diagram in Fig. 31-1. Using temporary connections, connect the neon lamp in parallel with the choke coil between terminals A6 and A7. Solder a 6" to 8" length of hookup wire to each terminal of one flashlight cell. Solder the free end of the negative battery lead to terminal C4 or to any convenient ground terminal.

Step 1: To show that an inductance can develop a counter emf.

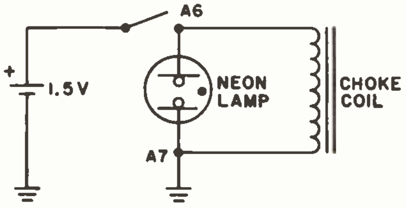

Fig. 31-1. The circuit used in Step 1.

You now have the neon lamp connected in parallel with the choke coil. Touch the positive battery lead to terminal A6. While observing the neon lamp, remove the battery lead from A6 to open the circuit. You should see the lamp flash or glow momentarily. Repeat the experiment. Touch the battery lead to A6 and hold it for a few seconds. Remove the battery lead while observing the bulb.

Now observe the bulb as you *touch* the battery lead to the terminal again. Remove the battery lead. You will find that the lamp lights only as you *open* the circuit.

Now touch the battery lead to the terminal and remove it quickly while observing the lamp. You should find that the length of time the circuit is closed has no noticeable effect on the brilliance of the flash.

Step 2: To show that the transformer windings have inductance and can produce a counter emf.

Connect the neon lamp across the 12.6 volt filament winding of the transformer. Unsolder the lamp from A6 and A7 and solder it to B5 and B7. While observing the neon lamp, touch the positive battery lead to B5. Open the connection and note the brilliance of the lamp flash.

Unsolder the lamp and connect it across the high voltage winding, terminals B1 and B3. Touch the positive battery lead to B3 and observe the lamp. As you open the battery connection, look carefully to see if the lamp flashes. Make and break the connection several times if necessary.

Step 3: To show that a transformer can step up voltage.

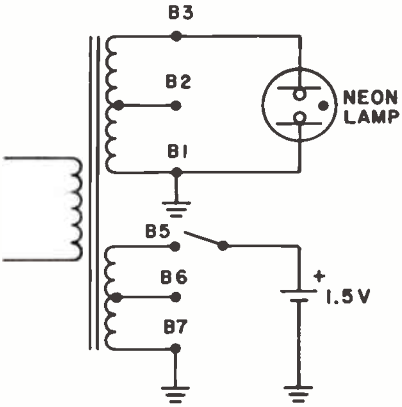

Fig. 31-2. The transformer connected to produce voltage step up.

You will use the circuit shown in Fig. 31-2. Leave the lamp across the high voltage winding of the transformer, but connect the battery across the low voltage winding between terminals B5 and B7.

Touch the battery lead to B5, then break the connection while observing the neon lamp. Note that the flash is the brightest yet obtained in this experiment, indicating the highest voltage.

Step 4: To test the transformer for continuity and isolation.

Set up your tvom for resistance measurements and measure the resistance of the high voltage winding from terminal B1 to terminal B3. The neon lamp will not affect your reading. Record the resistance reading in the chart in Fig. 31-3.

Now connect the ohmmeter across the low voltage winding, terminals B5 and B7 and measure the resistance. Place the value in the space provided in Fig. 31-3.

Next, disconnect the transformer leads from terminals B1 and B7. Make sure that the transformer and battery leads are not shorted to the chassis or to any terminals. Measure the resistance between the leads connected to terminals B3 and B5. Record the value in Fig. 31-3. You should read a very high resistance. When you have made this measurement, reconnect the red lead to B1 and the green lead to B7.

Connect the clip of your tvom to the chassis and the probe to terminal B5. Adjust the meter to read 3 volts dc. Touch the battery lead to the high voltage winding of the transformer at terminal B3.

Allow the meter a couple of seconds to settle down, then observe and jot down the reading in the margin of this page. Remove the tvom probe from terminal B5, then disconnect the positive battery lead from terminal B3.

Discussion: In this experiment, you saw that you were able to light a neon lamp, requiring about 65 volts from a 1-1/2 volt flashlight cell. The inductances of the coil and the transformer windings were responsible for the increase in voltage.

A neon lamp consists of a pair of electrodes placed in neon gas. When a high enough voltage is applied to the electrodes, the neon gas will "ionize" and begin to conduct, thus producing light. The chemical composition of the neon gas and the spacing of the electrodes establishes the voltage required to cause the gas to conduct.

H.V. WINDING	L.V. WINDING	B_3 TO B_5
200Ω	1.5Ω	∞

Fig. 31-3. Chart for recording your transformer resistance readings.

In the first step, the lamp was connected directly across the winding of the choke coil. When the flashlight cell was connected, the coil and the lamp were a parallel-connected load. However, when the battery was disconnected, the coil acted as the source of voltage. It was the voltage produced in the coil that lighted the lamp.

Now, let us review the action of an inductance. Current flowing through a conductor produces a magnetic field around the conductor. This magnetic field will vary in strength as the current in the conductor varies.

A counter emf (or voltage) is produced whenever the current in a coil changes. The amount of the counter emf is governed by the inductance and the rate at which the current changes. When you removed the battery lead from the circuit in Step 1, you caused an instantaneous change in the current from some level of current flow to 0, resulting in a very high counter emf. The fact that the lamp glowed proved that the voltage was 65 volts or more. Thus, the counter emf was at least 43 times as great as the voltage produced by the flashlight cell. Incidentally, the duration of the high voltage was less than one millisecond (1 thousandth of a second).

In Step 2 you saw that transformer windings, like the choke, also have inductance and can produce a large counter emf. Even though there are fewer turns (small inductance) on the low voltage winding than on the high voltage winding, you probably observed a brighter glow when testing the low voltage winding. A look at your readings recorded in Fig. 31-3 will give you a clue as to why you developed a greater counter emf with the low voltage winding. This winding has a very low resistance and thus will draw a large current from the battery to produce a large magnetic field. The much higher resistance of the high voltage winding draws less current and produces a smaller magnetic field than the low voltage winding. Thus, even though the inductance of the HV winding is large, the current is small and a small counter emf is produced.

You obtained the brightest flash when you used the circuit in Fig. 31-2. The lamp was connected across the high voltage winding and you applied voltage to the low voltage winding. The current supplied by the flashlight cell caused a magnetic field to be produced around the low voltage winding. When you opened the battery connection, the field collapsed and a high voltage was induced in the high voltage winding.

In Step 4, you used your tvom to make a few basic tests on the transformer. You read the continuity of the high voltage and low voltage windings and you tested the transformer for isolation.

The low dc resistances proved that the windings have continuity and are capable of passing current. The dc resistance between windings is quite high because there is no direct electrical connection between them. Also, you saw that there was no transfer of the dc voltage through the transformer. Only alternating or changing voltages are coupled from one winding to another.

Instructions for Statement No. 31: For this Report Statement, you will determine if a short circuit in one winding of a transformer affects the voltage induced in another winding.

Make sure the line cord is unplugged. The circuit of Fig. 31-2 should still be connected. Touch the battery lead to terminal B5 and quickly remove it. Make a mental note of the brilliance of the flash of the neon lamp across the high voltage winding.

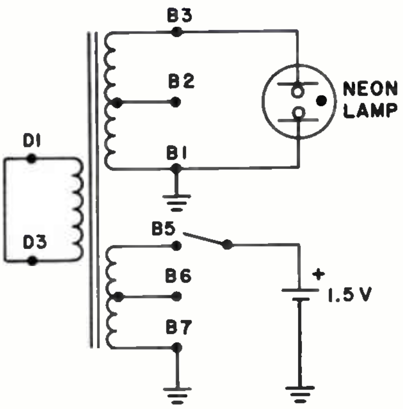

Fig. 31-4. The schematic diagram of the circuit used for Statement 31.

Next, place a short circuit across the transformer primary winding. Turn the on-off switch "on" and hold both prongs of the power cord against the metal chassis. This will give you the circuit shown in the schematic diagram in Fig. 31-4. Note that you are now using all three windings of the transformer, with the low voltage winding acting as the primary.

Touch the battery lead to terminal B5 and open the connection while observing the neon lamp.

Answer the Statement here and on the Report Sheet. Unsolder and remove the neon lamp and the flashlight cell from the chassis.

Statement No. 31: When I placed a short circuit across the transformer primary winding, I found that the voltage induced in the high voltage winding was

Assembling A Basic Power Supply

Before going further you will mount your etched circuit board and several other parts on your chassis and wire a simple power supply circuit. You will use the 7 pin tube socket on the circuit board and make connections to the circuit board and to the terminal strips on the chassis. You will also wire the neon lamp into the circuit so that it will show you when the circuit is energized.

Gather the parts listed below from the parts sent you with this kit and from those left over from the other kits.

1	**Etched circuit board**
1	**12BA6 tube**
9	**1/4" X 4-40 screws**
9	**4-40 hex nuts**
5	**Terminal lugs**
2	**100K-ohm resistors**
1	**Neon lamp**

First, attach the 5 terminal lugs to the circuit board at the locations shown in Fig. 15. Use 1/4" X 4-40 screws and 4-40 nuts. Position the lugs as shown, so they do not touch adjacent copper strips or terminals.

Mount the circuit board in the location shown in Fig. 15 with four 1/4" X 4-40 screws and nuts. Note that the tube socket is towards the chassis plate and the circuit board is near the center of the opening in the chassis.

Next, you will wire the circuit shown in the schematic in Fig. 16. The terminal lugs on the circuit board are numbered 1 through 5, as shown in Fig. 15. The broken line in Fig. 16 encloses the wiring on the etched circuit board itself. Note on the circuit board that the copper foil connects pins 2, 5 and 6 of the tube socket and lug 5. Pin 1 of the tube socket is connected to lug 3 and pins 3, 4 and 7 are connected to lugs 2, 1 and 4, respectively.

You can use the diagram in Fig. 15 for help in wiring the circuit shown in the schematic.

Note that lengths of hookup wire are connected from lug 3 to lug 5 on the circuit board and between terminals B2 and A2. The green lead and green/yellow lead of the power transformer, connected to terminals B6 and B7, are interchanged from their previous positions as are the red and red/yellow leads connected to terminals B1 and B2. The neon bulb is connected to A2 and A3 and a 100K-ohm resistor is connected from A3 to B3.

When you complete your wiring, check over your work and insert the 12BA6 tube in the socket.

Radio-TV parts may look perfectly all right and yet be defective. An important part of every assembly procedure is to make resistance tests to be sure that there are no shorts or opens. If the results of these tests are satisfactory, then it is safe to apply power and make voltage measurements.

CONTINUITY TESTS

For a power supply like the one you have wired, you should check the continuity of the circuits and be on the

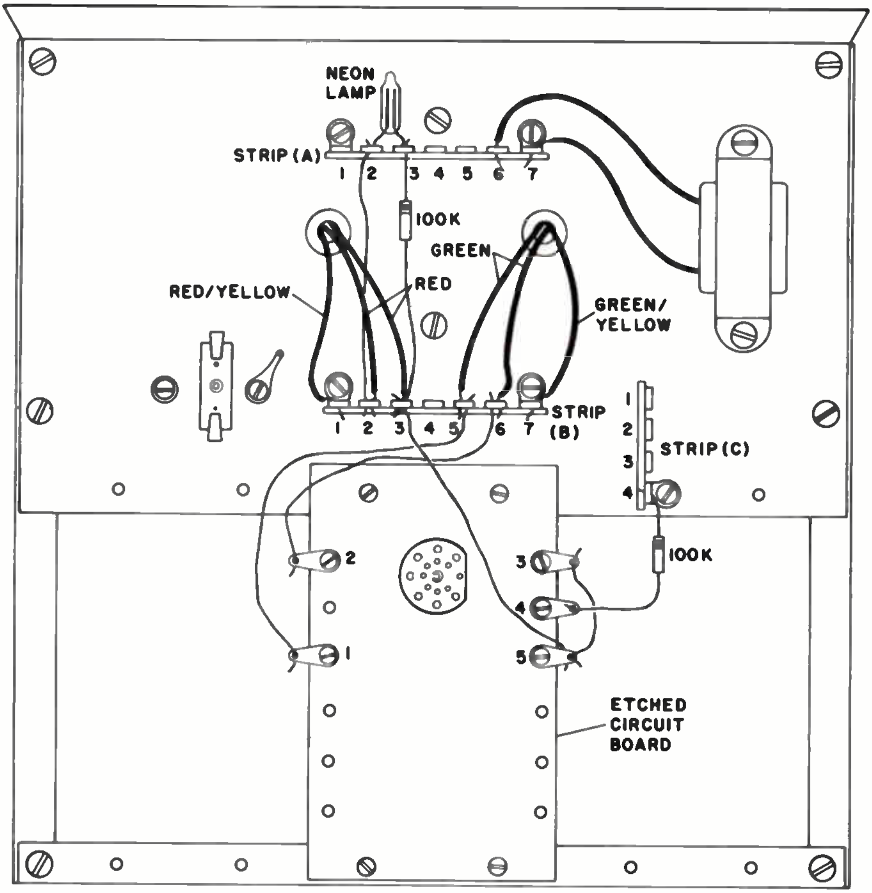

Fig. 15. Pictorial diagram of the power supply wiring.

lookout for a short between the cathode terminal of the rectifier tube and the chassis. A short of this type could not only ruin the tube, but it could also damage the power transformer.

You will use the ohmmeter section of your tvom to carry out the continuity tests. Turn your tvom on and turn the function switch to ohms. Do not plug in the line cord of your chassis until you are instructed to do so.

First, turn off the switch on the power supply: Turn the knob on the 500K-ohm potentiometer shaft all the way in the counterclockwise direction until you hear a click. With the switch in the off position, proceed with the continuity tests.

To test the line cord, switch, and primary transformer winding, turn the range switch to the R X 10K position, and connect the ohmmeter leads to the prongs of the power cord plug. You should get no reading on the ohmmeter, indicating that no continuity exists in the circuit. Now with the ohmmeter test probes still connected to the prongs, turn the power supply switch on. Immediately the meter pointer should move to the zero position. Turn the range switch to the R X 1 position. When you do this, the meter should indicate between 20 and 40 ohms, which is the resistance of the primary power transformer winding.

Next, connect your ohmmeter leads to lugs 1 and 2 of the circuit board. These lugs connect to pins 3 and 4 of the tube socket. You should measure about 1 ohm. This is the parallel resistance of the filament winding and the 12BA6 heater.

To check half of the high voltage winding of the power transformer, connect the ground clip to the chassis and touch the probe to lug 5. With the range switch in the R X 1 or R X 10 position, your reading should be approximately 80 ohms.

Next, measure the resistance from tube cathode (lug 4) to the chassis. Here you should get a reading of approximately 100,000 ohms, measured on the R X 10K ohmmeter range. A very low reading indicates a short. Look for solder that may have dripped down and shorted to the chassis, or for improper wiring.

VOLTAGE TESTS

If the results of the continuity tests are satisfactory, you can now check the voltages of the power supply. Plug the supply into a 117-volt, 60-Hz receptacle. The on-off switch is still in the on position. Set your voltmeter up for ac measurements, and turn the range switch to the 120-volt position. Measure the voltage between the chassis and lug 5 of the circuit board. Since you are measuring half of the high voltage winding of the power transformer, you should get a reading of approximately 65 volts.

Now set the range switch to the 30-volt position and measure the voltage between lugs 1 and 2 of the circuit board. You should get a reading between 12 and 13 volts.

To measure the line voltage, remove the line cord plug from the wall outlet, turn your chassis up on its back edge and connect the ground clip of your tvom to terminal D3. Turn the tvom range switch to the 300-volt range, and plug the line cord back into the wall outlet. Touch the tvom probe to terminal D2. You will get a reading of approximately 117 volts. The actual voltage in your area may be any value from 105 volts to 130 volts. Unplug the power cord and disconnect the meter ground clip.

When you have finished making these measurements and found that the continuity and the ac voltages of the power

supply are correct, you are ready to go ahead with the next group of experiments. If any readings were not correct, be sure to find out what is wrong before proceeding with the experiments. If you need help, write us, giving the results of all your measurements.

EXPERIMENT 32

Purpose: To show that when an ac voltage is applied to a rectifier and a resistor in series, a dc voltage will be produced across the resistor; and to show that the polarity of the voltage drop across the resistor depends on how the rectifier is connected into the circuit.

Introductory Discussion: The circuit you will use to show that there is a dc voltage across the load when an ac voltage source, a rectifier, and a load (in this instance a 100,000-ohm resistor) are connected in series is shown in Fig. 32-1. This is the half-wave rectifier circuit that you built and tested earlier. To simplify the discussion, we will consider the power transformer to be the ac source. Actually, of course, power is drawn from the power line to excite the primary winding of the power transformer.

To show that the voltage drop across the 100,000-ohm load resistor is a dc voltage, you will make use of the fact that under ordinary conditions your tvom will not respond to any ac voltage when the function switch is in the dc position. You will use the normal-reverse switch to indicate polarity. When the meter pointer deflects to the right (upscale), the polarity of the voltage at the terminal to which the probe is being touched is positive if the polarity switch is set to normal, and negative if the switch is in the reverse position.

We usually use diode tubes as tube-type rectifiers. As you know, a diode tube has two elements called a cathode and a plate (in addition to the heater). You will use your 12BA6 tube, which is a pentode, as a diode. By connecting the three grids to the plate externally, as shown in Fig. 32-1, we make the pentode act as a diode.

Experimental Procedure: For this experiment, in addition to the power supply circuit you have constructed, you will need:

1 HV silicon diode

Turn the tvom on and clip the ground lead to the experimental chassis. This is the same as clipping it to the 100,000-ohm resistor lead that goes to terminal C4 since C4 is grounded. Set the function switch to the dc position, the slide switch to normal, and the range

switch to the 120V position. You are now ready to proceed with the first step.

Step 1: To show that there is a dc voltage across the load resistor in series with a diode tube rectifier and an ac source.

Insert the plug of the power cord into an ac receptacle, and turn on the on-off switch. Allow the tube to warm up and touch the probe of your tvom to the end of the 100,000-ohm resistor that is connected to lug 4 of the circuit board. If you read less than about 25 volts, adjust the range switch to the 30V range, measure the voltage and record your reading in the first line of the table in Fig. 32-2. Turn your circuit off.

Step 2: To show forward and back resistance of a diode.

7Ω

Set the function switch of your tvom to ohms on the R X 1 range and clip the ground lead to the cathode lead of the silicon diode. Touch the probe to the anode lead and measure the resistance. (The leads are identified by a diode symbol on the body of the diode.) Be sure the meter is set to normal. You should read a low resistance. Record your reading on the first line in Fig. 32-3.

Reverse the tvom leads by placing the normal-reverse switch in the reverse position and again measure the resistance between the cathode and anode leads of the diode. Switch the ohmmeter to a higher range, if necessary, to get a reading. Record your value in the space provided in Fig. 32-3.

Step 3: To show that a silicon rectifier gives essentially the same results as a vacuum tube rectifier.

Remove the 12BA6 tube from the tube socket on the circuit board. Grasp the tube with a cloth if it is still hot. Connect and solder the silicon rectifier between lugs 4 and 5 on the circuit board as follows: Connect the cathode lead to lug 4 and connect the anode lead to lug 5.

Set your tvom to read positive dc voltage on the 120-volt range and clip the ground lead to the chassis. Turn the circuit on and measure the voltage across the 100K-ohm load resistor. Record your reading in the space provided for Step 3 in Fig. 32-2.

Step 4: To show that the polarity of the voltage across the load resistor depends on how the rectifier is connected in the circuit.

Set up the circuit shown in Fig. 32-4, in which the anode and cathode connections are the reverse of those in the circuit you just used. Interchange the diode leads: Connect the cathode lead to

lug 5 of the circuit board and connect the anode lead to lug 4.

To show that the polarity of the voltage drop across the load resistor has changed, turn on the experimental chassis, connect the ground clip of the tvom to the chassis, and momentarily touch the probe to lug 4. Note that with the slide switch in the normal position, you get a downscale reading.

Move the slide switch on the tvom to reverse and touch lug 4. Now you should get an upscale reading. This indicates that the point to which the probe is touched is negative with respect to the point to which the ground lead is connected. The reading you get should be just about the same as the one you got in Step 3, since the only difference between the circuits is that the connections to the rectifier are reversed. Record your reading on the third line of Fig. 32-2 as a minus (–) value, and turn off the power supply.

Unsolder and remove the silicon diode from the circuit board.

Discussion: The fact that a direct current flows through the load in the circuits you have set up is based on a fundamental property of a rectifier -- current will flow more easily through a rectifier in one direction than in the other.

In Step 2, you used your ohmmeter to show that the effective resistance of a diode depends upon the polarity of the voltage applied to it. When the plate or anode is *positive* with respect to the cathode, the resistance is low; when the anode or plate is *negative* with respect to the cathode, the resistance is high.

Your ohmmeter is wired so that with the polarity switch set to normal, the probe is slightly positive with respect to the ground clip. Thus, when the probe was connected to the anode and the ground clip was connected to the cathode, the diode conducted readily and you measured a low value of resistance. When you reversed your ohmmeter leads, you reversed the polarity of the voltage applied to the diode, and the effective resistance of the diode became quite high.

The tube-type rectifier has similar characteristics. When the plate is positive with respect to the cathode, the effective resistance between cathode and plate is low; when the applied voltage is reversed, the effective resistance is very high.

This is a good way of checking most solid-state diodes. Measure the resistance in both directions and compare your results. In one direction, you should have a high resistance and in the other, you should obtain a low resistance. Certain special purpose diodes, such as high voltage selenium types used in color TV sets, cannot be tested in this manner as they show a high resistance in both directions.

In each of the circuits you set up in this experiment, the plate or anode is alternately positive and negative during each ac cycle and current flows through the rectifier and load as a series of pulses. Since the voltage drop across the load is in direct proportion to the current flowing through it, the load voltage is also a series of pulses. If you were to connect a cathode ray oscilloscope across the load, you would get a pattern somewhat like that shown in Fig. 32-5.

As you can see, each voltage pulse extends in the same direction from the zero reference line. Therefore, the series of pulses contains a dc component that we can measure.

The rectifier circuit you used is known as a half-wave rectifier because it passes current during only half of the ac cycle. When there is no filter capacitor in the circuit (the effect of a filter will be shown later), the dc component that the meter indicates is much less than the peak value of the voltage pulses. The pulses reach a peak nearly equal to the peak value of the ac source voltage, but the tvom is capable of measuring only the average of the positive pulses, which is about one-third of the peak value.

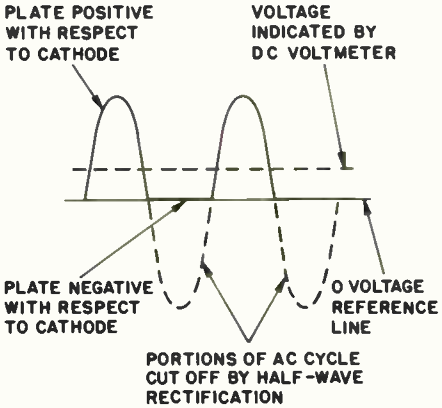

Fig. 32-5. The heavy line indicates the shape of the voltage across the load of the half-wave rectifier circuit.

Some important radio and TV servicing principles are shown by this experiment. First, as you know, you must set the polarity switch of your tvom to the proper polarity to make the instrument indicate dc voltages correctly. By the term "proper polarity" we mean that the polarity switch must be set so that the meter pointer moves to the right when you make a voltage measurement. If the meter pointer moves to the left, the switch must be moved to the opposite position.

In any device in a circuit, except the source, the terminal at which the electrons enter is the negative terminal. This fact lets you find the direction of the electron flow by examining the diagram. If there are tubes in the circuit, electrons always flow from the cathode to the plate, and this establishes the direction of electron flow through any parts in series with the tubes. Knowing the direction of electron flow, you can determine the polarity of the voltage drops across the parts.

Instructions for Statement No. 32: For your Report on this experiment, you will put the load between the plate of the rectifier tube and the ungrounded side of the high voltage winding. The circuit is shown in Fig. 32-6. You are to measure the dc voltage drop across the load, and compare it to the voltage drops you measured in Steps 1 and 3 of the experiment.

To change the circuit, proceed as follows: First, unsolder and remove the 100K-ohm resistor which is connected

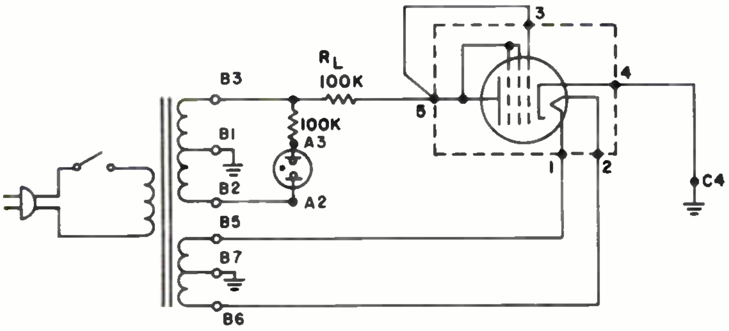

Fig. 32-6. The circuit for Statement 32.

from the circuit board to terminal C4. Unsolder and remove the length of hookup wire connecting terminal B3 to the circuit board.

Connect a length of hookup wire from lug 4 of the circuit board to terminal C4.

Connect the 100,000-ohm resistor between terminal B3 and lug 3 or 5. Solder all connections and insert the tube in the socket. Your circuit should now be like Fig. 32-6.

Connect the ground clip of your tvom to lug 5, plug the power cord into the ac outlet, and turn the circuit on. Carefully consider the direction of electron flow through the load resistor, and set your polarity switch to give an upscale reading when you touch the probe of your tvom to terminal B3. Make a note of your reading, then turn the circuit off. You now have sufficient information to complete the Statement.

Statement No. 32: When I measured the dc voltage across the 100,000-ohm resistor, I found that it was:

(1) much lower than
(2) considerably higher than
[✓ *(3) essentially the same as*]

the dc voltage I measured in Steps 1 and 3.

EXPERIMENT 33

Purpose: To demonstrate the basic operation of the full-wave rectifier circuit and to show that it has better regulation than the half-wave rectifier circuit.

Introductory Discussion: A half-wave rectifier circuit has a diode connected between the ac source and the load so that current passes to the load only once during each cycle. In a full-wave rectifier circuit, two diodes are connected in such a manner that one diode conducts on each half of the ac cycle. Thus, both the negative and positive halves of the ac voltage are used and current passes to the load twice during each cycle. Because of this, the full-wave rectifier can supply greater current than can a half-wave rectifier under similar circumstances and it is better able to supply a constant voltage to varying load resistances.

Experimental Procedure: For this experiment, you will need your chassis, your tvom and the following parts:

1 HV silicon diode
1 22K-ohm resistor
1 .25-mfd capacitor

Before you begin the experiment, construct the circuit shown in the schematic diagram in Fig. 33-1. First, unsolder and remove the 100,000-ohm resistor connected from terminal B3 to the circuit board and replace it with a short length of hookup wire. Then remove the wire connected between terminal C4 and lug 4 on the circuit board and connect the 100,000-ohm resistor in its place.

Connect the HV diode between terminals B2 and B4 with the cathode lead to B4 and connect a length of hookup wire from B4 to lug 4 on the circuit board.

Check over your wiring and make sure all connections are soldered.

Step 1: To demonstrate the operation of the full-wave rectifier circuit.

Turn the circuit on, allow the tube time to warm up, and measure the voltage across the 100K-ohm load resistor. Set the tvom to measure dc voltage on the 120-volt range, clip the ground lead to the chassis and touch the probe to lug 4. Read the meter and record the value in the chart in Fig. 33-2. Switch your tvom 60V to ac and measure the voltage from terminal B3 to the chassis. Move the probe to terminal B2 and note that you read the same voltage. You should have approximately 65 volts at both terminals.

64V Turn the chassis off and unsolder the resistor lead from lug 4 of the circuit board. Connect a .25-mfd capacitor from lug 4 to terminal C4.

Step 2: To show that the full-wave rectifier will charge a capacitor to the peak value of the applied voltage.

Set the function switch of the tvom to the dc position, turn the circuit on and allow time for warm-up. Touch the probe to lug 4 and measure the voltage across the .25-mfd capacitor. Note that it is 92V much higher than the voltage across the resistor alone. Record the voltage in the space provided for Step 2 in Fig. 33-2. Turn the circuit off.

Discharge the capacitor by shorting across its leads or by grounding lug 4 to the chassis momentarily. Connect the 100K-ohm resistor in parallel with the .25-mfd capacitor by connecting the free resistor lead to lug 4 of the circuit board.

Step 3: To measure the voltage developed across a load resistor shunted by a capacitor.

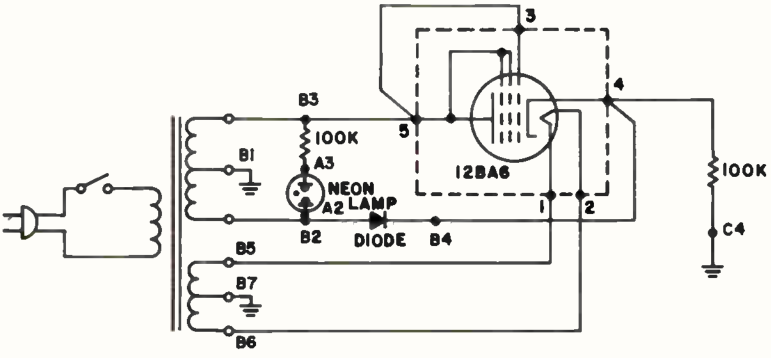

Fig. 33-1. Full-wave rectifier circuit for Experiment 34.

STEP	CIRCUIT	VALUE
1	100K Load Resistor	60V
2	.25-MFD Capacitor	92V
3	100K Resistor Shunted by .25-MFD Capacitor	82V
4	22K Resistor Shunted by .25-MFD Capacitor	67V
5	Half Wave With 22K Resistor and .25-MFD Capacitor	46V

Fig. 33-2. The chart used with this experiment.

Turn the circuit on, allow time for the tube to warm up and measure the voltage across the load. Record your voltage reading in the space for Step 3 in Fig. 33-2. Turn the circuit off and replace the 84 100K-ohm resistor with a 22K-ohm resistor.

Step 4: To measure the output of the full-wave rectifier with a heavier load connected across it.

Turn the circuit on and measure the voltage between lug 4 of the circuit board and the chassis. Note that it is lower than the voltage you measured in the preceding step. Record the voltage in the chart in Fig. 33-2.

Step 5: To show that the full-wave rectifier circuit has better voltage regulation than the half-wave rectifier.

Remove the 12BA6 tube from the socket and turn the circuit on. Without the tube, you have a half-wave rectifier, using only one-half of the transformer winding and the silicon diode. Measure the voltage across the 22K-ohm resistor and the capacitor and place your reading in the chart in Fig. 33-2. Turn the circuit off.

Discussion: The full-wave rectifier circuit is essentially two half-wave rectifiers arranged so they operate alternately and supply current to the same load.

The fundamentals of full-wave rectification are shown in Fig. 33-3. The transformer winding is center-tapped and the center tap is our point of reference. With respect to the center tap, the ends of the

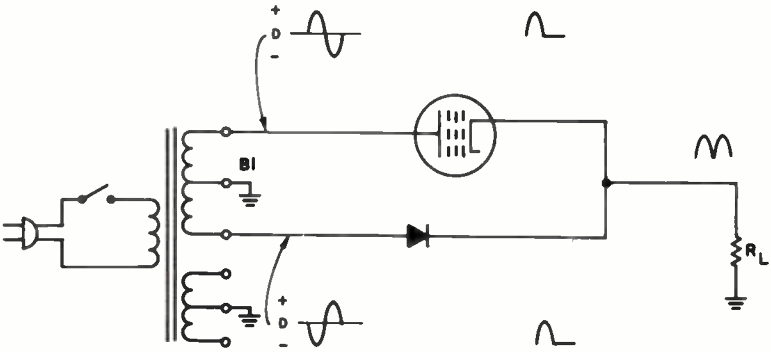

Fig. 33-3. Diagram showing the waveform in the full-wave rectifier circuit used in Step 1.

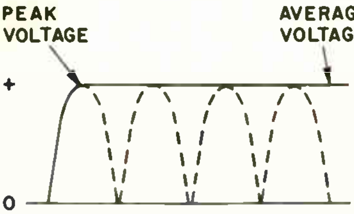

Fig. 33-4. Voltage across the capacitor in Step 2.

transformer winding are 180° out-of-phase with each other. Thus, during one half-cycle of the ac, the plate of the tube is positive, and the anode of the silicon diode is negative; during the next half cycle, the plate of the tube becomes negative and the anode of the diode becomes positive.

As you know, a diode conducts only when its plate or anode is positive with respect to its cathode. Therefore, the tube conducts and passes current through the load on one half-cycle and the silicon diode conducts and passes current on the other half-cycle. Thus, the spaces between the pulses produced by a half-wave rectifier circuit are filled in, as there are two pulses produced during each cycle.

Note that with full-wave rectification, there is always some positive voltage across the load. Therefore, the average voltage is higher. For this reason, you measured about 60 volts across the resistor in Step 1. You may remember that in the preceding experiment, you read only about 30 volts across the resistor in the half-wave rectifier circuit.

In Step 2, you should have found that the capacitor charged to approximately 90 volts, which is the peak value of the ac voltage. The peak value of a sine wave is equal to 1.4 times the rms voltage. Fig. 33-4 shows the waveform of the voltage across the capacitor. Note that the spaces between the pulses are filled in so that the average voltage is equal to the peak voltage.

When you connected the capacitor and 100K-ohm resistor in parallel across the output of the full-wave rectifier, you should have noticed some reduction in the dc output voltage. The capacitor charged each time the diode conducted and discharged through the resistor each time the rectifier output voltage passed its peak value. The waveform of the voltage across the resistor and capacitor is shown in Fig. 33-5. The effect of the capacitor was to produce a higher average voltage.

In Step 4, you increased the load on the rectifier circuit. You should have measured about 70 volts across the load. This voltage is lower than that measured in Step 3 because the capacitor discharges more quickly through the lower load resistance. As a result, the average voltage falls to a level nearer to that which you would have measured with no capacitance in the circuit.

The half-wave rectifier output voltage was much lower with the low load resistance. This is due to the fact that in the half-wave circuit, no voltage is supplied by the rectifier for a large percentage of the time. Thus, the capacitor is able to discharge almost completely between pulses as shown by the waveform in Fig. 33-6. In these last two steps, you can see

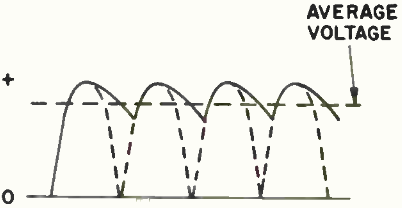

Fig. 33-5. Voltage across the capacitor and resistor in Step 3.

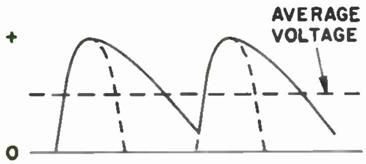

Fig. 33-6. Waveform across the capacitor and resistor in Step 5.

that the full-wave rectifier circuit has better regulation than the half-wave rectifier. Although both circuits develop about 90 volts across the capacitor alone, when a 22K resistor was connected across the capacitor, the output voltage of the full-wave rectifier fell to about 70 volts while the output of the half-wave rectifier was reduced to about 45 volts.

Instructions for Statement No. 33: For this Report Statement, you will disconnect the center tap of the transformer from the grounded terminal and measure the voltage across the load. Unsolder and disconnect the red/yellow lead from terminal B1 and push it out of the way. Put the tube back in the socket.

Turn the circuit on, measure the voltage between the chassis and lug 4 on the circuit board and answer the Statement here and on the Report Sheet. Turn your circuit off.

Statement No. 33: When I disconnected the transformer center tap lead, the voltage across the load:

[✓ *(1) decreased to zero.*]
(2) increased slightly.
(3) decreased slightly.

EXPERIMENT 34

Purpose: To demonstrate the basic operation of the bridge rectifier circuit and to show the effects of loading the circuit.

Introductory Discussion: In the previous experiments, you studied some of the characteristics of simple half-wave and full-wave power supplies. Now, you will take up the full-wave bridge rectifier circuit.

Full-wave bridge rectifier circuits are used in both high and low power applications. They are often used in the ac voltmeter sections of multimeters. The ac voltage applied to the input section of the meter is rectified by the bridge circuit and the resulting dc voltage is applied to the meter circuit. Full-wave bridge rectifier circuits using solid state diodes are found in power supplies in many TV receivers and transmitters.

The diagram in Fig. 34-1 shows how a full-wave bridge circuit works. The semiconductor diodes are labeled W, X, Y and Z. The ac voltage is fed to the bridge circuit at points A and D, and the load, represented by resistance R_L, is connected between points B and C.

The arrows indicate the directions of current flow. When point A is negative, with respect to point D, the current shown by the solid arrows flows from

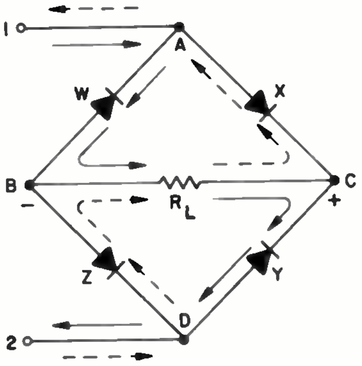

Fig. 34-1. Basic bridge rectifier circuit.

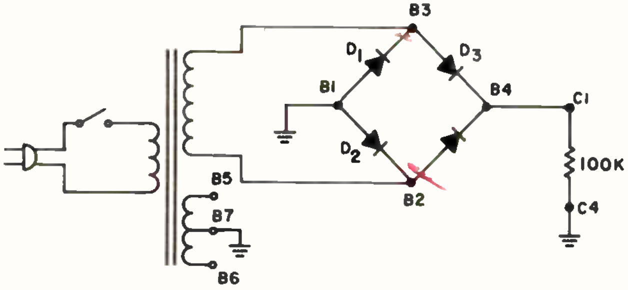

Fig. 34-2. Schematic diagram of the bridge rectifier circuit for Step 1.

point A through rectifier W, through R_L from left to right, and through rectifier Y to point D.

On the next half-cycle when point D is negative with respect to point A, the current flows as shown by the arrows drawn with broken lines. The current flows from point D through rectifier Z through the load resistor from left to right, and through rectifier X to point A.

Notice that the current flows through R_L in the same direction on both half-cycles of the applied ac voltage. Thus, point B is negative and point C is positive in the circuit in Fig. 34-1.

Experimental Procedure: For this experiment, you will need the following parts in addition to the chassis and tvom:

2 LV silicon diodes
1 HV silicon diode
1 .25-mfd capacitor

Construct the bridge rectifier circuit shown in the schematic diagram in Fig. 34-2. The wiring is shown in the pictorial diagram in Fig. 34-3. You should already have the red/yellow transformer lead disconnected from terminal B1. Also, there should be a HV silicon diode connected between terminals B2 and B4. The other HV diode is D_3. Use the LV diodes at D_1 and D_2.

When you have the circuit wired, be sure to remove the vacuum tube and then check your wiring to be sure there are no short circuits and that all connections are correct and soldered.

Step 1: To show that the bridge rectifier is a full-wave rectifier circuit and that a low dc voltage exists across each diode.

Set your tvom to measure positive 300 volts dc and clip the ground lead to the chassis. Turn the circuit on and measure the voltage across the 100K-ohm load resistor. You should read about 120 volts dc. Place your voltage reading in the chart in Fig. 34-4. 115

Touch the probe to terminal B2 and
55v measure the dc voltage across diode D_2.
55v Move the probe to terminal B3 and
measure the dc voltage across diode D_1. Note that the two voltage readings are about the same. Jot down the voltage readings in the margin of this page.

Turn the circuit off and replace the 100K-ohm resistor with a .25-mfd capacitor. You may disconnect the resistor lead from terminal C1 and leave the other lead connected to terminal C4. Solder the capacitor leads to terminals C1 and C4.

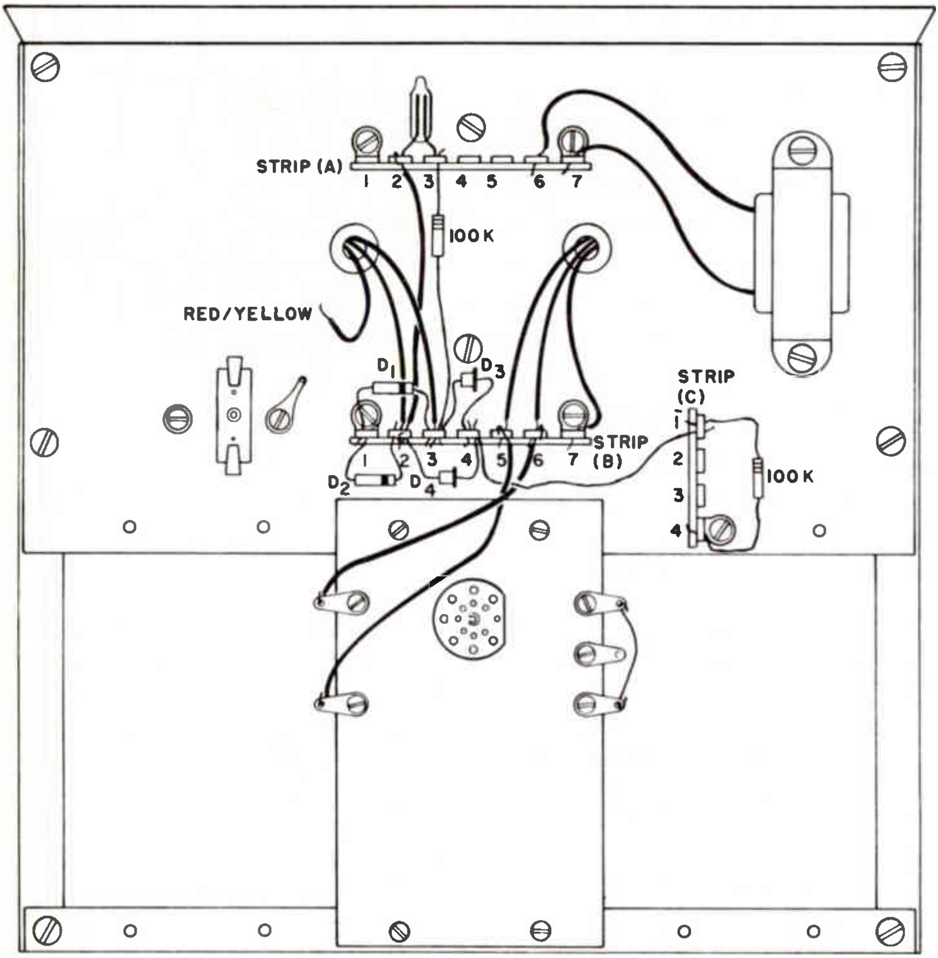

Fig. 34-3. Pictorial diagram of the circuit in Fig. 34-2.

Step 2: To show that the bridge rectifier will charge a capacitor to the peak value of the ac voltage.

Turn the circuit on and measure the voltage across the capacitor. Record the voltage in the space for Step 2 in the chart in Fig. 34-4. Turn the circuit off.

180V

Step 3: To show that the bridge rectifier will supply dc to a load shunted by a capacitor.

Connect the 100K-ohm resistor in parallel with the .25-mfd capacitor. Turn the circuit on and measure and record the voltage across the resistor and capacitor in the chart in Fig. 34-4. 160

Turn the circuit off and unsolder the resistor lead from terminal C1. Also, unsolder the lead of the LV diode, D_1, from terminal B3 and unsolder the lead of the HV diode, D_4, from terminal B2.

Step 4: To show that the bridge

rectifier can operate as a half-wave rectifier.

Energize the circuit and measure the voltage across the .25-mfd capacitor. It should read about the same as the voltage in Step 2. Record the voltage in the space for Step 4 in Fig. 34-4 and turn the circuit off. 180

Discussion: In this experiment, you operated your circuit from the full high voltage secondary winding of your transformer. Thus, the applied ac voltage was about 130 volts. This has a peak value of 130 X 1.4 or about 180 volts.

The dc voltage across the load resistor in Step 1 was about 120 volts. From previous discussions you know that this is the average value of the pulses which rise from zero to the peak voltage. The average value is about two-thirds of the peak value. Thus, you can be reasonably sure that the circuit is a full-wave rectifier, producing two positive pulses across the load during each cycle. The waveform of the output voltage is shown in Fig. 34-5A.

The rectifier circuit charged the .25-mfd capacitor to the peak value of the ac in Step 2. You should have measured about 180 volts, which is approximately the peak value of 130 volts ac.

Fig. 34-4. Chart for use with Experiment 34.

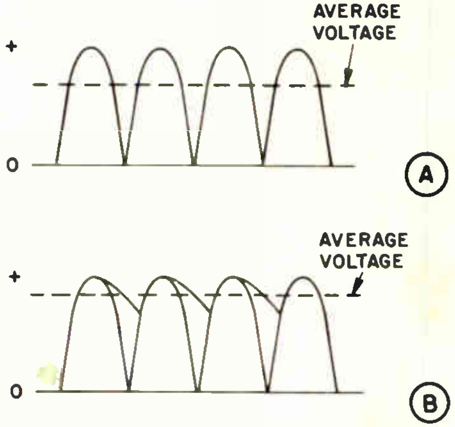

Fig. 34-5. Waveforms of voltages across (A) load resistor only in Step 1 and (B) load resistor and capacitor in Step 3.

In Step 3, you had a 100K-ohm load resistor shunted by a .25-mfd capacitor. You should have measured about 165 volts across the 100K-ohm load resistor and the capacitor. This is about an 8% drop from the voltage across the capacitor alone, and about a 40% increase over the voltage across the resistor alone. As in the previous experiment, the average voltage is higher than it was without the capacitor because the capacitor charges fully on each peak and discharges into the load between peaks producing the waveform shown in Fig. 34-5B.

You converted your bridge rectifier to a half-wave rectifier in Step 4 by disconnecting two of the diodes. A schematic diagram of the circuit used in Step 4 is shown in Fig. 34-6. The circuit should have charged the capacitor to the peak voltage of about 180 volts.

Refer to the schematic. Note that the two diodes are connected so that they pass current in the same direction and at the same time. When the polarity of the ac voltage is such that terminal B3 is

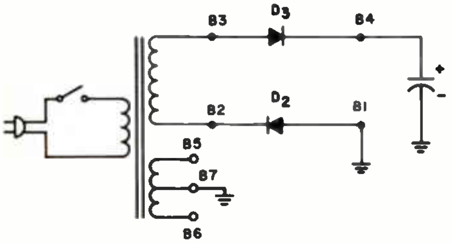

Fig. 34-6. Schematic diagram of the bridge circuit used as a half-wave rectifier.

positive with respect to terminal B2, current flows from B2 through diode D_2 to terminal B1 and ground. From ground, the current flows up to the negative plate of the capacitor. From the positive capacitor plate, current flows through diode D_3 and back to the transformer at terminal B3. On the other half-cycle of the ac voltage, the diodes do not conduct and no current flows.

Instructions for Statement No. 34: For this statement you will compare the operation of the circuit used in Step 4 with a circuit having three diodes.

Connect the 100K-ohm resistor in parallel with the .25-mfd capacitor. Turn the circuit on and measure the dc voltage across the capacitor and resistor. Jot down the value in the margin and turn the circuit off. 150V

Resolder the lead of the HV diode, D_4, to terminal B2 to form the circuit shown in the schematic in Fig. 34-7. Energize the circuit and measure the voltage across the resistor and capacitor again. Compare the results of the two tests and answer the Statement here and on the Report Sheet. Turn the circuit off. Unsolder and remove the two LV diodes and resolder the red/yellow transformer lead to terminal B1.

EXPERIMENT 35

Purpose: To show that there is a ripple voltage at the rectifier output; to show that 120 Hz ripple can be filtered more easily than 60 Hz ripple; and to show that this ripple can be filtered out with a choke and a capacitor.

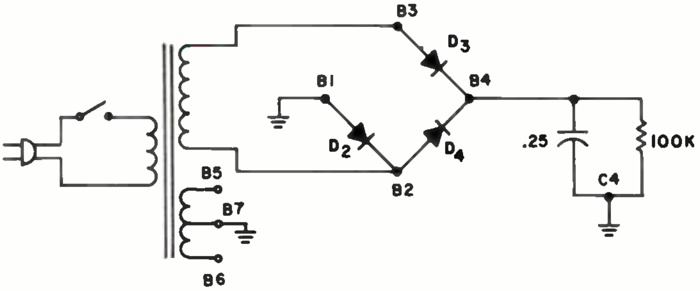

Fig. 34-7. The circuit used for Statement 34.

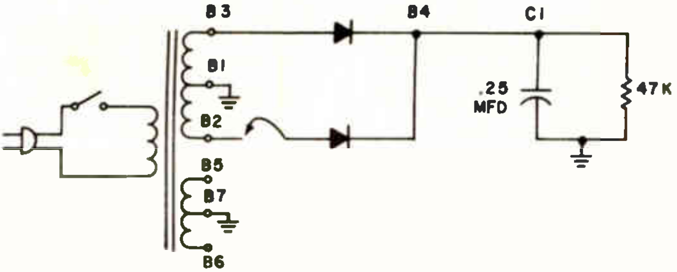

Fig. 35-1. The circuit used in Step 1.

Introductory Discussion: So far we have considered only the pure dc voltage across the load. However, if you connect an ac voltmeter across the load, you will find that there is also an ac voltage. This voltage is the ac component of the pulsating dc output of the rectifier. That is, it is not an ac voltage in the sense that its polarity is alternately positive and negative with respect to the zero reference level, but it is a rise and fall in the dc voltage value. For all practical purposes, however, it acts like any other ac voltage.

A capacitor connected across the load will have a definite effect on this ac component. In this experiment you will measure the ripple voltage and see how it can be reduced to a very small value so that almost pure dc can be supplied to the load.

Experimental Procedure: In addition to your tvom and the parts mounted on your chassis, you will need the following parts:

- 2 20-mfd, 150V electrolytic capacitors
- 1 47K-ohm resistor

Heat your soldering iron and carefully examine the tip. Clean and re-tin it if necessary. Also, check the calibration of your tvom.

The circuit which you will use in this experiment is shown in Fig. 35-1. You will only have to unsolder the anode lead of the diode from terminal B2 and replace the 100K-ohm resistor with a 47K-ohm resistor.

Step 1: To measure the ac ripple voltage and the dc voltage produced by a half-wave rectifier across the 47K-ohm load shunted by a .25-mfd capacitor.

Set the function switch of your tvom to ac and set the range switch to the 120-volt position. Clip the ground lead to the chassis and measure the ac voltage between terminal C1 and ground. If your reading is less than about 25 volts, set the range switch to the 30-volt position. Observe the reading and record it in the chart in Fig. 35-2. 12V

Now set the tvom to dc and measure the dc voltage across the load. Make this measurement and record your value in Fig. 35-2. Turn off the circuit.

Step 2: To show that 120-Hz ripple can be filtered more easily than 60-Hz ripple.

Convert your circuit to a full-wave rectifier by resoldering the free HV diode lead to terminal B2. Energize the circuit and measure the ac ripple voltage across the load resistor and the .25-mfd capacitor. Set the tvom to ac and touch the probe to terminal C1. Record the voltage in the space for Step 2 in Fig. 35-2.

Switch the tvom to dc, set the range switch to 120 volts, and measure the dc output voltage between terminal C1 and the chassis. Record the value and turn your circuit off.

Step 3: To measure the ac ripple voltage and the dc voltage across the load shunted by a higher capacitance.

The change to make in the circuit is shown in Fig. 35-3. Disconnect and remove the diode connected between terminals B2 and B4. Also, disconnect the lead of the .25-mfd capacitor from terminal C1. Connect a 20-mfd electrolytic capacitor from terminal C1 to terminal C4 or some other convenient ground terminal. The positive lead of the electrolytic capacitor must connect to terminal C1.

Fig. 35-2. Enter your readings here for Experiment 35.

You are now ready to make your voltage measurements. Turn the power supply on and measure the ac ripple voltage across the load resistor. Record your reading in Fig. 35-2. Notice that the ac ripple voltage is extremely small compared to that obtained in Step 1, showing that the use of a larger capacitor at this point reduces the ripple.

When you are measuring ac voltages on the 1.2V or 3V range, you may notice that the meter pointer moves upscale, even when the probe is disconnected from the circuit. This is normal. It is due to stray voltage pickup. If the meter reads zero when the ground clip is shorted to the positive probe, the meter will read accurately when it is connected into a circuit.

Set your tvom to measure the dc voltage across the load, make this measurement, and record your results in Fig. 35-2. Turn off the power supply. Notice again the change between the readings in Step 1 and Step 3. Obviously, the large capacitor in the circuit caused the increase in the dc voltage.

Step 4: To show how the ripple voltage at the output of the rectifier can be reduced by a filter so that almost pure dc is applied to the load resistor.

The changes to be made are shown in Fig. 35-4. Unsolder and remove the length of hookup wire connecting terminals B4 and C1. Connect a second 20-mfd electrolytic capacitor from terminal B4 to terminal B7 with the positive lead to B4. Connect one lead of the choke coil mounted on your chassis to terminal B4. Connect the other choke lead to terminal C1. Solder all connec-

tions and recheck your wiring. You are now ready to continue making your measurements.

Set the tvom for ac measurements and measure the ac ripple voltage across the load resistor between the chassis and terminal C1. If you cannot measure any ripple voltage, simply make a dash in the space provided in Fig. 35-2. Now reset your tvom, and measure the dc voltage across the load resistor. Record your results in Fig. 35-2. Turn off the power supply.

Discussion: In this experiment, you have observed the fact that filtering the output of a rectifier increases the dc voltage and decreases the ac ripple voltage across the output.

In Steps 1 and 2, you saw that the small capacitor was better able to filter the full-wave rectifier output than the half-wave output. This is because the full-wave circuit produces two pulses of voltage during each cycle. Thus, the capacitor is recharged twice as often as it is in a half-wave circuit. The capacitor has less time to discharge between pulses and therefore, it maintains a higher average voltage.

The 20-mfd capacitor which you used in Step 3 produced a higher dc voltage with lower ripple than you obtained with the full-wave rectifier circuit and the small capacitor. Each time the rectifier conducted, the capacitor became fully charged. Because it has such a high capacity, the electrolytic capacitor stored more energy and discharged very little between pulses. Thus, the average dc voltage across it was high.

You should have measured nearly the

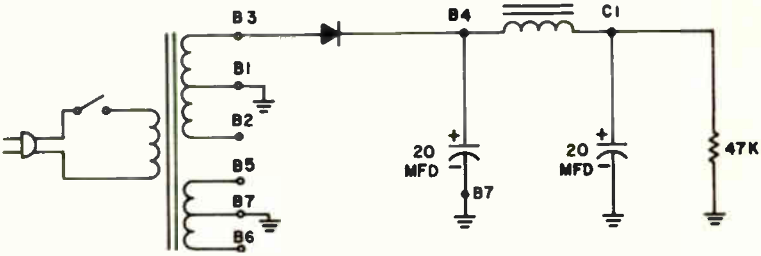

Fig. 35-4. The rectifier and π circuit for Step 4.

same dc voltage in Step 4 that you measured in Step 3, but with almost no ripple. The network which you used in Step 4 is a low pass pi filter, consisting of two capacitors and a choke. The capacitor connected between the cathode of the rectifier and ground is called the input filter capacitor and the one across the load is called the output filter capacitor.

Refer to the schematic diagram in Fig. 35-4. Notice that the choke, output filter and resistor form a load for the rectifier and input filter capacitor. The combined ac and dc voltage is applied to this load. The capacitor has low reactance to ac and high reactance to dc. On the other hand, the choke has high reactance to ac, and low reactance to dc. Thus, when applied to the choke and a capacitor, the ac and dc voltages divide differently.

Because the choke has high reactance to ac, most of the ac voltage is developed across it. The dc resistance of the choke is low compared to the dc resistance of the load resistor, resulting in little dc voltage drop across the choke. Most of the dc voltage, therefore, is developed across the output filter capacitor and the load resistor.

Pi filter networks using resistors instead of chokes are used in some low power equipment such as ac-dc receivers. The use of a resistor gives considerable savings in weight, space and cost. As long as the circuit current is not high, a circuit of this type can provide adequate filtering.

In order to provide the filtering, the value of the resistor must be high compared to the impedance of the output filter capacitor. The ripple voltage is developed across the resistor and the output filter capacitor in series. If the impedance of the capacitor is quite low, most of the ripple will appear across the resistor and little of it will appear across the load.

The dc current drawn by the load also flows through the filter resistor. Because the resistor value must be fairly high, there is a substantial voltage drop across it. This voltage drop is in series with the load, thereby making available less voltage for the load.

Instructions for Statement No. 35: For this statement, we are going to determine the ripple reduction factor of the filter circuit. To do this, we divide the amount of ripple voltage across the input filter capacitor by the amount of the ripple voltage across the output filter capacitor. For example, if you have 3 volts at the input and .1 volt at the output, you would divide 3 by .1, and obtain a ripple reduction factor of 30.

The circuit we will use is shown in Fig. 35-5. The .25-mfd capacitor is used as the input filter capacitor, so unsolder and remove the 20-mfd electrolytic capacitor connected to terminal B4 and connect the .25-mfd capacitor from terminal B4 to terminal B7 or C4.

Set the tvom for ac voltage measurements, and turn the range switch to the 120-volt position. Measure the ac ripple voltage at the rectifier cathode, terminal B4. If necessary, adjust the range switch

to a lower range. Now measure the output ripple voltage across the load by touching the probe of the tvom to terminal C1. Reduce the setting of the range

switch as necessary to get a usable reading. Now, divide the output ripple voltage into the input ripple voltage. The number you get as the answer is the ripple reduction factor. Turn off the power supply and answer the Statement here and on the Report Sheet.

EXPERIMENT 36

Purpose: To show the effect of a high power factor in the filter capacitors on the ac ripple voltage and the dc voltage at the output of a filter, and to show how servicemen check a capacitor for a high power factor.

Introductory Discussion: Electrolytic capacitors are used almost exclusively in radio and TV power supplies. An electrolytic capacitor, like all other capacitors, has two purposes. It acts as a high resistance for dc and a low resistance for ac.

As you have learned from your regular lessons, a perfect capacitor acts as an open, or offers an infinite resistance to the flow of dc. Also, in a perfect capacitor there is no loss during charge and discharge when ac is applied. In practice, these desirable results cannot be obtained. All capacitors have some leakage, and there is always some power loss.

A practical capacitor can be pictured as shown in Fig. 36-1. Fig. 36-1A shows the effect of leakage, and Fig. 36-1B shows the effect of power loss. In practical circuits, some leakage or some power loss can be tolerated. However, if the resistance of the leakage path becomes too small, circuit operation is affected, and we say that the capacitor is leaky or entirely shorted.

If the series resistance in Fig. 36-1B becomes too large, circuit operation is affected, and we say that the capacitor has developed a high power factor or has lost capacity. A high power factor is the result of an increase in the resistance between the capacitor plates themselves, or of drying out of the dielectric.

We will use the circuit shown in Fig. 36-2 to demonstrate the effects of high power factor in both the input and output filter capacitors.

Experimental Procedure: In addition to your tvom and the parts mounted on the chassis, you will need:

- 2 20-mfd, 150-volt electrolytic capacitors
- 1 3000-ohm resistor
- 2 22K-ohm resistors

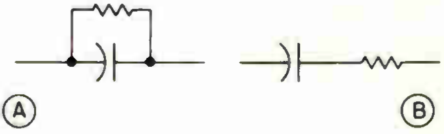

Fig. 36-1. (A) Leakage in a capacitor. (B) Power loss.

Proceed as follows: First remove the .25-mfd capacitor from terminal strip B and replace it with a 20-mfd, 150V electrolytic capacitor. Be sure to connect the positive lead to terminal B4. Disconnect the 47K-ohm lead resistor and replace it with two 22K-ohm resistors connected between terminals C1 and C4. Solder the connections.

Your circuit should now be wired as shown in Fig. 36-2. Check it over carefully, comparing it to Fig. 36-2. Examine both sides of the terminal strips to make certain that solder has not dripped down and shorted to the chassis.

Also, check for a short in the B supply with your ohmmeter, before applying power. To do this, set your tvom for ohmmeter measurements with the range switch in the R X 1K position. Put the ground lead on the chassis, and touch the positive probe to the rectifier terminal, B4. The capacitors will slowly charge up and should eventually give a reading of 11,000 ohms. This is the resistance of the load composed of the two 22K-ohm resistors in parallel. If the resistance is considerably less than this, there is a short or incorrect wiring, which you should find and correct before going on.

Step 1: To measure the normal dc and ac output voltages of the circuit shown in Fig. 36-2.

Set the function switch to dc, set the range switch to the 300-volt position and set the polarity switch to normal. Clip the tvom ground lead to the chassis, turn on the power supply and touch the positive probe to terminal C1. Record the reading as the dc output voltage for Sfep 1 in Fig. 36-3. 570

Now set up your tvom for ac measurements, and measure the ac voltage between terminal C1 and the chassis. If no perceptible voltage is present even on the 1.2-volt range, make a dash in the space provided, or record any reading you obtain. Turn off the supply.

Step 2: To determine the effect of a high power factor in the input filter capacitor on the dc output voltage and the ac ripple voltage.

To simulate a high power factor in the input filter capacitor, disconnect the positive capacitor lead from terminal B4. Solder one end of the 3000-ohm resistor to terminal B4, and then solder the capacitor lead to the other lead of the 3000-ohm resistor, as shown in Fig. 36-4. Arrange these two leads so that they will not touch the chassis. You can now imagine that the resistor is actually inside the capacitor, in series with the positive lead and the capacitor plates. You can consider the end of the 3000-ohm resistor

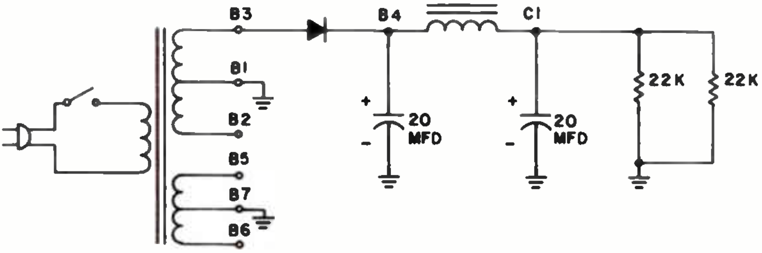

Fig. 36-2. The circuit for Step 1.

Fig. 36-3. Enter your readings here for Experiment 36.

connected to terminal B4 as the capacitor lead. Now we will measure the dc and ac output voltages with a defective input capacitor to see what has happened.

Set up your tvom to measure dc voltages as you did before, with the switch in the 300-volt position. Measure the dc voltage between terminal C1 and the chassis. Reduce the range switch setting if necessary to a lower range, and record the reading for the dc output voltage in Step 2.

Now measure the ac output voltage between the chassis and terminal C1. If there is no perceptible reading, indicate this by a dash; but if you do get a reading, show the value in the space for ac output voltage in Step 2 in Fig, 36-3. Turn off the supply.

You should find that the dc output voltage has dropped considerably, and you should have been able to measure an ac output voltage, showing that the ripple voltage at the input of the filter has increased considerably.

Now let us see how a serviceman would test a defective capacitor by using a good one of the same size.

Step 3: To determine the effect of shunting a suspected capacitor with one of approximately the same size known to be in good condition.

Connect your dc voltmeter between the chassis and terminal C1, using the slip-on alligator clip over the positive probe. Turn the power supply on, and note the voltage reading. Now pick up the third 20-mfd, 150-volt electrolytic capacitor, holding it by the case. Note carefully the positive and negative markings. Hold the capacitor with the negative lead touching the chassis and move the capacitor around until its positive lead touches terminal B4. You may notice a snap or spark when the connection is made. Hold the capacitor firmly in place, keeping your fingers off the hot lead. Notice the effect on the output voltage. It should increase almost to its original value. Record this value in Fig. 36-3 as the dc output voltage for Step 3.

Then, still holding the capacitor carefully by its case, lift it up and touch both leads to the chassis. The capacitor will discharge with a sharp snap and spark. Always discharge a capacitor, because if you don't, you might get an unpleasant

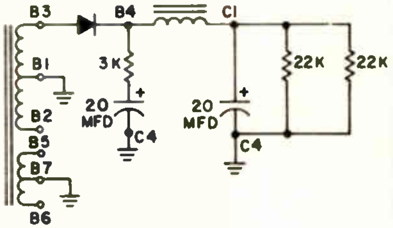

Fig. 36-4. The circuit for Step 2.

shock later. There is no danger as long as you hold the capacitor by its insulating case.

Leave your voltmeter connected to the output of the power supply, turn off the power supply, and set the voltmeter switches for ac measurements. Turn the power supply back on, and note that you still get the same reading as in Step 2 for the ac output voltage. Now, again hold the negative lead of the 20-mfd capacitor against the chassis, and allow the positive lead to touch terminal B4. Notice that when the capacitor makes contact across the defective capacitor, the ac output voltage drops to the same value as Step 1 for ac output voltage. Record this in Fig. 36-3.

Thus, you have seen what happens when an input capacitor develops a high power factor, and you have seen that you can check the capacitor by shunting it with a good one of about the same size. In a test like this, you must be sure to use the proper polarity. If you were to reverse the polarity on the test capacitor, you would probably ruin the capacitor. Even if it did not damage the part, the test would be worthless with the capacitor connected in this manner.

You have now finished the tests with the input filter capacitor; so remove the 3000-ohm resistor from the circuit, and unsolder the positive lead of the input capacitor from the resistor lead. Resolder the positive lead to terminal B4. The circuit is now the same as in Fig. 36-2.

Step 4: To show the effect of a high power factor in the output filter capacitor.

Disconnect the positive lead of the electrolytic capacitor from terminal C1. Solder one lead of the 3000-ohm resistor to lug C1. Then, solder the positive capacitor lead to the free resistor lead. Place the two leads so they cannot touch the chassis.

Connect the ground clip of the tvom to the chassis of the power supply, and connect the positive probe to terminal C1. Set your tvom to measure the dc voltage across the 11K-ohm load resistor, and turn the range switch to the 300-volt position. Turn on the power supply, and record the reading in the space for dc output voltage for Step 4 in Fig. 36-3.

The voltage should be the same as that in Step 1 in Fig. 36-3. This shows that a high power factor in the output filter capacitor has no effect on the dc output voltage. Now turn off the power supply.

Set the function switch to ac, and turn on the power supply. Reduce the range switch setting a step at a time until you get an easily read ac output voltage. Record this voltage in the space provided for ac output voltage in Step 4 in Fig. 36-3. Note that this voltage is considerably higher than in Step 2, showing that the filter action has definitely been affected.

Now, with the equipment still turned on and your meter indicating the ac output voltage, take your 20-mfd test capacitor, touch the negative terminal to the chassis, and the positive terminal to terminal C1 or to any point in electrical contact with C1. Good contact is necessary. The ac output voltage should drop to zero. Discharge your capacitor by touching both of its leads to the chassis of the power supply, and turn off the supply.

Discussion: From the tests you have made, you have learned that a defect in the input capacitor does not affect the circuit in the same way as one in the output capacitor. You have learned the following facts:

(1) A high power factor in an input filter capacitor decreases the dc voltage and increases the ac ripple voltage at the output.

(2) A high power factor in the output filter capacitor has no effect on the dc operating voltages but increases the ac ripple voltage across the load considerably.

In both cases, the capacitor can be easily tested by shunting it with a good one of about the same size. If the symptoms clear up, the one being tested is definitely bad, and should be replaced. The test capacitor does not need to have exactly the same capacity, but should have a working voltage at least equal to that of the one under test. Also remember that you must observe the proper polarity when making these tests. Immediately after making the test, discharge the test capacitor by touching its two leads to the chassis.

Instructions for Statement No. 36: You have seen the effect of a high power factor in both the input and output filter capacitors. The lead connecting to the foil inside the case may break, thus opening the capacitor. We are going to simulate this by disconnecting one of the capacitor leads and checking the ripple voltage. You are to find out the results of an actual open in the output filter capacitor compared to the results of a high power factor that you simulated by using the 3000-ohm series resistor.

Disconnect the positive capacitor lead from the 3000-ohm resistor, remove the 3000-ohm resistor from the circuit, and arrange the free capacitor lead so that it cannot short to the chassis. Clip your tvom to the chassis and to terminal C1. Set your tvom for ac measurements, turn on the power supply, and note the reading. You will then be able to answer the Statement. 1V AC

EXPERIMENT 37

Purpose: To show how two rectifiers can be connected to a voltage source to give twice the voltage that can be obtained from a single rectifier; and to show how they can be used for either half-wave or full-wave rectification.

Introductory Discussion: Tubes used in ac-dc radio receivers today are designed to operate on power supply voltages of 90 to 100 volts dc. A half-wave rectifier that is capable of supplying this voltage is shown in Fig. 37-1. It is the type of rectifier circuit that is usually found in ac-dc receivers. The tubes used in early ac-dc receivers required 180 volts dc or more. Therefore, vacuum tube rectifier circuits that could double the line voltage were used in these receivers. They are not often found in today's inexpensive ac-dc sets.

Voltage doublers, however, are widely used in TV sets, where eliminating the power transformer gives a much greater saving than in a radio receiver. You are likely to have to work on one at some time in your servicing career. For this

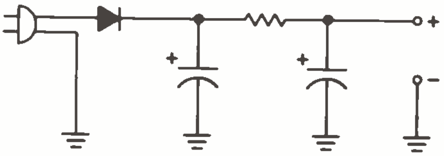

Fig. 37-1. A rectifier circuit capable of supplying about 90V dc.

reason, the study of how voltage-doubler power supplies operate is important to you.

Voltage-doubler power supplies are divided into two types: full-wave and half-wave. The full-wave doubler is generally used in supplies where the current demands are heavy and where an isolation transformer is used. Its output voltage has a ripple frequency of 120 Hz. Therefore, it can be more easily filtered than the output voltage of a half-wave voltage doubler, which has an output ripple of 60 Hz.

The half-wave voltage doubler is often used in TV receivers which have no power transformers. The ac line is connected directly to the negative side of the doubler circuit. You may also see half-wave doublers in TV high voltage supplies because in the high voltage supply the current demands are very low. Hence, filtering is not a problem.

Instead of using the power line directly as a source of voltage in this experiment, we will use half of the high voltage winding of the power transformer. This gives protection from the power line and permits us to experiment with somewhat lower voltages. Regardless of the source voltage used, the basic principles are the same.

Experimental Procedure: In addition to your tvom and the power supply parts, you will need:

1 20-mfd, 150-volt electrolytic capacitor
1 .25-mfd capacitor
1 12BA6 tube

Examine your soldering iron tip to be sure it is clean and well tinned.

You must first partially dismantle your power supply. Remove the two 22K-ohm resistors from terminals C1 and C4. Unsolder the two choke leads, and unsolder the red/yellow transformer lead from terminal B1. Also disconnect the two 20-mfd electrolytic capacitors. Remove any excess solder on the terminal strips, and make certain that no solder has bridged from the lugs to the chassis.

Fig. 37-2A shows how a rectifier can be connected to an ac voltage source to produce a rectified voltage that is positive with respect to the red/yellow side of the voltage source. Fig. 37-2B shows a rectifier connected to produce a rectified voltage that is negative with respect to the red/yellow side of the voltage source. We will combine these two circuits to

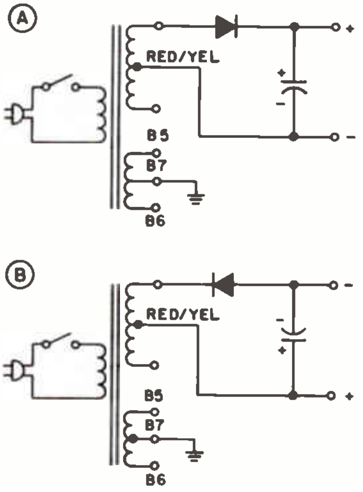

Fig. 37-2. Rectifier connected to (A) a positive supply and (B) a negative voltage with respect to the transformer center tap.

make a full-wave voltage doubler. The circuit is shown in Fig. 37-3.

Wire the circuit shown in the schematic diagram in Fig. 37-3. First, connect the red/yellow transformer lead to terminal B4. Connect a rectifier diode from terminal B3 to terminal A6; the cathode connects to A6. Connect another rectifier diode from terminal A4 to terminal B3. Connect the cathode to B3. Connect a 20-mfd, 150V electrolytic capacitor from terminal A4 to terminal B4, with the positive lead to B4. Connect another 20-mfd electrolytic capacitor from terminal B4 to terminal A6, with the positive lead to A6. Check your work against the schematic and solder all connections.

Check the connections carefully, because when more than two leads are soldered to a single terminal, it is very easy for one of the leads, usually the one on the bottom, to come loose. The circuit is now wired as shown in Fig. 37-3, and you can proceed with the experiment.

Step 1: To show that the circuit in Fig. 37-3 gives twice the voltage that a single rectifier would.

Measure the ac source voltage between terminals B4 and B3. Record your measurement in Fig. 37-4. Turn off the supply after each measurement.

65v

Now measure the dc output voltage of rectifier D_1 by measuring across capacitor

70v

C_1. Connect the ground clip of the tvom to terminal B4, and the probe to terminal A6. Note the polarity marked on the electrolytic capacitor in Fig. 37-3 so you will know how to set the polarity switch on the tvom. Record your reading in Fig. 37-4.

Measure the dc voltage developed by rectifier D_2 by measuring the voltage

80v

across capacitor C_2. Leave the ground clip of the tvom on terminal B4, note the polarity of the voltage to be measured as shown on the electrolytic capacitor in Fig. 37-3, and set your polarity switch accordingly. Touch the probe to terminal A4, and record the voltage you measure in Fig. 37-4.

As you can see from Fig. 37-3, capacitors C_1 and C_2 are in series, so that the voltages across them add. Measure this voltage by clipping the ground lead of the tvom to terminal A4, note the polarity so you can set the polarity switch properly, and put the range switch in the 300-volt position. Touch the probe to terminal A6, and record your voltage in Fig. 37-4 as the dc output without load. You should get approximately twice the voltage that you got across either C_1 or C_2.

180v

Notice that the dc voltage is much higher than the peak of the rectified ac source

voltage. Turn off the power supply. As a final measurement in this step, let us see how much the output voltage drops when a load is applied. Connect the two 22K-ohm resistors in series, and connect the outside leads of the 44K-ohm resistance between terminal A4 and terminal A6. Solder the connections. Now measure the dc voltage between terminals A4 and A6, and record the value in the space provided in Fig. 37-4. Note that the voltage dropped when the load was applied just as you have observed in the various rectifier circuits with which you previously experimented.

Before starting to disassemble this circuit, you should discharge the filter capacitors. To discharge the capacitors, strip a quarter of an inch or so of insulation from both ends of a 6-inch piece of hookup wire. Unplug the chassis from the power line, and holding the wire by the insulation, short terminal A6 to terminal B4. You may see a spark as the capacitor discharges. Do this several times. Now discharge capacitor C_2 by touching the ends of the hookup wire to terminals B4 and A4. When the capacitors have been discharged, it will be safe to touch the circuits without danger of shock.

Step 2: To show that in a half-wave voltage doubler, the rectified voltage stored in one capacitor is added to the line voltage so the sum of the two voltages acts as the source voltage for the second rectifier.

The circuit that you will use is shown in Fig. 37-5. First, remove the 44K-ohm load resistor (the two 22K-ohm resistors in series) from terminals A4 and A6. Unsolder and disconnect capacitor C_2 from terminals A4 and B4. Move the red/yellow transformer lead from B4 to A4. Move the negative lead of capacitor C_1 from B4 to A4.

Move both diode leads from terminal B3 to terminal B4. Connect capacitor C_2 between terminals B3 and B4, with the positive lead to B4. Solder all connections and check your work against the schematic in Fig. 37-5.

To measure the ac source voltage, set up your tvom for ac voltage measurements, and connect the ground clip to terminal B3. Turn on the power supply, and touch the probe to terminal A4. Record the ac voltage measured in Fig. 37-6.

Now, set your tvom for positive dc voltage measurements. With the ground

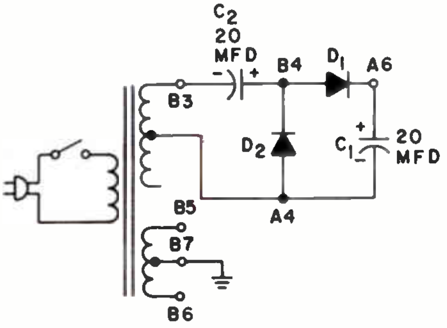

Fig. 37-5. The half-wave voltage doubler circuit.

lead connected to terminal B3, touch the probe to terminal B4. The voltage you measure is that developed across capacitor C_2, the 20-mfd, 150-volt capacitor connected between these terminals. Record the value in Fig. 37-6.

To measure the voltage at the output of rectifier D_1, turn off the power supply, connect the ground lead of the tvom to terminal A4, set the range switch to the 300-volt range, turn on the power supply, and touch the probe to terminal A6. Record the voltage you measure in Fig. 37-6. Note that it is approximately the same as the dc output voltage in Step 1 of Fig. 37-3. Turn your equipment off.

Discussion: In Fig. 37-3 the rectifiers function on alternate cycles of the power line, so the ripple voltage developed in the circuit between the output terminals (A4 and A6) is 120 Hz.

When the red transformer lead is positive with respect to the red/yellow lead in Fig. 37-3, we have current flow through rectifier D_1, which charges capacitor C_1 with the polarity shown. (Remember that the lead marked + on the rectifier is actually the cathode.) When the ac across the power transformer has this particular polarity, rectifier D_2 will not conduct. On the next half-cycle, the red/yellow lead is positive with respect to the red lead. Then rectifier D_1 will not conduct. However, rectifier D_2 does conduct, and in so doing, charges capacitor C_2 with the polarity shown. The two capacitors, of course, retain their charges, and since they are in series with the correct polarity, the voltage between terminals A4 and A6 is twice that of either capacitor.

In the half-wave voltage doubler in Fig. 37-5, there is a 60 Hz ripple between the output terminals A6 and A4. When the red lead in Fig. 37-5 is negative with respect to the red/yellow lead, rectifier D_2 will conduct, charging up capacitor C_2 to the polarity shown. This time rectifier D_1 will not conduct. On the next half-cycle, the red lead becomes positive with respect to the red/yellow lead and the voltage across C_2 is added to the transformer voltage. The polarity is incorrect for conduction through D_2, but D_1 will conduct, and its output will charge C_1 to the peak of this voltage. As you have seen, it is roughly equal to the output voltage of the full-wave doubler.

Note in Fig. 37-5 that one side of the ac source (the red/yellow lead) is connected to the negative side of the output at terminal A4. Therefore, the half-wave doubler can be used without an isolation transformer in an ac line operated receiver, since one line is common to the input and the output of the power supply.

Voltage doubler circuits, such as those in Figs. 37-3 and 37-5, are able to double the source voltage only when operated on ac voltage. They will not act as doublers if the line voltage is dc. This is of little importance because there are few areas today where dc power line voltage is available.

Voltage doublers have the same difficulties as ordinary power supplies. The filter capacitors become leaky or develop

a high power factor and the rectifiers may fail. Where a high power factor is suspected, the capacitors can be checked by shunting them with others of about the same size known to be in good condition. Where you suspect leakage, the capacitors are checked with an ohmmeter.

Instructions for Statement No. 37: In the high voltage supplies of TV receivers, voltage triplers are often used. You will build such a system to get the information to answer the Statement.

Insert the 12BA6 tube in the socket on the circuit board. You should still have leads connecting terminals B5 and B6 to lugs 1 and 2 of the circuit board for the 12BA6 heater voltage. Disconnect the power supply from the ac line. Run a lead from lug 4 on the circuit board to terminal B3 and solder both connections. Make certain that the connections already on terminal B3 do not come loose.

Connect a .25-mfd capacitor from lug 5 on the circuit board to terminal A4, again taking care that the leads already connected to terminal A4 do not come loose, and solder does not drip down and short to the chassis. You should have a wire connecting lugs 3 and 5 on the circuit board. The circuit should now be wired like that shown in Fig. 37-7.

Connect the ground clip of your tvom to the .25-mfd capacitor lead that goes to lug 5. Clip the positive probe of the tvom to terminal A6. Plug the power supply in, and turn it on. Note that the voltage goes up to approximately 170 volts, and then drops down as the .25-mfd capacitor slowly discharges. As the tube heats up, the voltage will start to rise rather rapidly, and will soon come to a stop. Record the voltage you measure on the margin of this page. You are now ready to answer the statement.

Tube And Transistor Fundamentals

In the following experiments, you will demonstrate triode vacuum tube and transistor fundamentals. You will then use the tube and transistor in voltage regulator circuits. We will review briefly the operation of tubes and transistors before going further.

You know that a tube passes current from cathode to plate. The current is in the form of electrons which are emitted by the heated cathode. When the plate is at a positive potential, the electrons are attracted to it.

The control grid, which is an element placed near the cathode in triodes, tetrodes, pentodes, etc., controls the electron flow, and hence the amount of current reaching the plate. The cathode-to-grid voltage or bias is normally slightly negative. By varying the bias, the plate current can be increased or decreased.

As you learned from your regular lessons, a transistor is similar to a triode tube. It has three elements - a collector, base and emitter, and can be used for many of the functions served by vacuum tubes.

Bipolar transistors, which are the most widely used type of transistor, are made in either of two classifications: PNP or NPN. You received a PNP type in this kit. In a PNP transistor, current passes from collector to emitter. This conduction takes place when the base is more negative than the emitter and the collector is more negative than the base.

The amount of collector-to-emitter current is controlled by the emitter-to-base current. The collector current increases as the base-to-emitter current increases.

EXPERIMENT 38

Purpose: To show that when the plate of a triode tube is positive with respect to the cathode, the tube can complete a path for direct current and to show that grid-to-cathode voltage can control the conduction of a triode.

Introductory Discussion: In previous experiments, you have connected two or more resistors in series across the battery and have noted how the battery voltage divides between the resistors. We will repeat this experiment using the high voltage supply instead of a battery. We will first simulate the cathode-plate circuit of a tube with a resistance. Then we will substitute the cathode-to-plate path of the tube for one of the resistors. You will find that the voltage will still divide between the remaining resistor and the cathode-plate path within the tube. You will use various values of resistors in series with the tube and see that the voltage division will change when one of the resistors in the circuit changes.

Following this, you will see that the series resistor can be placed between the negative side of the power supply and the cathode of the tube or between the plate and the positive side of the supply. You will find that the tube operation is similar in either case. You will see how we can vary the cathode-plate resistance of a tube. You will use a low voltage battery to supply bias voltage and measure the resulting plate current.

In this experiment you will use your 12BA6 tube connected as a triode. Previously, you used it as a diode, with the control grid connected to the plate. Now you will have to disconnect the control grid from the plate circuit, as the control grid will be supplied separately. Always be sure to turn off the supply and discharge the capacitors before you make circuit changes to avoid being shocked.

Experimental Procedure: For this experiment, you will need the following parts in addition to the experimental chassis and your tvom:

1 **100K-ohm resistor**
2 **22K-ohm resistors**
2 **1.5-volt flashlight cells**

Fig. 38-1 shows the circuit you will use in the first step of this experiment. The circuit consists of a half-wave rectifier power supply and a voltage divider. The 100K-ohm resistor we will call the load resistor, R_L, and the 44K-ohm resistance will represent the cathode-to-plate resistance of the tube. Before wiring the circuit, unsolder and remove from the chassis the two rectifiers and the three capacitors used for Statement 37. Also unsolder the red/yellow power transformer lead from terminal A4 and solder it to terminal B1. Remove the lead connected between terminal B3 and lug 4 of the circuit board.

Now connect a rectifier diode between terminals B3 and B4, with the cathode lead connected to B4. Connect a 20-mfd, 150V electrolytic capacitor between terminals B4 and B1, with the positive lead to B4.

Connect a 100K-ohm resistor between terminal B4 and lug 5 of the circuit board. If necessary, solder a short length of wire to the resistor lead. Connect the series-connected 22K-ohm resistors from terminal C4 to lug 5.

If you have not already done so, remove the 12BA6 tube from the tube socket. Also, remove the wire connecting lugs 3 and 5 on the circuit board. Note that you have a series circuit connected across the high voltage power supply and you are using lug 5 of the circuit board merely as a tie point.

Step 1: To measure the voltage drop across the 44K-ohm resistance.

Connect the ground lead of your tvom to the chassis and set the meter for measuring positive dc voltage on the 120-volt range. Plug the experimental chassis power cord into an ac receptacle and turn the equipment on. Touch the probe of your tvom to lug 5 and measure the voltage. Record the measurement under "Plate-Cathode Voltage" in the space for Step 1 in the chart in Fig. 38-2. 28v This is the voltage drop across the 44K-ohm resistance.

The voltage drop across the 100K-ohm load resistor can now be found by measuring the B supply voltage at terminal B4 and subtracting the voltage drop across the 44K-ohm resistance. For example, if the voltage across the 44K-ohm resistance

is 24 volts, and your B supply voltage is 80 volts, the voltage across the 100K-ohm resistance is 56 volts. For convenience we call this resistor R_L. Enter the voltage you calculated for the drop across R_L in the proper space in Fig. 38-2.

Step 2: To measure the plate voltage of a tube with a 100K-ohm load resistor.

Change the circuit so it will be wired according to the schematic in Fig. 38-3. Unsolder and remove the 44K-ohm resistance. Connect a length of hookup wire from lug 4 on the circuit board to terminal C4. Connect a short length of hookup wire from lug 4 to lug 3 of the circuit board. Finally, insert the 12BA6 in the socket.

Connect your tvom to measure the dc voltage at the plate, pin 5, of the tube (lug 5). Turn the circuit on and notice that the voltage rises immediately to the B supply voltage. As the tube warms up, the voltage will decrease. Record the plate voltage in Fig. 38-2. Subtract it from the B supply voltage value and record the difference as the voltage across R_L. Turn off the circuit and discharge the filter capacitor of the power supply.

Step 3: To show that decreasing the plate load resistance increases the plate voltage.

Remove the 100K-ohm load resistor connected between terminal B4 and circuit board lug 5. The two 22K-ohm resistors should still be connected in series. Connect them in place of the 100K-ohm resistor.

Turn the circuit on and allow time for the tube to warm up. Then measure the voltage at the plate of the tube, lug 5. Record this as the plate voltage for Step 3 and compute the voltage drop across the load resistance R_L. Record this voltage also in Fig. 38-2.

Step 4: To show that the load resistor can be in either the plate or cathode circuit.

You will use the circuit in Fig. 38-4. After turning the circuit off and discharging the filter capacitor, unsolder and remove the 44K-ohm load resistance. Connect a piece of hookup wire in its place between lug 5 and terminal B4. Remove the length of hookup wire connected in the cathode circuit between terminal C4 and lug 4 of the circuit

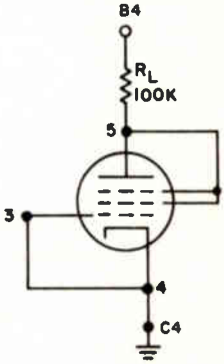

Fig. 38-3. The circuit for Step 2.

board. In its place, connect the 44K-ohm resistance.

Connect your voltmeter across the 44K-ohm resistance and turn the circuit on. Note that the voltage is zero at first and rises gradually as the tube warms up.

Because the meter is connected directly across the load resistance, you are measuring the voltage across R_L. Record this voltage in the space for R_L for Step 4 of Fig. 38-2. Subtract this voltage from the B supply voltage and enter the difference in Fig. 38-2 as the plate voltage.

Step 5: To show that the grid voltage will vary the resistance of the cathode-plate path.

With the circuit turned off, unsolder and remove the 44K-ohm resistance and connect a length of hookup wire in its place, between terminal C4 and lug 4. Remove the length of hookup wire between lug 5 and terminal B4. Connect the 44K-ohm resistance in its place.

The two 1.5-volt D cells should be still connected in series to form a 3-volt battery. If they are not, reconnect them. Connect the battery between the cathode and grid of the tube as shown in Fig. 38-5. Solder the positive battery lead to a convenient ground terminal and the negative battery lead to lug 3. Check your work to see that the circuit is wired according to Fig. 38-5.

Connect your tvom to measure the dc voltage between the chassis and the plate of the tube at circuit board lug 5. Energize the circuit. Allow time for the tube to warm up and observe the voltage reading. Record the plate voltage for this step in Fig. 38-2. Compute the voltage across R_L and record it in the chart. Turn the equipment off.

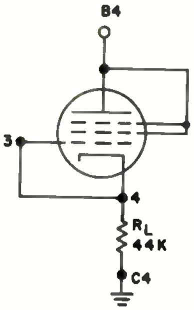

Fig. 38-4. The tube with the load resistance in the cathode circuit.

Discussion: In this experiment you have demonstrated some of the very important facts about vacuum tube circuits. These are:

(1) The cathode-plate path inside a tube will conduct current and this path has a definite resistance.
(2) If a resistor is placed in series with either the plate or cathode, the source voltage will divide between the tube and resistor.
(3) Changing the value of the resistor will change the voltage division between the tube and the load resistor.
(4) If a voltage is applied that makes the grid of the tube negative with respect to the cathode, the tube acts as a higher resistance and it conducts less current.

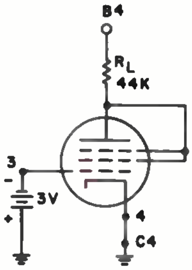

Fig. 38-5. The circuit for Step 5.

(5) When the load, R_L, is in the plate circuit, the plate voltage is equal to the supply voltage less the drop across R_L.

Instructions for Statement No. 38: For this statement, you will determine whether or not or how much current flows in the grid circuit used in the last step.

Unsolder the negative battery lead from circuit board lug 3 and connect a 100,000-ohm resistor in series between the battery lead and lug 3. Turn the circuit on and allow the tube to warm up. Measure the voltage across the 100K-ohm resistor. Using the Ohm's Law formula for current (I = E/R) compute the grid current. Answer the Report Statement here and on the Report Sheet. Turn the circuit off.

Unsolder and disconnect the 3-volt battery from the chassis. Unsolder and disconnect the 44K-ohm resistor. Also remove the length of hookup wire connected between lug 4 and terminal C4.

Statement No. 38: The grid current in the vacuum tube circuit with negative grid voltage was:

(1) between 5 and 15 ma.

(2) more than 20 ma.

EXPERIMENT 39

Purpose: To show that a transistor consists of two semiconductor junctions and to show that the base-emitter current can affect emitter-collector path resistance.

Introductory Discussion: You will use your power transistor in this experiment. This is a PNP-type germanium power transistor. The designation PNP refers to the characteristics of the materials which make up the emitter, base and collector elements of the transistor. The base is doped with a donor material which gives it an excess of electrons or negative characteristics. The emitter and collector are doped with an acceptor material. This material takes electrons from the germanium and leaves the emitter and collector with positive characteristics.

When a voltage is applied to a PN junction so that the negative voltage is applied to the N-type material and a positive voltage is applied to the P-type material, we say that the junction is forward biased. When the opposite polarity is applied, of course, the junction is reverse biased. For proper operation of a transistor, the base-emitter junction must be forward biased and the base-collector junction must be reverse biased.

Experimental Procedure: For this experiment, you will need the experimental chassis (with the transistor mounted), your tvom and the following:

1 100-ohm resistor
1 1,000-ohm resistor
1 47K-ohm resistor
1 10K-ohm resistor
2 1.5-volt flashlight cells

Be sure the chassis is turned off or unplugged from the power line for the first two steps of this experiment.

Step 1: To measure the dc resistance between the elements of the transistor.

You will use the ohmmeter section of your tvom to measure between the terminals of the transistor, which are identi-

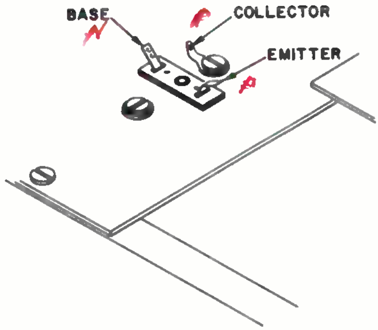

Fig. 39-1. How to identify the power transistor terminals.

fied in the sketch in Fig. 39-1. You will record your readings in the chart in Fig. 39-2.

Begin by measuring the forward resistance of the base-emitter junction. Set the tvom function switch to ohms and set the polarity switch to normal. Now the probe of the tvom is positive with respect to the clip. This is a PNP transistor so connect the tvom clip (negative) to the base and touch the probe (positive) to the emitter. Use the R X 100 range. Read the meter and record the resistance in the space for the B-E (base-emitter) forward resistance.

Switch your tvom to reverse and measure the resistance of the base-emitter junction in the reverse direction. Use the R X 1K or R X 10K range and record the resistance reading in the chart.

Now move the probe to the collector terminal, set the polarity switch to normal and measure the forward base-collector resistance. Use an appropriate ohmmeter range. Record the resistance in Fig. 39-2.

Switch the polarity to reverse, choose a convenient ohmmeter range and measure the base-collector resistance in the reverse direction. Place this value in the chart.

Now move the clip of the tvom to the emitter terminal, set the polarity to normal and measure the emitter-collector resistance. Place this value in the first column in the chart. Switch the tvom to reverse and take the final resistance reading. Touch the probe to the collector and measure the emitter-collector resistance in the opposite direction. Record this value in the chart.

Step 2: To measure the currents crossing the transistor junctions.

For this step, you will make indirect current measurements. You will measure the voltage drop across either a 100-ohm resistor or a 10,000-ohm resistor and compute the current by using the Ohm's Law formula, I = E/R. When you use the 100-ohm resistor, the current in milliamperes (ma) will be 10 times the voltage reading in volts. For example, a reading 2.4 volts across 100 ohms is 24 ma. When you use the 10,000-ohm resistor, the current in ma is 1/10 the voltage reading in volts. Thus, a reading 2.4 volts across 10,000 ohms represents a current of .24 ma or 240 microamperes (μa).

Fig. 39-2. Record your results for Step 1 here.

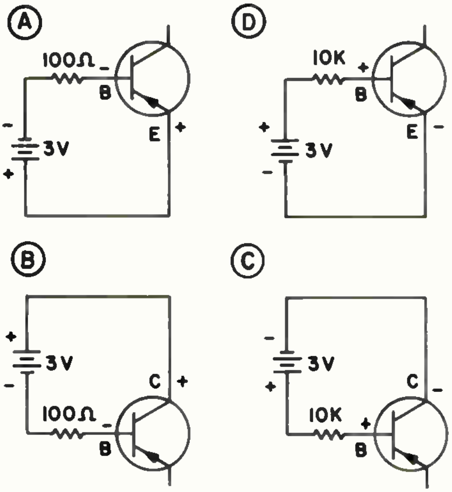

Fig. 39-3. Connections for measuring the forward and reverse currents of the two transistor junctions.

Wire the circuit shown in Fig. 39-3A. You should still have the two 1.5V flashlight cells connected in series, forming a 3-volt battery. Solder one lead of a 100-ohm resistor and a 10,000-ohm resistor to the transistor base terminal. Solder the positive lead of the 3-volt battery to the emitter terminal and solder the negative battery lead to the free lead of the 100-ohm resistor. Measure the dc voltage across the 100-ohm resistor, compute the current and record the value in the space for the base-emitter forward current in the chart in Fig. 39-4.

Change your wiring to that shown in Fig. 39-3B. Note that the negative battery lead still connects to the 100-ohm resistor and the positive battery lead is now connected to the collector terminal. Measure the voltage drop across the 100-ohm resistor and compute the forward base-collector current. Record the value in the chart in Fig. 39-4.

Modify your circuit as shown in Fig. 39-3C. Replace the 100-ohm resistor with the 10K-ohm resistor and reverse the battery polarity. Measure the voltage drop across the 10K-ohm resistor and compute the current. Record it in the space for base-collector reverse current in the chart in Fig. 39-4.

Change your circuit to that shown in Fig. 39-3D by moving the negative battery lead to the emitter terminal. Measure the voltage across the 10K-ohm resistor, compute the current and record it in the space for the base-emitter reverse current in Fig. 39-4.

Discussion of Steps 1 and 2: Thus far, you have proved two important facts about transistors:

(1) They consist of two PN junctions which act very much like semiconductor diodes, and

(2) the emitter-collector resistance is relatively high in both directions.

In Step 1, the low voltage across the ohmmeter leads biased the junction being measured. When applied in the forward direction, this caused the junction to pass current readily and, in turn, gave a low resistance reading. On the other hand, when you reversed the tvom polarity, you reversed the polarity of the voltage applied to the transistor junction. The slight reverse bias was sufficient to reduce the conduction of the junction and produce a very high resistance reading.

The diode action of the junctions was shown more clearly in Step 2 in which you used an external battery and series

BASE-EMITTER	23.4mA	.008mA

resistors to measure the junction currents. The resistor values were chosen to give reasonable meter indications without affecting the transistor action excessively. By comparing the forward and reverse currents in the chart in Fig. 39-4, you can see that the forward currents are many times the values of the reverse currents for both junctions.

From your regular lessons, you know that forward current across a PN junction is carried out by the majority carriers and reverse current is through minority carriers. Thus the forward and reverse currents you measured in both steps are indicative of the majority and minority carriers respectively crossing the PN junction.

The data accumulated in the chart in Fig. 39-2 can be helpful in checking transistors for condition and type (NPN or PNP). First, you found the resistances across each junction to be high in one direction and low in the other. This indicates that the junctions are neither shorted nor open. Consequently, you can assume that the transistor is not defective.

Second, you found that to forward bias the junctions a negative voltage is applied to the base. This means that the base must be N-type material and the emitter and collector must be P-type material. Therefore, the transistor is a PNP type. It must be remembered that this is only a rough check for transistors.

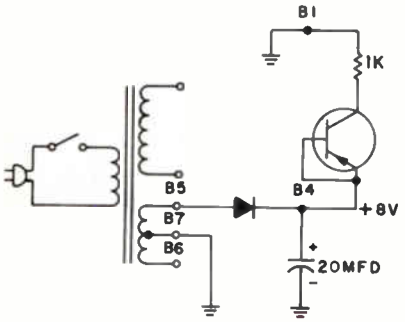

Fig. 39-5. Circuit used for Step 3.

BIAS	COLLECTOR CURRENT
0	.14MA
3V-47K	5MA
3V-10K	6.7MA

Fig. 39-6. Record your results for Step 3 here.

Step 3: To show that base-emitter current can control the emitter-collector resistance.

Construct the circuit shown in Fig. 39-5. Move the anode lead of the silicon diode from terminal B3 to terminal B5. Connect a length of hookup wire from terminal B4 to the emitter terminal of the transistor. Connect a 1,000-ohm resistor from the collector terminal of the transistor to terminal B1. Connect a short length of hookup wire from the emitter to the base terminal.

Energize the circuit and measure the dc voltage across the 1,000-ohm resistor. Convert the reading to current. Since the resistor value is 1,000 ohms, the current in ma is equal to the voltage in volts. This is the collector or collector-emitter current. Record the current in the chart in Fig. 39-6.

Turn the circuit off and connect the 3-volt battery into the base-emitter circuit. Refer to the schematic diagram in Fig. 39-7A. Note that the positive battery lead is connected to the emitter and the negative battery lead is connected

$\frac{2.6V}{10K\Omega}$ $10K\overline{)2.600}$ .26 ma

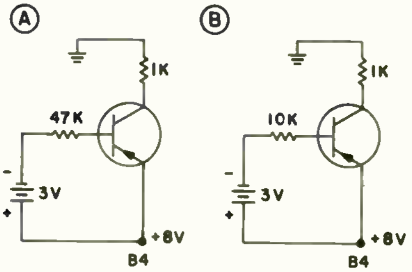

Fig. 39-7. Circuit used for Step 3 and Report Statement 39.

through a 47K-ohm resistor to the base.

When you have finished the wiring changes, energize the circuit and measure the collector current again. That is, measure the voltage across the 1,000-ohm resistor and convert it to current. Record the current value in Fig. 39-6. Turn the circuit off and replace the 47K-ohm resistor with a 10K-ohm resistor. Then, energize the circuit and measure the collector current again. Record the value in Fig. 39-6. Turn the circuit off.

Discussion of Step 3: A transistor is normally operated with a forward bias on the base-emitter junction and reverse bias on the base-collector junction. You had this condition when you connected the battery into the circuit.

Initially, with the base shorted to the emitter, the collector current was low. This indicates that the resistance between the emitter and the collector is high. By connecting the 3-volt battery and the 47K-ohm resistor between the emitter and base, you permitted about 50 μa of current to flow across the emitter-base junction. This base current resulted in a significant decrease in the resistance of the emitter-collector path of the transistor and permitted about 4 ma of collector current to flow.

When you substituted the 10K-ohm resistor for the 47K-ohm resistor, you increased the base current to about 270 μa. The increased base current caused a further reduction in the emitter-collector path resistance, resulting in a substantial increase in collector current.

Before leaving this circuit, note the directions of the currents and the polarities of voltages applied to the junctions in Fig. 39-7B. Because this is a PNP transistor, the base is slightly negative (about .2V) with respect to the emitter. Thus, current flows from the negative side of the battery, through the 10K-ohm resistor to the base. Current crosses the base-emitter junction and flows from the emitter back to the positive side of the battery.

The emitter-collector voltage is applied so that the base-collector junction is reversed biased. In a PNP transistor, this means that the collector will be negative with respect to the base. The primary current path is from the negative terminal of the power supply through the 1K-ohm resistor to the collector. Within the transistor, current crosses the collector-base and base-emitter junctions. From the emitter, the current flows back to the positive terminal of the source voltage.

Instructions for Statement No. 39: For this Report Statement, you will compare the base current and the collector current in the circuit shown in Fig. 39-7B.

Turn the circuit on and measure the current through the 1K-ohm collector load resistance. (You can use the value from Fig. 39-6 if you wish.) Now, move the voltmeter probe and ground clip and measure the voltage across the 10K-ohm base resistor. Using the procedure outlined earlier, calculate the base current.

Now, you have enough data to answer the Report Statement. Answer the State-

ment here and on the Report Sheet and turn the circuit off. Also, unsolder and disconnect the 3-volt battery.

Statement No. 39: When I compared the base and collector currents, I found that:

(1) the base and collector currents were about equal.

(2) the base current was slightly greater than the collector current.

[✓ *(3)*] *the collector current was between 20 and 30 times the base current.*

EXPERIMENT 40

Purpose: To demonstrate the fundamentals of voltage regulation and to show the operation of basic shunt and series regulators.

Introductory Discussion: In many electronic applications the voltage supplied to the various circuits must be stabilized (regulated) against variations in load and input voltage. There are a number of different methods used to regulate both high and low voltages. In this experiment we will investigate simple shunt and series regulators in both high and low voltage applications. We will be primarily concerned with regulators which stabilize voltages for variations in *load* current.

The percent regulation of a power supply for load variations is expressed using the following relationship: % regulation =

$$\frac{E_{\text{no load}} - E_{\text{full load}}}{E_{\text{full load}}} \times 100$$

For example, if the no load output of a certain power supply were 110 volts and the full load voltage were 100 volts, the percent regulation would be: % regulation =

$$\frac{110 - 100}{100} \times 100 = \frac{10}{100} \times 100 = 10\%$$

A perfect power supply would have zero percent regulation since the no load and full load voltages would be the same. The larger the percent regulation, the poorer the power supply is said to be regulated.

The basic shunt regulator consists of a series resistance connected between the power supply and the load, and a constant-voltage variable-current device connected in parallel with the load. As the load current varies, so does the current of the shunt regulator to maintain a constant output voltage.

In the basic series regulator, a variable resistance device is connected between the power supply and the load. As the load current varies, the series resistance is changed to keep the output voltage steady. We will examine both shunt and series regulators in this experiment.

Experimental Procedure: For this experiment you will need the experimental chassis, your tvom and the following parts:

1	100-ohm resistor
1	220-ohm resistor
1	1K-ohm resistor
1	2.2K-ohm resistor
1	4.7K-ohm resistor
1	22K-ohm resistor
1	47K-ohm resistor
1	12BA6 tube
1	Neon lamp
2	HV diodes
2	LV diodes
2	20-mfd electrolytic capacitors

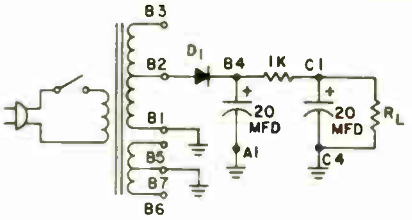

Fig. 40-1. The circuit used for Step 1 and Step 2.

By now you have worked with the experimental chassis enough that you should be familiar with the terminal strips and the schematic symbols used in the diagrams. Therefore we will not give detailed instructions for changing the wiring around for the various steps in this experiment.

Step 1: To measure the regulation of a typical half-wave high voltage power supply.

Construct the circuit shown in Fig. 40-1. Use a high voltage diode for D_1 and be sure to observe the polarity of the two electrolytic capacitors when you connect them into the circuit. The output terminal of the supply is terminal C1. Do *not* connect resistor R_L (the load resistor) yet.

When you have the circuit wired, turn on your tvom and set it to read 120 volts dc. Clip the probe to terminal C1 and the ground clip to the chassis. Turn the circuit on and read the no load output voltage. Record this reading in Fig. 40-2 under "NO LOAD VOLTAGE" for Step 1. Without disconnecting the tvom, turn the circuit off. Notice that the output voltage drops very slowly even though you have turned the power off. This is because the two 20-mfd capacitors are fully charged and are loaded only by the tvom. They would retain this charge quite a long time and if you were to start making circuit changes now you could receive a nasty shock from the "dead" circuit.

To discharge the filter capacitors, take a screwdriver and quickly short terminal C1 to the chassis. This will discharge both of the capacitors. This is *always* a good practice to follow when working with circuits operating at high voltages: With the power off, short the output filter capacitor to discharge it before working on any of the circuits.

With the power supply discharged, remove the tvom probe and solder a 22K-ohm resistor from C1 to C4. This will be your load resistor. Reconnect the tvom probe to C1, turn on the power and

record the FULL LOAD VOLTAGE for Step 1 in Fig. 40-2. Using the formula given previously, calculate the percent regulation and enter this value in Fig. 40-2. With the tvom still connected to terminal C1 turn the power to the circuit off. Notice that the voltage decreases rapidly to zero with the 22K-ohm load in place.

Step 2: To show that a bleeder resistor will improve the power supply regulation.

By placing a fixed load on the power supply the voltage regulation will be improved. You have demonstrated this before in an earlier Training Kit, but now you will see the bleeder resistor used in a real power supply. You will use a 47K-ohm bleeder as shown in Fig. 40-3. Solder it into the circuit, turn the power on and measure the no load output voltage. Record this in Fig. 40-2 for Step 2. Turn the power off, discharge the filter capacitors and connect the 22K-ohm load resistor as before. Turn the power on and record the full load voltage in Fig. 40-2. Calculate the percent regulation and enter it in Fig. 40-2 also.

Step 3: To show the operation of a basic shunt regulator.

With the power off, wire the neon shunt regulator shown in Fig. 40-4. Do not connect R_L yet. Turn the power on and measure the no load output voltage at terminal C3. Record this value in Fig. 40-2 for Step 3. Turn the power off and discharge the filter capacitors. Connect the 22K-ohm load resistor across the neon lamp, turn the circuit on and measure the full load output voltage. Record this in Fig. 40-2 and calculate the percent regulation. Enter this value in Fig. 40-2 also. Turn the power off and discharge the filter capacitors.

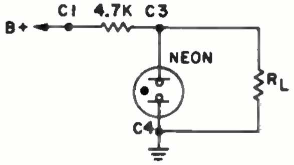

Fig. 40-4. The neon shunt regulator used in Step 3.

Step 4: To show the operation of a basic series regulator.

For this step you will use the circuit of Fig. 40-5. The neon lamp and 4.7K-ohm resistor are already connected. To construct the circuit, install the 12BA6 tube in the socket of the etched circuit board.

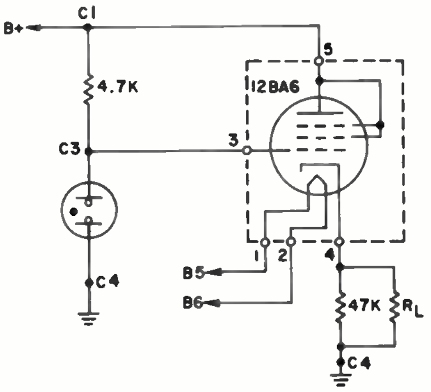

Fig. 40-5. The simple series regulator used in Step 4.

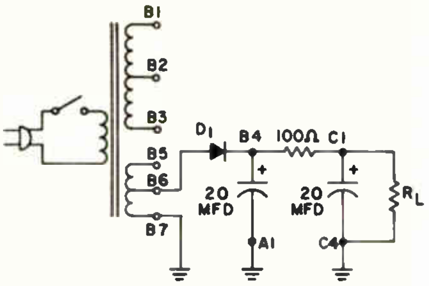

Fig. 40-6. Basic low voltage supply used in Step 5.

Lug 1 and lug 2 should still be connected to terminals B5 and B6. Be sure to remove the 22K-ohm resistor before you connect lug 3 of the circuit board to terminal C3.

When you have wired the circuit, check your connections and turn on the power. It will take a few seconds for the tube to warm up. When the tube has warmed up, read the no load output voltage at lug 4 of the circuit board. Record this value in Fig. 40-2. Turn the power off, discharge the filter capacitors and connect the 22K-ohm load resistor from lug 4 of the circuit board to terminal C4. After allowing the tube to warm up, read the full load voltage at lug 4 of the circuit board. Record this in Fig. 40-2 and calculate the percent regulation. Enter this value in Fig. 40-2 also.

Disconnect the leads and resistors from the etched circuit board and remove the etched circuit board from the chassis. Also remove the 4.7K-ohm resistor and the neon lamp.

You will perform the following steps using the basic low voltage power supply of Fig. 40-6. Disconnect the green lead from terminal B6 and the green/yellow wire from terminal B7. Reconnect the green/yellow lead to terminal B6 and the green lead to terminal B7. To construct the circuit of Fig. 40-6, move the anode lead of D_1 from terminal B2 to terminal B6 and replace the 1K-ohm resistor with a 100-ohm resistor.

Step 5: To measure the regulation of the basic low voltage power supply.

Turn the power on and measure the no load voltage at terminal C1. Use the 12 volt dc range of your tvom. Record your reading in Fig. 40-7. Connect a 2.2K-ohm load resistor from terminal C4 to terminal C1 and read the full load voltage. Record this value in Fig. 40-7 and calculate the percent regulation. Enter this value in Fig. 40-7 also.

The low voltage equivalent of the neon lamp shunt regulator used in Step 3 of this experiment is the Zener diode. We do not have such a diode, but for our purposes we can use a series of forward-biased silicon diodes to perform roughly

STEP	NO LOAD VOLTAGE	FULL LOAD VOLTAGE	PERCENT REGULATION
5	9.3	7.6	22.3
6	1.75	1.73	1.16
7	1.72	1.70	1.18

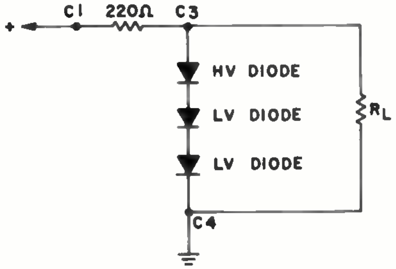

Fig. 40-8. Simple low voltage shunt regulator used in Step 6.

the same job. A forward-biased silicon diode will have a voltage drop of about 0.7 volts if we pass enough current through it. Three diodes connected in series will produce a fairly constant 2.1 volts (3 X .7). You will connect the two low voltage diodes and the remaining high voltage diode in series to make the shunt regulator of Fig. 40-8. Since we will consider the three diodes together as a circuit element, simply tack solder the diodes together: cathode lead of the HV diode to the anode lead of one LV diode; cathode lead of the LV diode to the anode lead of the other LV diode. Solder the anode lead of the diode assembly to terminal C3 and the cathode lead to terminal C4. Connect a 220-ohm resistor between terminals C1 and C3. Terminal C3 is now the output of the low voltage shunt regulated power supply.

Step 6: To see how the basic low voltage diode shunt regulator works.

Turn on the power and measure the no load output voltage at terminal C3. Record this value in Fig. 40-7. Connect the 2.2K-ohm load resistor from terminal C3 to terminal C4 and read the full load output voltage. Record this value in Fig. 40-7 as well as the calculated percent regulation.

Step 7: To show the operation of a transistor series regulator.

Without changing the basic power supply connections, wire the series regulator shown in Fig. 40-9. Notice that now the output voltage is between terminals C1 and C3, and *not* to the chassis. This is necessary to simplify the wiring since the PNP transistor must be placed in the *negative* lead of the power supply. Refer to Experiment 39 if you have forgotten which are the base and emitter terminals of the transistor. After you have completed wiring the circuit of Fig. 40-9, carefully recheck your wiring to be sure all parts and leads are correctly placed.

Clip the probe of your tvom to terminal C1 and the ground clip to terminal C3. Turn the power on and record the no load output voltage in the space provided in Fig. 40-7. Connect the 2.2K-ohm load resistor between terminals C1 and C3, record the full load voltage and percent regulation in Fig. 40-7 and turn off the power.

Discussion: In the first step you measured the regulation of a typical high voltage power supply. You saw how a bleeder resistor, while lowering the no load output voltage, improved the power

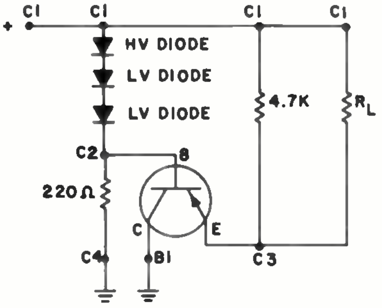

Fig. 40-9. Low voltage series regulator used in Step 7.

supply regulation. Going one step further, you saw how the neon lamp could be used to provide extremely good regulation in Step 3. Neon lamp regulators make use of the characteristics of neon gas that when the gas becomes ionized (by applying a high enough voltage), the voltage drop is very constant and independent of the current through the gas. As a shunt regulator, when the applied load draws current from the supply, the current through the neon decreases but the voltage across it remains constant.

The neon lamp was used as a stable reference voltage for the series regulator of Step 4. The 12BA6, connected as a triode, was used as a cathode follower. The tube supplied cathode current to the load and the neon acted only as a stable reference voltage to set the grid and cathode voltage.

Step 5 and Step 6 were basically similar to Steps 3 and 4 using the low voltage power supply. The series regulator of Step 7 is the transistor equivalent of the circuit used in Step 4. The forward-
1.82 biased diodes provided the reference voltage while the transistor acted as a variable resistance to maintain the output voltage steady with changes in load current.

Instructions for Statement 40: For this Statement you will double the voltage applied to the transistor series regulator of Fig. 40-9 and see how well the circuit regulates input voltage variations.

Leave the 2.2K-ohm resistor connected and move the anode of the rectifier, D_1 from terminal B6 to terminal B5. Turn the power on and measure the output voltage between terminals C1 and C3. Compare this voltage with the full load voltage recorded for Step 7 in Fig. 40-7.

Answer the Report Statement below and on your Report Sheet.

Statement No. 40: When I doubled the voltage applied to the transistor series regulator I found the output voltage:

[✓ *(1)*] *did not change significantly.*
(2) increased considerably.
(3) almost doubled.

WIRING THE PILOT LAMP

This completes your experimental work in this Training Kit. You will now install and wire the neon lamp in its permanent location, where it will serve as a pilot lamp. You will need a 100K-ohm resistor.

Unplug the power cord of the chassis. Push the lamp into the grommet in the front panel from the inside, as shown in Fig. 17, so that about 1/4" projects on the outside of the chassis. Connect the leads to terminals 1 and 2 of strip E but do not solder. Connect and solder a 100K-ohm resistor from terminal 1 of strip E on the front panel to terminal 4 of the on-off switch on the back of the potentiometer.

Connect a length of hookup wire from terminal 2 of strip E to terminal 3 of strip D. (Note: this terminal has a power cord and black transformer lead connected to it.) Solder the connections.

Turn the switch off and plug in the power cord. The neon lamp should not light. If it does, unplug the power cord, unsolder the resistor lead from terminal 4 and solder it to terminal 5 on the back of the switch and plug the cord in again.

Your pilot lamp should then be wired directly across the primary winding of the power transformer. Thus, it will light only when the circuit is energized.

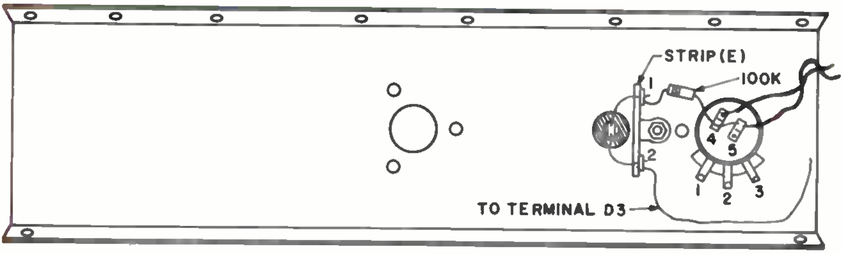

Fig. 17. Pilot light wiring.

LOOKING AHEAD

This completes your experimental work on power supplies. After you have answered all the statements on the Report Sheet, send it to NRI for grading. While you are waiting for your next kit, unsolder and remove all resistors and capacitors wired to terminal strips A, B and C and the circuit board.

Clean the terminals on top of the chassis and on the circuit board. Hold the chassis up and heat the terminals, allowing the solder to run down on the tip of your soldering iron. You should also clean and straighten the leads on your components so they will be usable in your future experiments.

Check the tip of your soldering iron. If necessary file and re-tin the tip, using the procedure given in the first group of experiments.

Cashing In On Discontent

Discontent is a good thing -- if it makes you want to do something worthwhile. If you had not been discontented, you would never have enrolled in the NRI course.

Practically everyone is discontented. But some of us are "floored" by discontent. We develop into complainers. We find fault with anything and everything. We end up as sour and dismal failures.

Those of us who are wise use our discontent as fuel for endeavor. We keep striving toward a goal we have set for ourselves. We are happy in our work. We face defeat, and we come out the victors.

At this minute you may be discontented with many things -- your progress with your course, your earning ability, yourself.

Make that discontent pay you dividends. Don't let it throw you down. If you do, you may never be able to get up again. Keep striving to remove the cause of your discontent. Remember that it's always darkest before the dawn. And a real NRI man works hardest and accomplishes most when he is face to face with the greatest discouragements.

INSTRUCTIONS FOR PERFORMING EXPERIMENTS 41 THROUGH 50

In any modern AM/FM or TV receiver there are only a few basic parts such as resistors, capacitors, inductors (transformers and coils) and amplifying devices (tubes and transistors). You have already conducted experiments using resistors and capacitors that show how they act in ac and dc circuits. Now you are going to demonstrate the action of tube and transistor amplifiers and learn how tubes and transistors can be used in practical circuits.

Although tubes and transistors will do the same job, they work in different ways. For this reason, the basic tube and transistor experiments will be carried out separately.

The first four experiments show how a tube produces signal amplification. After completing this section, you will demonstrate how transistors work and how they can produce amplification.

In the remaining experiments, you will study oscillator circuits and cascade amplifiers. You will show that an oscillator is actually a self-excited amplifier and then you will build up and demonstrate the various types of oscillator circuits. This section includes both L-C oscillators and R-C oscillators.

You will demonstrate both R-C coupled and DC (direct coupled) cascade amplifiers in the final experiment. You will see how the individual circuits work and you will demonstrate how the amplifier stages affect each other. In this experiment you will also get valuable experience in finding defects in practical amplifier circuits.

Each experiment in this manual illustrates some important fact you will need in your servicing career. Study each experiment carefully -- make sure you understand both what you are going to show before you start, and the conclusion drawn from each experiment in the discussion.

CONTENTS OF THIS KIT

The contents of this kit are illustrated in Fig. 1 and listed below it. Check the parts you received against this list to be sure you have all of them. Some of the parts sent to you may be slightly different in appearance from those pictured in Fig. 1.

Do not discard any of these parts or the parts from previous kits until you have finished your NRI course or unless instructed to do so. Do not cut the leads of any part.

IMPORTANT: If any part in this kit seems to be missing, look for a substitute. If any part is obviously defective, or has been damaged in shipment, return it immediately to NRI as directed on the "Packing and Returned Material" slip included with this kit.

THE 12AT6 TUBE

The 12AT6 tube supplied in this kit is really two tubes in one. It consists of a high-gain triode section and a double diode section. The triode and the two diode plates all use the same cathode. The diodes can be used to rectify small signal voltages. Because of their small physical size and close spacing to the cathode, they could not be used to rectify high currents or high voltage as found in a receiver power supply.

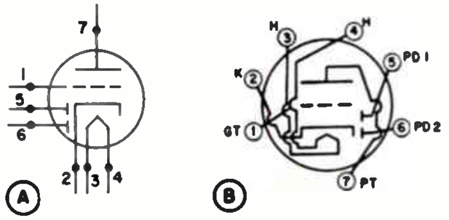

Fig. 2. Schematic symbol for a 12AT6 tube (A) and connections of the elements to the pins (B).

A diagram of a 12AT6 tube showing the elements schematically and the arrangement of the pins is shown in Fig. 2. The standard practice for numbering the tube pins has been followed in this diagram -- that is, it is assumed that you are looking at the base of the tube (or at the bottom of the tube socket). Notice that pin 1 is at the left of the space where there is no pin, and that the numbers increase as you go around the tube clockwise from this pin. This is the numbering system used for all miniature tubes.

Note that the triode grid connects to pin 1, and is marked GT. The cathode is connected to pin 2, and is marked K. The cathode is common to the triode and diode sections. The heater, marked H, connects to pins 3 and 4. The two diode plates are marked PD1 and PD2, and are connected to pins 5 and 6. The triode plate, marked PT, is connected to pin 7.

This tube heater or filament requires an operating voltage of 12 volts at a current of .15 ampere. The maximum plate voltage rating for the triode section of this tube, when it is used as an amplifier, is 300 volts, applied between the triode plate and the cathode. However, in these experiments we will use a voltage of approximately 100 volts.

TRANSISTORS

You received two small junction transistors in this kit. They are low power NPN silicon transistors. Such transistors are normally used as high gain amplifiers for small signals or as oscillators.

Each of these transistors has a base of P-type material and an emitter and collector of N-type material. This is just the opposite of the PNP transistor you used in the preceding kit.

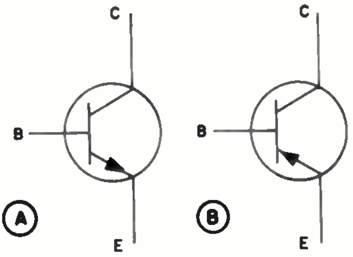

Fig. 3. The schematic symbol for (A) an NPN transistor and (B) a PNP transistor.

The schematic symbols for an NPN and PNP transistor are shown in Fig. 3. Note that the only difference between them is the direction of the arrow. In an NPN transistor symbol, the arrow points away from the base and, in a PNP transistor symbol, the arrow points toward the base.

Because a transistor can be damaged by rough handling or excessive heat, you must be careful with it. This will be discussed further when you connect the transistor into a circuit.

INSTRUCTIONS FOR PERFORMING THE EXPERIMENTS

Each of the experiments described in this manual will contribute to your knowledge of circuit action and develop your skill in handling parts, in making measurements, in adjusting circuits to resonance, and in learning how circuit defects can prevent proper operation. Do not rush through the experiments. Spend enough time on each one to make sure you not only get acceptable results, but also thoroughly understand each principle involved.

The extra practice in soldering you will get as you go through these experiments will be very helpful if you make every effort to make your soldering better each time. But if you are careless, the extra practice will make bad habits harder to break. Remember you need very little solder to make a good connection. The parts must be clean and enough heat must be applied to melt the solder into a smooth flowing liquid and burn off the rosin. If there is rosin in a joint, the poor connection may affect your experiments. After the solder has cooled, test the strength of the connection by pulling the leads gently with a pair of longnose pliers. Even an expert will have trouble soldering with an iron with a pitted, corroded, or untinned tip. A beginner will have more trouble and may not be able to tell if he has a good soldered connection even though the parts seem to be held together. Make it a habit to check the tip of your iron periodically, re-filing it when necessary and keeping it bright and tinned.

To get the greatest benefit from each experiment, make sure you understand the principles and the procedure before you set up the circuits and take your measurements. If any part of the theory involved in the experiment puzzles you, refer to the lesson texts in your course where the principles are covered, and read them carefully.

If you fail to get acceptable results from any experiment, review the instructions carefully. Make sure your tvom is properly calibrated and the 9-volt battery is in good condition. If it is weak, replace it. Make sure that you connect the tvom properly to the experimental circuit. If the ground clip is disconnected from the chassis of the experimental circuit and you touch only the probe to the circuit, you will get erratic readings, which are meaningless.

We shall not give you detailed instructions on the adjustment and use of your tvom in these experiments, so failure to get the proper readings may be caused by some error in your use of the instrument. If you are not absolutely sure that you know every detail of how to adjust and use your tvom, refer to the instructions given in Kit Manuals 2T and 3T.

Examine each experimental circuit to see that you have set it up correctly and have the correct components in the circuit. Then check for possible defective parts and for poorly soldered connections. Also make sure that the power supply furnishes the right plate and filament voltage for the experiment. Be patient and thorough in your search for any trouble that develops.

If you are unable to get the correct

results, or to locate the source of trouble, write to us for help. Use the special Consultation Blank enclosed with this kit. Describe the trouble briefly but completely. Also describe the tests you have made and the results of those tests. Be sure to include the actual values found in any measurements you have made so that we will have facts and figures on which to base our reply.

As you have done in previous kits, record your results in the charts or tables provided, as you perform each experiment. After you have completed each experiment, fill out the Statement at the end of the experiment and on the Report Sheet.

Be sure to turn your experimental equipment and tvom off when you are not performing experiments.

Preliminary Assembly

You will begin to prepare the experimental chassis for the experiments in this kit by assembling and mounting an etched circuit board. Then you will wire the HV power supply you will use throughout this kit.

The diagram in Fig. 4 shows the locations of the holes in the chassis. Refer to it as necessary.

If any resistors or capacitors are still attached to the terminals on top of your chassis, remove them at this time.

WIRING THE CIRCUIT BOARD

To prepare the etched circuit board, you will need these parts.

- **1 Circuit board (EC25)**
- **1 7-pin socket (SO76)**
- **13 Terminal lugs (LU8)**
- **12 1/4" X 4-40 screws**
- **12 4-40 hex nuts**

Mount the tube socket on the foil side of the circuit board as shown in Fig. 5. (Fig. 5 shows the circuit board mounted on the chassis.) Line the pins up over the holes and push the socket down tightly to seat the pins. Then solder the 7 pins to the copper foil.

Attach twelve terminal lugs on the foil side of the board at the places shown in Fig. 5. Attach each lug with a 1/4" X 4-40 screw and nut. Position each terminal so that it does not short to adjacent terminals or strips on the circuit board and tighten the nuts.

Remove circuit board EC24 from the

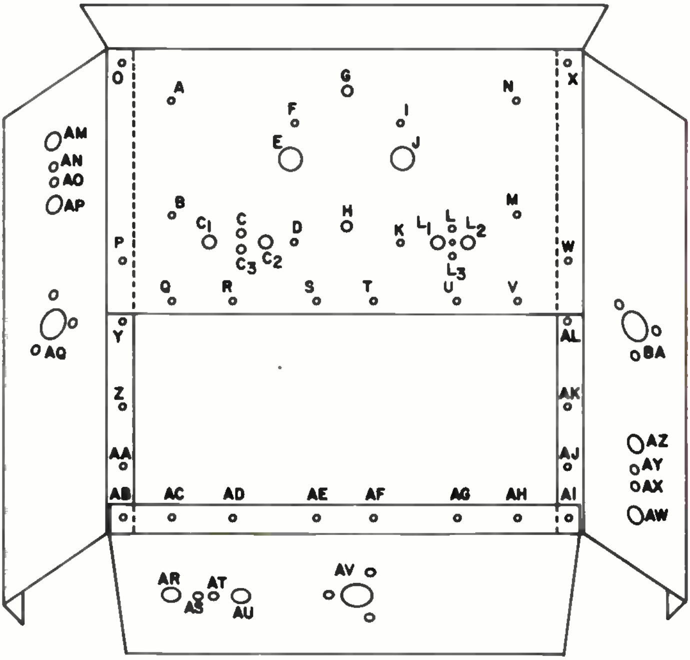

Fig. 4. How to identify the holes in the experimental chassis.

experimental chassis and mount the new board, EC25, in its place, as shown in Fig. 5. Attach this board with four 1/4" X 4-40 screws and nuts. Place a terminal lug under the mounting screw at hole AE, as shown.

Refer to Fig. 5 to identify the terminal lugs on circuit board EC25.

Connect and solder a length of hookup wire from terminal B5 to lug 4 on the circuit board.

Connect and solder a length of hookup wire from terminal B6 to lug 5 on the circuit board.

Connect and solder a length of hookup wire from lug 6 to terminal B1.

ASSEMBLING THE HV POWER SUPPLY

The HV power supply will be wired on terminal strip A. You will need the following parts:

- 2 HV silicon diodes
- 2 20-mfd, 150V electrolytic capacitors
- 1 68K-ohm resistor

The diodes and capacitors were left over from the previous kit.

Construct the circuit shown in the schematic diagram in Fig. 6. Fig. 5 also shows the wiring on the chassis. First, unsolder the red and red/yellow power transformer leads from terminal strip B. Connect a length of hookup wire between terminal A6 and B3.

Solder the red/yellow transformer lead to terminal A1. Connect one red transformer lead to terminal A2 and connect the other red lead to terminal A3.

Connect an HV diode between terminals A2 and A4, with the cathode lead to A4. Solder terminal A2.

Connect a second HV diode between terminals A3 and A4, with the cathode lead to A4. Solder terminal A3.

Connect one lead of the filter choke to terminal A4. Connect the other lead of the filter choke to terminal A6.

Connect and solder a 68K-ohm resistor between terminals A6 and A7.

Connect a 20-mfd, 150V electrolytic capacitor from terminal A1 to terminal A4. The positive lead connects to A4. Solder both connections.

Connect another 20-mfd, 150V electrolytic capacitor from terminal A6 to terminal A7, with the positive lead to A6. Solder both connections.

Check your wiring to be sure that the polarities of the diodes and the capacitors are correct and that there are no short circuits. Also, be sure that all connections are soldered.

To test the power supply, short terminals A4 and A6 to the chassis momentarily to discharge the electrolytic capacitors. Then, connect your ohmmeter to measure the resistance between the chassis and terminal A6. Set the range switch to R X 10K, set the polarity switch to normal and touch the probe to terminal A6. You should read at least 40,000 ohms.

If you get this reading, you are ready to test the power supply for voltage. Set the function switch on your tvom to dc and set the range switch to the 120V position. Energize the circuit and measure the voltage. You should read 80 volts or more. If the voltage is negative, the diodes are installed incorrectly; if the voltage is quite low, look for a capacitor or diode installed incorrectly, a poor connection or a resistor of too low a

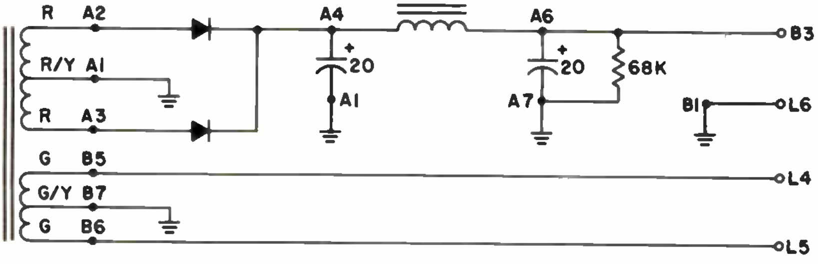

Fig. 6. Schematic of HV power supply.

value between terminals A6 and A7. If you have trouble and cannot locate it, write for help before you go on with your experiments.

You now have a full-wave rectifier circuit operated from the center-tapped high voltage winding of the power transformer. The circuit is quite conventional in all respects. The resistor connected across the output of the filter network is primarily a bleeder resistor. Its purpose is to present a constant load to the power supply and to discharge the filter capacitor slowly when the power is turned off.

Vacuum Tube Fundamentals

The primary function of a triode or other type of tube having a control grid is amplification. Amplification, as you know, is increasing the strength of a signal so it can provide a useful output. An example of this is found in a public address system. The amplifier builds up the weak signal produced by the microphone and makes it strong enough to operate a speaker.

You have already conducted experiments that show that current flows from cathode to plate in a triode and that the amount of current can be controlled by the grid voltage. In the following experiments you will demonstrate bias, biasing methods and practical amplifier circuits.

EXPERIMENT 41

Purpose: To show that a voltage applied to the control grid of a vacuum tube will control the plate current; and to show that the effect the grid voltage has on the plate current depends upon the polarity of the control grid voltage with respect to the cathode.

Introductory Discussion: In a previous experiment you saw that the cathode-plate path of a tube is conductive. When the tube was connected to the source in series with a resistor, the voltage divided between the tube and the resistor. This resistor is called the plate load of the tube, because it is usually in the plate circuit and because it translates variations in plate current into voltage variations.

In these experiments we will not actually measure the plate current flowing through the tube and the load resistor. Checking the voltage drop across the tube or across the resistor will show whether current is flowing, when the current changes, and whether it increases or decreases.

Remember that when the current increases, there will be *less* voltage across the tube and *more* voltage across the plate load resistor. When the plate current of the tube decreases, there will be more voltage across the tube, and less voltage across the plate load resistor.

In a previous experiment, you compared the plate voltage with the grid not connected to anything, and with the grid shorted to the cathode. The resultant change in plate voltage showed that the grid does affect the plate current. In this experiment, you are going to apply voltage between the control grid and the cathode. You will use the two 1.5-volt cells you received in a previous kit. You will be able to make the control grid either positive or negative.

Experimental Procedure: In conducting this experiment, you will need the parts mounted on the chassis, and the following parts:

2	1.5-volt flashlight cells
1	220-ohm resistor
1	100K-ohm resistor
1	12AT6 tube
1	Test clip

After checking your soldering iron tip to be sure it is in good condition, check the condition of the flashlight cells. You have used them in several kits, so you may need to replace them.

To test the two flashlight cells, connect them in series to form a 3-volt battery as you did in previous experiments by connecting a piece of hookup wire from the negative terminal of one cell to the positive terminal of the other. Then set your tvom for dc and measure the voltage of the series-connected cells. The results that you get for this test may show that the cells are good. However, to get a true indication of their condition, you must measure the voltage under load conditions.

To measure the cells under load, connect a 220-ohm resistor between the positive and negative terminals of the series-connected cells. Measure the voltage across the resistor; it should be at least 2.5 volts. If it is not, you will have to obtain new flashlight cells to do this experiment.

When you are sure you have good flashlight cells, unsolder the resistor from the cell terminals, but leave the cells connected in series. Then, put a rubber band or tape around the two cells to hold them together. Lay them on your work surface near the chassis. Cut off about ten inches of hookup wire, solder one end to the ends of the cells that are joined together. This is the positive terminal of one cell and the negative terminal of the other. Solder the free end of this wire to terminal B7.

Connect and solder a 100K-ohm resistor from terminal B3 to lug 8 on the circuit board.

Solder a 10-inch length of hookup wire to lug 7 on the circuit board. Remove about 1/2 inch of the insulation at the other end. The circuit is now wired as in Fig. 41-1. You are now ready to conduct the experiment.

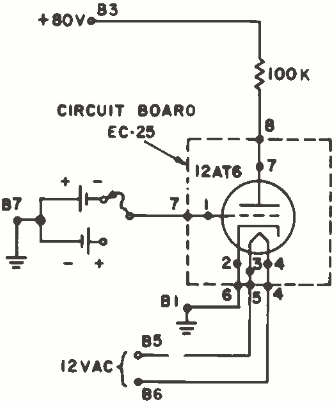

Fig. 41-1. The circuit used in Step 1.

Carefully install the 12AT6 tube in the tube socket. Do not push too hard when you install it or you may break the circuit board.

Step 1: To measure the plate voltage with zero voltage on the control grid.

Set up your tvom for dc voltage measurements; clip the ground lead to the experimental chassis. Slip the test clip which you received in Kit 2T over the probe of the tvom. Clip the probe to lug 8. Turn the circuit on and hold the free end of the tube grid lead against the chassis. This will ground the circuit.

After the tube heats up, observe the voltage reading at the plate. Record the reading in Fig. 41-2.

Step 2: To measure the plate voltage with +1.5 volts applied to the control grid of the tube.

5.00
.35
4.65

STEP	MEASUREMENT	VALUES
1	PLATE VOLTAGE WHEN GRID VOLTAGE = 0	5V
2	PLATE VOLTAGE WHEN GRID VOLTAGE = +1.5V	.35V
3	PLATE VOLTAGE WHEN GRID VOLTAGE = −1.5V	55V
4	CHANGE IN PLATE VOLTAGE WHEN GRID VOLTAGE = +1.5V	[illegible] -4.65
5	CHANGE IN PLATE VOLTAGE WHEN GRID VOLTAGE = −1.5V	+50V

Fig. 41-2. Record your results for Exp. 41 here.

Connect the free lead from the control grid to the positive terminal of the 3-volt battery. This will put a positive voltage of 1.5 volts between the control grid and the cathode. Measure the plate voltage and record your reading for Step 2 in Fig. 41-2.

The plate voltage should have dropped considerably, showing that the application of a positive voltage between the control grid and the cathode of the tube has reduced the resistance in the cathode-plate path of the tube, increasing the plate current, and increasing the voltage drop across the plate load resistor.

Step 3: To show the plate voltage when −1.5 volts is applied between the control grid and the cathode.

Move the free control grid lead to the negative terminal of the 3-volt battery and measure the plate voltage. Record your reading in the space provided for Step 3 of Fig. 41-2. In this case, the negative voltage between the control grid and the cathode has increased the resistance in the path between the cathode and the plate of the tube. This reduces the plate current and sharply reduces the voltage drop across the plate load resistor.

Turn your equipment off.

Step 4: To calculate the change in plate voltage when the grid is made 1.5 volts positive.

Subtract the plate voltage in Step 2 from the value you obtained in Step 1, when the grid was at zero potential. For example, suppose the voltage measured in Step 1 was 11 volts and in Step 2, 1 volt. By subtracting 1 volt from 11 volts, we find that the voltage between the plate and cathode of the tube decreased 10 volts. Compute the change in plate voltage using your readings, and record it in the space provided in Fig. 41-2. Indicate the decrease by placing a minus sign in front of your value.

Step 5: To find the change in plate voltage when the control grid has −1.5 volts applied between it and the cathode.

In this case, subtract the voltage in Step 1 from the voltage in Step 3. Indicate this increase in plate voltage by placing a plus sign (+) in front of your value for Step 5 in Fig. 41-2.

Discussion: The results shown in Steps 4 and 5 in Fig. 41-2 show that a positive voltage applied to the control grid does not cause as much change in the plate voltage as does an equal amount of negative voltage applied to the control grid.

If we were to apply a signal such as a sine wave between the grid and the cathode of the tube under these conditions, the resultant signal across the plate load would be highly distorted, because the negative portion of the signal voltage would be amplified far more than the positive portion.

In the next experiment, we will see how the circuit can be modified to give more linear amplification. By this we mean that a change in grid voltage in a positive direction will cause the same amount of change in the plate voltage as an equal grid voltage change in the negative direction. It is these changes in voltage across the plate load that represent the amplified signal.

Instructions for Statement No. 41: For this Statement you will increase the dc voltage between the grid and the cathode to 3 volts negative, and note the effect on the plate current.

To do this, unsolder the lead that goes from the junction of the two cells to terminal B7, and connect it to the free positive terminal at the other side of one of the cells. Solder the lead from the control grid, lug 7, to the free negative terminal of the other cell. This gives the circuit shown in Fig. 41-3, with 3 volts negative between the control grid and the cathode. Leave the tvom probe clipped to circuit board terminal 8. Connect the ground lead of the tvom to the experimental chassis. Now, turn on the power supply, and give the tube time to heat up.

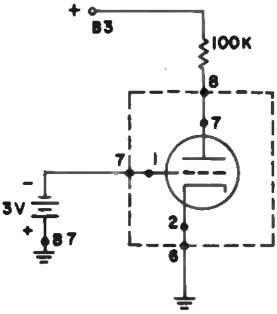

Fig. 41-3. The circuit for Statement 41.

Note the voltage reading on the tvom in the margin of this page. Then, while looking at the meter pointer, grasp the tube lightly, and pull it straight up out of its socket. Note the change in reading when the tube is removed. A slight flicker of 1 or 2 volts can be considered as no change at all. You now have sufficient information to answer the Statement here and on the Report Sheet. Unsolder the lead from the negative battery terminal and turn your circuit and your tvom off.

Statement No. 41: I found that with −3 volts applied between the control grid and the cathode, the cathode-plate path of the tube became, for all practical purposes:

[✓ *(1)*] *an open circuit.*
(2) a low-resistance circuit.
(3) a medium-resistance circuit.

EXPERIMENT 42

Purpose: To show that we can get linear amplification in a vacuum tube by applying a suitable negative voltage to the control grid; and

To show that the tube reverses the phase of the grid voltage 180°.

Introductory Discussion: In the last experiment, the plate voltage variation when the control grid was made 1.5 volts positive was quite different from the plate voltage variations when the grid was made 1.5 volts negative. We said the operation of the tube was nonlinear and a signal voltage amplified by such a circuit would be distorted. When the variations in plate voltage caused by applying positive and negative voltages to the control grid are approximately equal, we say that the tube operation is linear. A signal amplified by this circuit will have the same wave shape as the applied signal. Nonlinear operation of an amplifier tube, therefore, can result if incorrect voltages are applied to the electrodes.

If a negative voltage of the correct value, called a "bias", is applied to the grid, and then varied by a signal, the variations in plate current and plate voltage will be linear. That is, when the control grid is kept negative at all times, a signal that shifts the bias in a positive direction (toward zero) will cause a definite decrease in plate voltage. A signal that shifts the bias in a more negative direction (away from zero) by the same amount will cause an equal increase in plate voltage.

In this experiment, you will vary the grid voltage by using a 1K-ohm potentiometer as a voltage divider across a 3-volt battery. The midpoint of the battery will be grounded and connected to the cathode as shown in Fig. 42-1. By changing the potentiometer setting, you can then make the grid 1.5 volts negative, 1.5 volts positive, or any value in between.

In conducting the experiment, you will find that changing the grid voltage in one direction changes the plate voltage in the opposite direction. Thus, if the grid is made more negative, the plate voltage will increase (become more positive). If the grid is made less negative, the plate voltage will decrease (become less positive). When the tube is properly biased, equal grid voltage variations of opposite polarities will cause plate voltage variations that are approximately equal in magnitude.

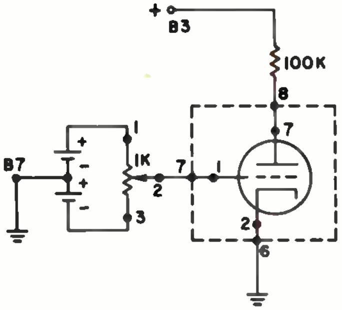

Fig. 42-1. The circuit for varying grid bias.

The exact plate voltage variation that you will obtain will depend upon the characteristics of your tube, the care with which you set the grid bias values and take your readings, and the accuracy with which you have adjusted the zero set on your tvom.

Turn on your tvom a few minutes before you start your work. Then, if you make the zero adjustment just before you start taking measurements, the calibration should not drift. Observe the meter pointer zero position each time before you take measurements and, if necessary, readjust the zero so your results will be as accurate as possible.

When measuring the bias voltages, you will use the 3-volt range of the tvom. The function switch will be set for dc and you will have to switch polarities. When measuring plate voltages, be careful to change the range switch to 120 volts and to see that the polarity switch is set to normal. You can reduce the range selector setting when making plate voltage measurements if necessary.

If you forget and measure plate voltage with the range switch on the 1.2 or 3-volt range or the polarity switch at reverse, the meter pointer will slam off the scale. This may damage your meter so you should train yourself to avoid such carelessness. Always have a good idea of what you are going to measure and always check the tvom switch settings before touching your probe to the circuits.

Experimental Procedure: To conduct this experiment, you will use the tvom, the experimental chassis with the HV power supply and circuit board mounted, and the following parts:

1 Potentiometer mounting bracket
1 3/8" X 6-32 screw
1 6-32 nut
1 No. 6 lockwasher
1 1K-ohm potentiometer
1 Pointer knob

The 100K-ohm resistor should already be connected between terminal B3 and pin 7 of the tube. Wire should be connected from the control grid lug (lug 7) and from the positive terminal of the 3-volt battery to the chassis.

Attach the potentiometer mounting bracket to the right front corner of the chassis at hole AJ. Turn the bracket so that it faces away from the chassis. Attach the bracket with a 6-32 screw, lockwasher and nut. Now, mount the 1K-ohm potentiometer in the bracket with the shaft to the right. Position the potentiometer so that its terminals point upward and tighten the nut.

Rotate the shaft of the 1K-ohm potentiometer fully counterclockwise and attach a pointer knob. The knob is held by a setscrew. If necessary, loosen the setscrew with a small screwdriver. Install the knob in the "7 o'clock" position and tighten the setscrew.

Now you are ready to construct the circuit shown in the schematic diagram in Fig. 42-1. Connect the free end of the lead from lug 7 to the center terminal of the 1K-ohm potentiometer. Cut two pieces of hookup wire about 12 inches long and connect these leads to the two outside terminals of the 1K-ohm potentiometer. The leads will be long enough to reach the positive and negative terminals of the two cells when the cells are lying on your workbench.

The flashlight cells should still be connected in series. If you mistakenly removed the wire joining them, replace it. Connect the hookup wire from terminal B7 to the junction of the two cells. Connect the free end of the wire from one terminal on the potentiometer to the positive terminal of the 3-volt battery, and the free end of the lead from the other terminal of the potentiometer to the negative terminal of the 3-volt battery.

Plug the power cord into an ac wall outlet, and turn on the power supply and let the tube warm up.

Step 1: To measure the plate voltage with 0 volts applied to the control grid.

Connect the ground clip of the tvom to the experimental chassis, set the function switch to dc, and the range selector switch to 3 volts. Touch the probe to the control grid circuit of the tube at lug 7 of the circuit board.

With the probe in place, adjust the knob on the potentiometer until the meter registers exactly 0 volts. Remove the probe, and turn the range selector switch to the 120-volt range.

If the meter pointer is no longer at zero, readjust the zero control. For exact readings, you should check this adjustment on each measurement. In service work, the error introduced by a slight shift in the meter pointer from zero can usually be ignored.

Now touch the probe to circuit board lug 8 and read the meter. If necessary, switch to a lower range. Record the plate voltage in the space for Step 1 in Fig. 42-2.

In the previous experiment you measured the plate voltage with +1.5 and −1.5 volts applied to the grid. You will use smaller positive and negative voltages in the next two steps to see if there is any improvement in the linearity of the output (plate) voltage variations.

Step 2: To measure the plate voltage when the grid voltage is +.5 volt.

Following the same procedure as in Step 1, set the control grid voltage to +.5 volt, measure the plate voltage, and record the value in the appropriate column in Fig. 42-2.

STEP	GRID VOLTAGE	PLATE VOLTAGE	GRID VOLTAGE CHANGE	PLATE VOLTAGE CHANGE
1	0	12V		
2	+.5V	4V	+.5V	+8V
3	−.5V	20V	−.5V	+16
4	−.75V	40V		
5	−.25V	20V	+.5V	20V
6	−1.25V	60V	−.5V	20V

Fig. 42-2. Record your results for Exp. 42 here.

The change in grid voltage was +.5 volt. This has already been recorded in the table. Now, to find out how much the plate voltage changed when the bias was +.5 volt, subtract the plate voltage value you obtained in Step 2 from the value you measured in Step 1. Record it in the last space for Step 2 in Fig. 42-2. Since it is a decrease, put a minus sign in front of it.

Step 3: To measure the plate voltage when the grid voltage is −.5.

Set the grid voltage to −.5 volt, measure the plate voltage, and record it in Fig. 42-2. Be certain to set the switches on the tvom to the proper positions when making these measurements. When measuring a negative grid voltage, set the polarity switch to reverse. Set it to normal for the plate voltage measurement.

In this step, the change in grid voltage was −.5 volt. Find the difference between the plate voltage for Step 1 and the plate voltage for Step 3. Record it in the correct space in Fig. 42-2. Since it is an increase, put a plus sign in front of it.

The change in plate voltage recorded in Step 2 would be as great as the change you recorded in Step 3 if it were not for the fact that the control grid in Step 2 was positive. When the grid is made positive with respect to the cathode, some of the electrons will be attracted to the grid instead of flowing past it to the plate. This, of course, prevents as much decrease in the resistance between the cathode and plate as would be expected, and, as you noticed in Steps 2 and 3, the plate voltage does not vary in step with the grid voltage.

In the remainder of this experiment,

you will see what happens when we use a negative bias at all times, and vary it .5 volt in each direction.

Step 4: To measure the plate voltage when –.75 volt is applied to the control grid.

Adjust the potentiometer so that exactly –.75 volt is applied to the control grid. Then measure the resultant plate voltage. Record the reading in Fig. 42-2.

Step 5: To measure the change in plate voltage when the control grid is driven .5 volt positive from –.75 volt to –.25 volt.

Set the bias to –.25 volt and record the value in Fig. 42-2. Here we are using –.75 volt as the reference value. By decreasing the grid bias from –.75 volt to –.25 volt, we have made the grid less negative (more positive) by +.5 volt. For this reason, we placed a plus sign in front of the grid voltage change in Fig. 42-2. The change is in the positive direction, but the voltage actually applied to the grid is still negative.

Notice that driving the grid voltage .5 volt in a positive direction causes the plate voltage to decrease. Subtract the plate voltage in Step 5 from that in Step 4, and record it in Fig. 42-2. Put a minus sign in front of it to show that the voltage has decreased.

Step 6: To measure the plate voltage when the control grid is driven .5 volt negative, from –.75 volt to –1.25 volts.

Set the bias to –1.25 volts, measure, and record the plate voltage. To find the change in plate voltage caused by a –.5 volt change in grid voltage, subtract the plate voltage in Step 4 from that in Step 6. Record the change in Fig. 42-2. Since the plate voltage increased in this step, put a plus sign in front of it. Turn the circuit off.

Notice that the change in Step 5 is opposite in polarity to that in Step 6, and that the changes are more nearly equal in magnitude than those in Steps 2 and 3. Your readings in Steps 5 and 6 may not be exactly equal. The variations are due to the characteristics of the tube, how accurately you have read your meter, the accuracy with which you set the bias values, and the accuracy of your tvom zero set adjustment. Do not worry about small variations. The important thing is that you see that the values are nearly the same.

Discussion: You have proved in this experiment that when a suitable negative bias is applied to the control grid, the tube operation will be linear, as indicated by the values of plate voltage change in Steps 5 and 6. When you varied the bias voltage an equal amount on either side of the reference voltage value of –.75 volt, the plate voltage changed by an equal amount.

The bias applied to the grid in this experiment was a dc voltage, and the plate voltage was also dc. In a receiver, however, an ac signal is applied in series with the dc bias; the result is a pulsating dc grid voltage that never becomes positive. A large pulsating dc voltage appears in the plate circuit. Thus, the pulsating portion of the dc plate voltage is the amplified signal.

We can show the effect the grid voltage has on the plate voltage by studying the signal waveforms in the output of an amplifier stage. At A in Fig. 42-3 we have

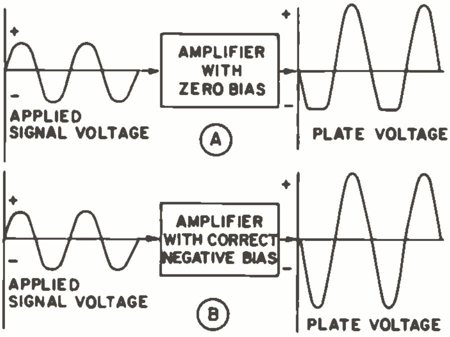

Fig. 42-3. Incorrect bias in a tube causes distortion of the signal, as shown at (A). When the bias is correct, all parts of the signal are amplified the same amount, and no distortion is introduced, (B).

shown a signal voltage applied to an amplifier with zero bias. We have not drawn the schematic of the amplifier, but have merely represented it by a box. To the right of the amplifier, we have shown the resultant variation in plate voltage. Notice that the plate-voltage swing in the negative direction is not as large as the plate-voltage swing in the positive direction. However, the signal in the plate circuit is definitely larger than the grid-voltage variations, indicating that the signal has been amplified. The wave shape at the output of the stage, as you can see, is quite different from that applied to the grid. Thus, the output signal is distorted.

At B in Fig. 42-3, we have shown the same signal voltage applied to an amplifier using the correct negative bias on the control grid. Note that again the plate-voltage variations are larger than the grid-voltage variations, showing that amplification has taken place. This time, the two halves have been amplified the same amount. The tube has amplified the signal without introducing distortion.

From this you can see that correct bias is necessary to avoid distortion. Thus, when the signal at the output of an amplifier stage is distorted, one of the first things you would look for is incorrect bias voltage. In a later kit you will actually hear the distortion introduced by incorrect bias voltage and learn the probable causes of incorrect bias in typical circuits.

In this experiment you have also proved that changing the control grid voltage in a positive direction causes the plate voltage to change in a negative direction. Changing the control-grid voltage in a negative direction drives the plate voltage in a positive direction.

Study the results that you obtained for Steps 5 and 6 in Fig. 42-2. In Step 5, with +.5 volt applied, the direction of the output voltage swing was negative. In Step 6, the grid voltage was −.5 volt. The plate-voltage swing then was in the positive direction.

Thus, a tube connected as shown in Fig. 42-1 reverses the phase of the voltage applied to the control grid by 180°.

This is of no importance as far as the amplification of the signal is concerned. However, it is of real importance in the overall design and operation of radio and TV receivers, as you will later demonstrate.

Instructions for Statement No. 42: For this Statement, you will operate the tube −2 volts on the control grid. Again change the grid voltage .5 volt positive and .5 volt negative and notice the change in plate voltage. To make the change, disconnect the ground lead from the junction of the two cells, and connect it to the positive terminal of the 3-volt battery. The lead from one terminal of the potentiometer should already be connected to this battery terminal.

Set the bias to −2 volts, and measure the plate voltage. Note the value in the margin of this page. Change the bias to −1.5 volts, and again measure the plate voltage, and make a note of the value. Finally, set the bias to −2.5 volts and measure the plate voltage. Calculate the change in plate voltages as you did previously, and answer the Statement here and on the Report Sheet.

Turn off the supply and disconnect the 3-volt battery from the circuit. The easiest way is to unsolder the leads from the terminals of the potentiometer and the lead from terminal B7. Set the battery aside for use in a later experiment. Unsolder the hookup wire from terminal 2 of the potentiometer.

Statement No. 42: With a −2 volt bias on the grid, I found that when I changed the bias .5 volt in the positive and negative directions, the resultant plate voltage variations were:

(1) more linear than
[✓ *(2) less linear than*]
(3) about the same as

the variations with a bias of −.75 volt.

EXPERIMENT 43

Purpose: To demonstrate the methods of obtaining bias voltage without using a separate battery.

Introductory Discussion: Bias voltage is essential for any amplifier stage which must amplify without excessive distortion. However, a separate bias battery is not normally used in modern circuits, although a separate negative voltage supply is still used in some special-purpose applications. In receivers, bias is obtained from the signal, the amplifier circuit itself or from the B power supply.

The four primary biasing methods are: conduction bias, self bias (cathode bias), fixed bias, and grid-leak bias. You have studied all these methods in your regular lessons. Conduction bias relies on the random movement of electrons within the tube while self bias is produced by tube-plate current flow. Fixed bias uses a voltage divider across the B power supply. Grid-leak bias, on the other hand, is derived from the input signal to an amplifier stage.

Experimental Procedure: For this experiment, you will need the following parts in addition to those mounted on the chassis:

2	**1K-ohm resistors**
1	**3.3K-ohm resistor**
1	**47K-ohm resistor**
1	**10-megohm resistor**
1	**100K-ohm resistor**
1	**.1-mfd capacitor**
1	**3-volt battery**

Before starting work on the new circuits, clean the chassis wiring and remove excessive solder from the terminal lugs.

The circuit you will build for the first step in this experiment is shown in Fig. 43-1. The 100K-ohm resistor is already in the circuit, so all you need to do is

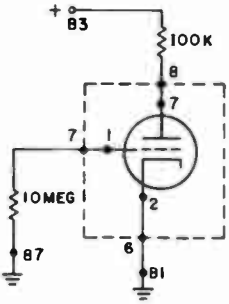

Fig. 43-1. Amplifier using conduction bias.

connect the 10-megohm resistor from the grid of the tube to ground. To do this, connect the resistor from lug 7 to terminal B7.

Step 1: To demonstrate conduction bias.

Connect the tvom ground clip to the chassis, and touch the probe to lug 7. Set the polarity switch to reverse, and the range switch to the 1.2-volt range. Turn on the power supply, and watch the meter. As the tube heats up and the space charge builds up around the cathode, the voltage across the 10-megohm resistor, which is the grid bias, will gradually rise to −1 volt or a little more.

Now, to show that the bias is independent of the B supply, you will open the plate circuit. Turn off the power supply, discharge the filter capacitor, and unsolder the 100K-ohm plate load resistor from terminal B3. Turn on the power supply again and note, when the tube warms up, the bias voltage is still there.

Still watching the meter, grasp the tube and remove it from its socket. You will see that the voltage drops to zero, showing that the bias is dependent on the presence of the tube in the circuit.

Turn off the power supply, and after discharging the filter capacitors, replace the tube in its socket. Resolder the 100K-ohm resistor to terminal B3.

Step 2: To demonstrate self bias.

The circuit used in this step is shown in Fig. 43-2. To construct the circuit, remove the 10-megohm resistor and replace it with a 47K-ohm resistor. Next, connect a 3.3K-ohm resistor in the cathode circuit. Unsolder and remove the short length of hookup wire between lug 6 on the circuit board and terminal B1 and replace it with the resistor.

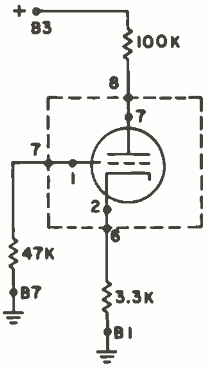

Fig. 43-2. Circuit using self bias.

Switch the tvom to the 3-volt range, connect the ground clip to the chassis and touch the probe to circuit board lug 7. The meter is connected to measure the grid voltage. Turn on the circuit, let the tube warm up and note that there is practically no voltage on the control grid.

Now, to measure the voltage drop across the 3.3K-ohm cathode resistor, touch the probe to lug 6 of the circuit board. Read the meter. Next connect the ground clip to circuit board lug 6 and touch the probe to lug 7. You are measuring grid voltage with respect to the cathode. You should get a negative reading. The voltage between the grid and cathode (pins 1 and 2 of the tube) should be approximately the same as the voltage between the chassis and the cathode lug 6.

To show that the voltage across the cathode bias resistance varies with the plate current, move the tvom ground clip to the chassis and clip the probe to lug 6. Turn the circuit on and observe the meter indication.

Next, apply +3V to the grid. Hold the

negative lead of the 3-volt battery against the chassis and touch the positive lead to lug 7 on the circuit board. Note that when you make the grid positive, the cathode bias voltage increases. Reverse the battery connections to place the negative 3 volts on the grid. Note that this reduces the cathode bias voltage to nearly zero.

Step 3: To show fixed bias.

Turn your circuit off and connect a 100K-ohm resistor between terminal B3 and lug 6. This gives you the circuit shown in Fig. 43-3.

Apply power and measure the voltage between the cathode (lug 6) and the chassis ground. Remove the tube from its socket and note that the voltage does not change significantly. Re-insert the tube. As you did in the preceding step, apply a positive 3 volts to the grid and note that there is very little change in the cathode voltage. Turn the circuit off and discharge the filter capacitors.

Step 4: To demonstrate grid-leak bias.

Unsolder and remove the 3.3K-ohm and 100K-ohm resistors connected to lug

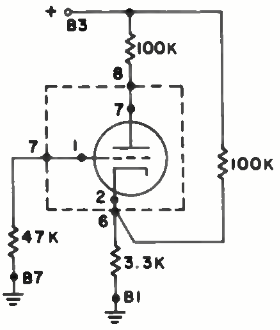

Fig. 43-3. Circuit using fixed cathode bias.

6. Connect a short length of hookup wire between lug 6 on the circuit board and terminal B1.

Connect a .1-mfd capacitor from lug 7 to terminal B6. Set the tvom to read −12V dc and apply power to the circuit. 3.5 V Allow time for warm-up and measure the voltage between the chassis and lug 7. Jot down the value in the margin of this page.

While observing the meter, remove and re-insert the tube. You should see the bias fall to zero whenever the tube is removed from the socket.

Discussion: You have demonstrated the principal methods of obtaining bias voltages for vacuum tube circuits. In the first step, you saw that conduction bias can be produced simply by using a high-value grid resistor. The maximum bias voltage which can be developed, however, is very low, so this method is only used for small amplifier stages. Cathode bias, or self bias, is produced by connecting a resistor in series with the tube cathode. Plate current flows through the resistor and develops a voltage drop across it. This makes the cathode positive with respect to B– or ground. The grid resistor is returned to ground and this places the grid at zero or ground potential. Therefore, the grid is negative with respect to the cathode.

A bypass capacitor can be connected in parallel with the cathode bias resistor to prevent the bias level from varying widely with variations in the signal. With a suitable capacitor, the cathode will remain at an average bias level.

In Step 3, you used fixed bias on the cathode. The 3.3K and 100K-ohm resistors formed a voltage divider across the supply voltage. The voltage drop across the resistor connected between the cathode and ground was the positive cathode bias voltage. The bias level was set primarily by the ratio of the resistor values, although it was increased somewhat by the tube cathode current.

Fixed bias is sometimes applied to the control grid instead of the cathode of the tube. A negative voltage obtained from a separate power supply or by modifying the B power supply is fed to the return side of the grid resistor.

Grid-leak bias, which you demonstrated in Step 4, derives bias voltage from the signal applied to the control grid. The cathode and grid of the tube act as a diode. The grid becomes positive on the positive part of each ac cycle and draws current. This current charges the coupling capacitor connected to the grid.

When the input signal swings in a negative direction, the grid-cathode conduction ceases and the capacitor begins to discharge. Current flows down through the grid resistor to ground and back through the source to the other plate of the capacitor. A negative bias voltage is thus developed at the grid, because the capacitor charges through the low resistance cathode-grid path of the tube and discharges through the large grid resistor.

Instructions for Statement No. 43: For this Report Statement, you will reduce the level of the 60-cycle ac signal applied to the grid and note the effect on the grid-bias voltage.

Disconnect the lead of the .1-mfd capacitor from terminal B6.

Connect two 1K-ohm resistors together to form a 2,000-ohm resistor. Solder one lead to terminal B6 and solder the other lead to terminal B7. These resistors form a voltage divider with about one-half the applied voltage existing between the junction of the two resistors and ground.

Energize the circuit and connect your tvom to measure negative dc voltage at the control grid, lug 7. Touch the free lead of the .1-mfd capacitor to terminal 3.5 B6. Read the bias voltage and jot down the value in the margin.

Now move the capacitor lead from terminal B6 to the junction of the two 1K-ohm resistors. This gives you an input signal of about 3V ac. Measure the grid voltage again. Compare the bias voltage in the two cases and turn your equipment 2 ✓ off. Answer the Statement here and on the Report Sheet.

Statement No. 43: When I reduced the signal level by one-half, the grid-leak bias voltage:

(1) increased by about one-half.
[✓ *(2) decreased by about one-half.*]
(3) remained the same.

EXPERIMENT 44

Purpose: To compare the grounded-cathode, grounded-grid and grounded-plate (cathode follower) types of vacuum tube amplifiers.

There are three different ways of applying a signal and removing the amplified signal from an amplifier stage. These are shown in Fig. 44-1.

The circuit shown at A is known as a "grounded-cathode" amplifier, the one at B a "grounded-plate"amplifier, and the one at C a "grounded-grid" amplifier.

The grounded-cathode circuit is the one most often used in radio and TV amplifier stages. The input signal is applied between the grid and ground, and

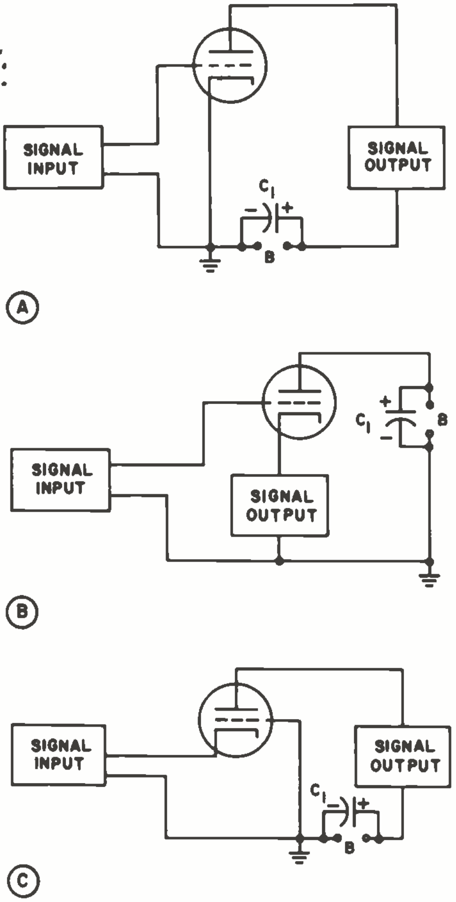

Fig. 44-1. Three types of amplifiers. (A) grounded-cathode amplifier; (B) grounded-plate amplifier; (C) grounded-grid amplifier.

the output is taken off between the plate and ground. The cathode can be connected directly to ground, or it can be grounded through a resistor. If a bias resistor is used between the cathode and ground, the resistor is generally bypassed with a capacitor. The impedance of the capacitor at the signal frequency is so low that practically no signal voltage is developed between the cathode and ground. Thus, the cathode is at ground potential as far as the signal is concerned.

In some cases, the cathode bias resistor is left unbypassed so an ac voltage is developed between the cathode and ground, which acts to reduce the signal voltage between the control grid and the cathode. The effect is the same as if a smaller signal voltage were being used, and the signal output is reduced. This effect is known as degeneration and is often deliberately introduced to stabilize amplifiers, to prevent oscillation, or to reduce distortion. However, this ac voltage is relatively low, and the circuit is still considered a grounded-cathode amplifier.

In the grounded-plate amplifier as shown at B in Fig. 44-1, the plate is kept at a high dc potential so it will attract electrons from the cathode. The plate, however, is bypassed by capacitor C_1 so that as far as the signals are concerned, the plate is at ground potential. Capacitor C_1 could be the output filter capacitor in the power supply.

The signal is applied between the grid of the tube and ground, as in the grounded-cathode type. However, the output is taken off between the cathode of the tube and ground. This type of amplifier is also called a cathode follower. Although we may call it an amplifier, it is impossible to have voltage amplification in a stage of this type. It does have some useful applications, primarily because it has a low output impedance and, therefore, can drive a low-impedance load.

The third type of amplifier is shown at C in Fig. 44-1. The signal to be amplified is applied between the cathode of the tube and ground. The output voltage is taken off between the plate of the tube and ground. If a bias resistor or supply is placed in the grid circuit, it is bypassed so the grid is at ground potential as far as signals are concerned. This circuit has gain, and the gain may exceed that of the grounded-cathode amplifier.

You will not ordinarily find an amplifier of this type in a radio receiver, but you may find it in the tuner of a television receiver.

In this experiment you will build the three types of amplifiers shown in Fig. 44-1, feed ac signals to their inputs, measure the signal voltage at their outputs and compare their gains.

Experimental Procedure: For this experiment, you will need the experimental chassis with the circuit board and wiring on it, your tvom and the following:

- 1 3.3K-ohm resistor
- 1 4.7K-ohm resistor
- 1 22K-ohm resistor
- 1 470K-ohm resistor
- 1 1-megohm resistor
- 1 .25-mfd capacitor
- 1 20-mfd, 150V electrolytic capacitor

Begin by constructing the grounded-cathode circuit shown in the schematic diagram in Fig. 44-2. The 1K-ohm potentiometer should still be mounted on the right front corner of the chassis with its terminals upward. The center terminal is terminal 2, the terminal nearest the front of the chassis is terminal 1, and the terminal toward the rear of the chassis is terminal 3.

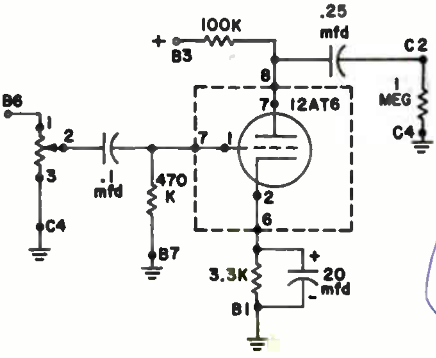

Fig. 44-2. The grounded-cathode amplifier circuit.

14V

Remove the jumper wire from terminal B1 to lug 6 and replace it with a 3.3K-ohm resistor.

Connect a 20-mfd electrolytic capacitor in parallel with the 3.3K-ohm resistor, with the polarity shown. Replace the 47K-ohm resistor between terminal B7 and lug 7 with a 470K-ohm resistor.

Complete the wiring using Fig. 44-2 and be sure to check all connections. You should now be ready to begin taking measurements.

Step 1: To determine the gain of a grounded-cathode amplifier.

Energize the circuit and let the tube warm up. Then adjust the input signal to the amplifier as follows. Set the tvom to measure ac voltage and connect the ground clip to the chassis. Adjust the 1K-ohm potentiometer for .2 volt ac at its center terminal. Switch your tvom to the low range for greater accuracy in adjusting the potentiometer. Move the tvom probe to circuit board lug 7 and notice that you have about the same voltage at the grid of the tube.

Set the tvom range switch to the 30-volt position and measure the ac signal in the plate circuit. Touch the probe to circuit board lug 8 and read the meter carefully. Record this value in the space for the output voltage in Fig. 44-3.

The .25-mfd capacitor and the 1-megohm resistor represent a fairly typical load on a voltage amplifier. Move the

tvom probe to terminal C2 and measure the voltage across the 1-megohm resistor. As you can see, it is about the same as the voltage at the plate of the tube.

Next, compute the gain of the amplifier from the information in the chart. To do this, divide the input voltage of .2 volt into the output voltage you just measured. Record the gain for this circuit in the chart in Fig. 44-3.

Move the probe to lug 6. Note that there is no appreciable ac voltage at the tube cathode.

To show that a lower value of load resistor will reduce the output voltage, turn the circuit off, and replace the 1-megohm resistor with a 22K-ohm resistor. Energize the circuit and measure the plate signal again at lug 8 of the circuit board. Jot down the value in the margin of this page.

14V

Step 2: To measure the gain of a grounded-plate amplifier.

Turn the power off and unsolder the lead of the 20-mfd electrolytic capacitor from terminal 6 of the circuit board and push it out of the way. Unsolder the lead of the .25-mfd capacitor from lug 8 and move it to lug 6 of the circuit board. Also, unsolder and remove the 100K-ohm plate-load resistor. Connect a short length of hookup wire in its place between circuit board lug 8 and terminal B3. You should now have the circuit shown in the schematic in Fig. 44-4. This circuit is generally called a cathode follower or grounded-plate amplifier.

Energize the circuit and set the 1K-ohm potentiometer for .2 volt ac at the grid of the tube. Move the probe to the plate circuit, terminal 8 of the circuit board, and note the absence of an ac signal.

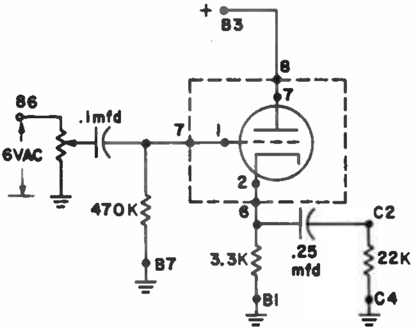

Fig. 44-4. The grounded-plate amplifier circuit.

The output signal appears in the cathode circuit. Touch the probe to circuit board lug 6 and measure the output voltage. Record your reading in the space provided in Fig. 44-3. Compute the "gain" by dividing the input signal of .2 volt into the output signal level. The gain should be somewhere between .5 and .1.

Replace the 22K-ohm resistor in the output circuit with a 4.7K-ohm resistor. Apply power to the circuit and note that the output voltage changes very little with the change in the load.

Step 3: To show gain in a grounded-grid circuit.

Turn the circuit off and wire the circuit shown in Fig. 44-5. Remove the

hookup wire between the plate terminal, lug 8, and terminal B3. Connect a 100K-ohm resistor in its place. Move the .1-mfd capacitor lead from lug 7 to lug 6 of the circuit board. Ground the grid by connecting a short length of hookup wire from lug 7 to terminal B7. Move the lead of the .25-mfd capacitor from lug 6 to lug 8. Replace the 4.7K-ohm resistor with a 1-megohm resistor.

Turn the circuit on and adjust for .2 volt ac at the tube cathode terminal, circuit board lug 6. If you cannot get .2 volt, set the potentiometer for maximum, then measure and record the voltage at the cathode in Fig. 44-3. Move the tvom probe to the center terminal of the potentiometer and measure the voltage there. Note that it is much higher than the voltage at the cathode.

2d Measure the output voltage at the plate terminal, lug 8 of the circuit board. Record the output voltage in Fig. 44-3, then compute the gain of the amplifier. Record the gain in the space provided in the chart.

Discussion: In this experiment you demonstrated amplifier circuits. You saw that when an ac signal is applied to a tube along with sufficient bias voltage, an input signal is produced. In all three circuits you used cathode bias. Cathode-to-plate current flowing from ground up through the 3.3K-ohm resistor made the cathode positive. Since the grid was returned to ground and remained at about ground potential, the grid-to-cathode voltage was negative.

From your chart in Fig. 44-3, you can see that the grounded cathode amplifier, which is a conventional amplifier circuit, has high voltage gain, with a gain of about 40. In carrying out Step 1, you should have found that there was little if any loss in the signal voltage across the .1-mfd input coupling capacitor. This is due to the fact that the grid circuit has a relatively high input impedance. Because no current flows, no signal power is dissipated in the grid circuit. The grid signal has only to vary the potential between the grid and cathode in order to control the tube plate current.

The grounded-cathode amplifier also has high output impedance. This means that the load resistance must be high if the tube is to have high amplification. As you demonstrated, connecting a low-resistance load caused a substantial reduction in the signal voltage at the plate.

The larger capacitor across the cathode resistance prevented the cathode bias voltage from varying with plate current. Therefore, the variations in plate current were proportional to the variations in grid voltage and high gain was realized.

The grounded-plate amplifier, which is called a cathode follower, has no voltage gain. A "gain" of .8 to .9 is typical of the circuit you used in Step 2. As you have already learned, a cathode follower is used primarily for matching a high impedance source to a low impedance load.

The input impedance is high as illustrated by the absence of signal voltage drop across the input coupling capacitor, and the output impedance is quite low.

The output impedance of a cathode follower is lower than the value of the cathode resistor. When you reduced the output load resistance to 4700 ohms, you should have observed very little reduction in the level of the signal at the cathode. This indicates that this load resistance is high compared to the amplifier output impedance.

In general, the characteristics of the grounded-grid amplifier are opposite to those of the cathode follower. The grounded-grid circuit, which you used in Step 3, has relatively high gain, low input impedance and high output impedance. Thus, it is useful for matching the impedance of a low impedance source to a high impedance load. In Step 3, you should have measured a gain of about 40.

Grounded-grid amplifiers are most often used to couple cathode followers to conventional amplifier stages. The fact that the grid is grounded makes the grid act as a shield between the cathode and plate. Consequently, it provides shielding between the amplifier input and output circuits and prevents signal energy from being coupled back through the tube.

The low impedance of the grounded-grid amplifier is largely due to the low value of resistance across which the input signal is developed. Voltage divider action results in most of the signal being dropped across the coupling capacitor between the signal source and the tube.

In this experiment, the word ground refers to signal ground. This may be dc ground, such as a connection to the chassis or B–. It may also be a point having a capacitor connected between it and B– (ground) such that no signal is developed at that point. Thus, in Step 2, the plate was at signal ground while having a potential of +80V applied.

From this experiment, we can make the following conclusions:

1. The conventional (grounded-cathode) amplifier has high gain, high input impedance and high output impedance;

2. The grounded-plate (cathode follower) amplifier has no gain, high input impedance and low output impedance; and

3. The grounded-grid amplifier has high gain, low input impedance and high output impedance.

Instructions for Statement No. 44: For this Statement, you will change the grid circuit of a grounded-grid amplifier and determine the effect of the gain. With the circuit turned off, unsolder and remove the length of hookup wire connecting circuit board lug 7 and terminal B7. Connect a 470K-ohm resistor and a 20-mfd electrolytic capacitor in parallel between these terminals, as shown in the schematic diagram in Fig. 44-6.

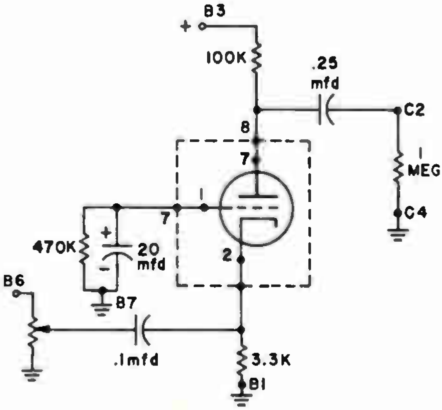

Fig. 44-6. The circuit for Statement 44.

Energize the circuit, measure the input and output signal voltages as before. Turn your equipment off and compute the gain.

Compare the gain with the gain for Step 3, which you recorded in the chart in Fig. 44-3. You are now ready to answer the Statement.

Transistor Fundamentals

In the first four experiments you have seen how a tube works and how it amplifies the signal. In the next six experiments you will see how a transistor works, how it is biased, how it amplifies signals and the various ways in which signals are applied to and removed from transistor circuits.

In these experiments, you will use the low power NPN transistor. This transistor is just the opposite of the transistor used in the preceding kit. It is a silicon NPN transistor, made of a piece of silicon which has been doped with impurities which give the base a P characteristic and the emitter and collector N characteristics. The transistor cannot safely pass high currents. The base current should not exceed a few milliamperes and the collector current should be limited to about 20 ma. The transistor has high gain. This means that small changes in base-emitter current can produce relatively large changes in the collector current.

A transistor is normally operated with forward bias on the base-emitter junction and reverse bias on the base-collector junction. Because we will be using an NPN transistor, the base should be positive with respect to the emitter and the collector should be positive with respect to the base. Note that this makes the emitter the least positive (or most negative) element of the transistor.

PRELIMINARY CONSTRUCTION

First you will assemble the low voltage power supply. This supply will be constructed on the circuit board which you received in Kit 1T. You will need the following parts:

1 Circuit board (EC24)
2 LV silicon diodes
2 200-mfd, 35V electrolytic capacitors
1 100-ohm resistor
1 1K-ohm resistor
4 1/4″ X 4-40 screws
4 4-40 hex nuts

Mount circuit board EC24 on the left side of the chassis over the 500K-ohm potentiometer and the neon lamp. Secure the board with four 4-40 screws and nuts.

Fig. 7 shows the circuit board, EC24, with the complete power supply assembled and mounted on the chassis. Refer to this figure as you mount the parts.

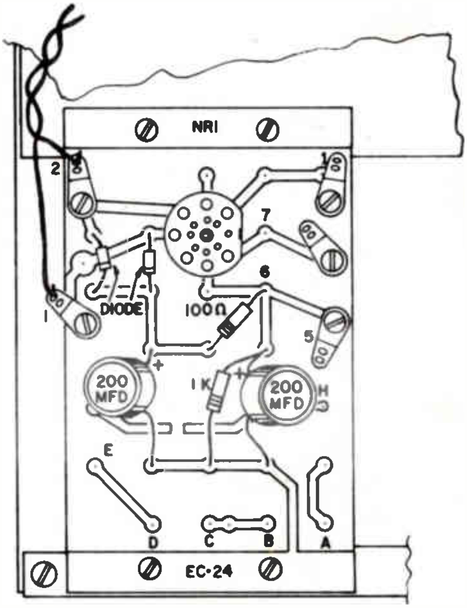

Fig. 7. Assembling the LV power supply.

You received the circuit board and the diodes in Kit 1T. In wiring EC24, push the parts down against the board and cut off the excess lead lengths.

Identify the anode and cathode leads of the two low voltage silicon diodes. Install each on the foil side of the board as shown, with the cathode lead toward hole D on the circuit board. Solder the leads.

Identify the leads of the two 200-mfd electrolytic capacitors and mount them as shown in the diagram. Note that the positive lead of each capacitor is toward the tube socket. Solder their leads to the foil.

Position the 100-ohm resistor as shown and install it on the board. Solder the leads.

Connect a 1K-ohm resistor to the foil as shown. Electrically, the resistor is between lug 5 and ground.

Check your work against the drawing very carefully.

Connect lengths of hookup wire between terminals B5 and B6 and terminal lugs 1 and 2 on the circuit board.

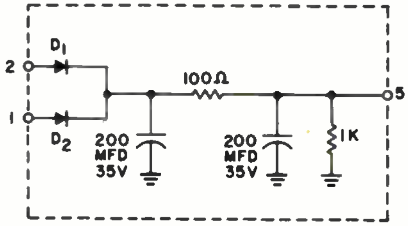

Fig. 8. Schematic diagram of the LV power supply on circuit board EC24.

Before you turn the circuit on, check the wiring against the schematic diagram in Fig. 8. Note that you have a full-wave rectifier operating off the center-tapped low voltage winding of the power transformer. The two 200-mfd capacitors and the 100-ohm resistor form a pi type filter network, producing filtered dc at lug 5 of the circuit board.

To test your low voltage power supply wiring, apply power to your chassis and measure the dc voltage between circuit board lug 5 and the chassis. You should read approximately 8 volts dc. Turn the power off.

Next, you will install an NPN transistor (TS21) on circuit board EC25. The transistor should not be subjected to physical strain or excessive heat on the leads. Therefore you should use the following procedure to install it: Identify the leads and bend them to fit the connections; grasp each lead with your longnose pliers and hold it in the molten solder. The pliers will serve as a heat sink and carry away the excess heat.

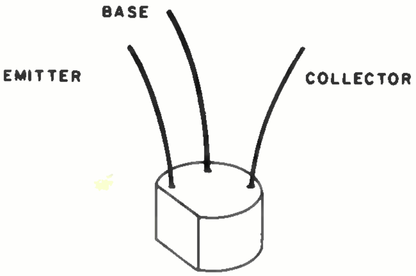

Fig. 9. Identifying the leads of the 2N5134 transistor.

Refer to Fig. 9 to identify the transistor leads. This is a bottom view. Note that there is a flat spot on the transistor case next to the emitter lead. Fig. 10 shows how to position the leads. Bend

the leads and install the transistor as shown.

Unsolder and disconnect the filament leads to lugs 4 and 5 of EC25. Also unsolder and remove the lead between terminals A6 and B3. Unsolder and remove the parts connected to lugs 6, 7, and 8, terminals C2 and C4 and the 1K-ohm potentiometer.

EXPERIMENT 45

Purpose: To show the need for bias current in transistors; to show that a transistor can provide amplification and to show that the collector load resistance will affect the gain of a transistor amplifier.

Introductory Discussion: In an earlier experiment, you found that the current flowing in the collector circuit of a transistor can be controlled by placing a potential across the base-emitter junction. Now you will demonstrate the operation of a practical amplifier circuit and plot the relationship between base current and collector current.

In parts of this experiment, you will have to determine and compare currents. You will use the indirect method which you have used before to determine the current in these circuits: measure the voltage drop across a series resistor and divide the voltage by the resistance value. To simplify these computations, remember that in a 1,000-ohm resistor, the current in ma is equal to the voltage across the resistor in volts.

That is, if you measured 3.6 volts across a 1,000-ohm resistor, the current would be 3.6 ma. In measuring the current in a 10,000-ohm resistor, the current in microamperes is equal to the voltage across the resistor multiplied by 100. For example, if you measured 0.36 volts across a 10,000-ohm resistor, the current would be 36 microamperes.

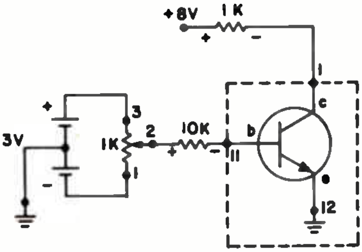

Fig. 45-1. The circuit for Step 1 and Step 2.

Experimental Procedure: In order to perform this experiment, you will need the experimental chassis with two circuit boards mounted, the tvom, and the following parts:

1	1,000-ohm resistor
1	4,700-ohm resistor
1	10K-ohm resistor
2	Flashlight cells

You should already have a 1K-ohm potentiometer and two circuit boards mounted on the experimental chassis. The low voltage power supply is wired on circuit board EC24 and the NPN transistor is mounted on circuit board EC25.

Construct the circuit shown in the schematic in Fig. 45-1 and in the diagram in Fig. 45-2. The dashed line in the schematic of Fig. 45-1 encloses the wiring

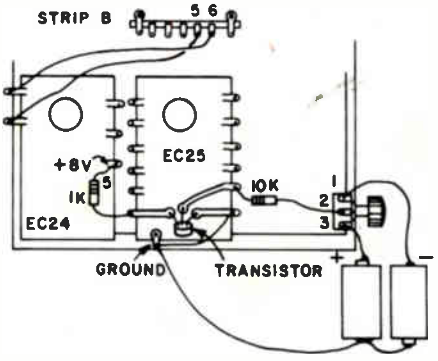

Fig. 45-2. Wiring layout for Step 1.

on circuit board EC25. When you complete your wiring, you will be ready to proceed with the experiment.

Step 1: To show that the base-emitter junction of a transistor must be forward biased for the transistor to operate and pass collector current.

Connect the tvom to measure the voltage between the chassis and the center terminal of the 1K-ohm potentiometer on the right side of the chassis. Set the potentiometer for −1 volt at terminal 2. Move the tvom leads to measure the voltage dropped across the 1K-ohm collector load resistor connected between lug 1 on circuit board EC25 and the +8V dc supply at lug 5 of EC24. With the tvom polarity switch set to "normal," connect the ground clip to lug 1 of EC25 and the probe to lug 5 of EC24.

Turn the circuit on and measure the voltage across the 1K-ohm resistor. Compute the current in the collector circuit. Record the current on the first line in the collector-current column in Fig. 45-3. The value should be close to zero.

BASE VOLTAGE	COLLECTOR CURRENT
−1 −.6	0
0	0
+ 1 +.6	1 mA.

Fig. 45-3. The chart for use with Step 1.

Using the same procedure, set the potentiometer for zero volts at terminal 2 of the 1K-ohm potentiometer and measure the corresponding collector current. Record the value in the chart in Fig. 45-3. Repeat the measurement with the potentiometer set to provide +1 volt at terminal 2. Record your results and turn off the power.

Step 2: To show that a transistor can amplify signal current.

Connect the tvom across the 10,000-ohm resistor which is connected in series with the base of the transistor. Observe the polarity of the voltage shown in Fig. 45-1 and connect your tvom leads accordingly. With the circuit turned on, adjust the 1K-ohm potentiometer for a voltage of .3 volt across the resistor. This reading corresponds to a base current (I_b) of .030 ma or 30 μa.

Without changing the adjustment of the 1K-ohm potentiometer move the tvom leads to the 1K-ohm collector load resistor and measure the collector current. Record this current in the collector current column of Fig. 45-4. Next, measure the collector voltage between the collector and the chassis and record it in Fig. 45-4.

Following the same procedure, set the base current to 20 microamperes (0.2 volt) and measure and record the collector current and the collector voltage. Finally adjust the base current to 40

microamperes (0.4 volt) and record the collector current and voltage measurements.

Step 3: To show that the collector load resistance affects the voltage gain.

Turn your circuit off and replace the 1,000-ohm collector load resistance with a 4700-ohm resistor. Fig. 45-5 shows a schematic diagram of this circuit.

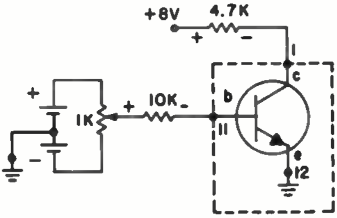

Fig. 45-5. The circuit used for Step 3.

Turn the circuit on and adjust the 1K-ohm potentiometer for a base current of 30 microamperes (0.3 volt across the 10,000-ohm resistor). Next measure the voltage between the collector terminal, lug 1, and ground. Record your reading in Fig. 45-6. Repeat the measurements using base currents of 20 microamperes and 40 microamperes and record the base current and collector voltage readings in Fig. 45-6. When you finish these measurements, turn the circuit off.

BASE CURRENT	COLLECTOR VOLTAGE
.03 ma	4.4V
.02 ma	6.2V
.04 ma	3.6V

Fig. 45-6. The chart for Step 3.

Discussion: In Step 1, you measured the collector current with different voltages applied to the base circuit. The base-emitter current is commonly called base current. You should have read close to zero collector current with both −1 volt and 0 volt applied to the base circuit.

Forward base current is required for conduction in a transistor. This is an NPN transistor, so when the base-emitter junction was reverse biased or when no voltage was applied, you had only "leakage" current through the emitter-collector path. Conduction took place when you forward biased the base-emitter junction by applying a positive voltage.

Assuming that we wanted to amplify a signal which varies in both the positive and negative directions, we needed a forward bias current so the negative portion of the signal would not reverse bias the transistor.

In Step 2 you measured the collector current with three values of base current. If you assume from the information in the chart in Fig. 45-4 that the bias current is 30 microamperes, you should see that the collector current variations are almost proportional to the changes in base current. If we use 30 microamperes of base current as a reference, we find an increase or decrease of 10 microamperes of base current causes about a .5 ma variation in collector current.

For linear amplification, a base bias current is needed. The signal causes the base current to vary above and below the bias level. This bias must be high enough so that, as the signal varies, the base current never reaches the cutoff level, which is near zero, because this would distort the amplified signal.

The only thing you changed in the circuit for Step 3 was the collector load

$\frac{.1V}{10K\Omega}$ ₮ $10k\overline{).10000}$ .01 m

resistance. By comparing the collector voltage readings for Steps 2 and 3 in the charts in Figs. 45-4 and 45-6, you can see that the variations in collector voltage are much greater with the higher value collector load resistor. This means that the voltage amplification is greater since the input signal variations were unchanged.

Notice the phase relationship between input and output voltages in this circuit. An increase in base voltage causes an increase in base current. This increases the collector current, producing a greater voltage drop across the collector load resistor. When we measure the collector voltage with respect to ground, we find that the voltage has decreased. The phase of the signal is reversed between input and output, just as it is in the conventional vacuum-tube amplifier circuit.

Instructions for Statement No. 45: For this Statement you will determine the amount of base current at which the transistor reaches saturation. (Saturation occurs when an increase in the input current produces no appreciable change in the output.) Connect your tvom to measure the voltage between the collector and ground, and turn the power on. Increase the base voltage until the collector reaches its minimum or saturation value. Then measure the voltage across the 10,000-ohm base resistor and determine the base current. Answer the Statement, turn the circuit off, and disconnect the 3-volt battery.

Statement No. 45: As I increased the base current, I found that the transistor became saturated with a base current of:

[✓ *(1)*] *less than 1 ma.*
(2) approximately 3 ma.
(3) between 6 and 10 ma.

EXPERIMENT 46

Purpose: To compare the characteristics of the common base, common emitter, and common collector transistor amplifier circuits.

Introductory Discussion: The three configurations for a transistor amplifier are common emitter, common base, and common collector. In many ways, they are similar to the three vacuum tube amplifier configurations which you have already seen. You have already worked with the common emitter transistor amplifier.

In each transistor amplifier configuration, as shown in Fig. 46-1, the input and output signals share one common element. In the common base circuit, the input is applied between the emitter and base and the output is taken between the collector and the base. In the common

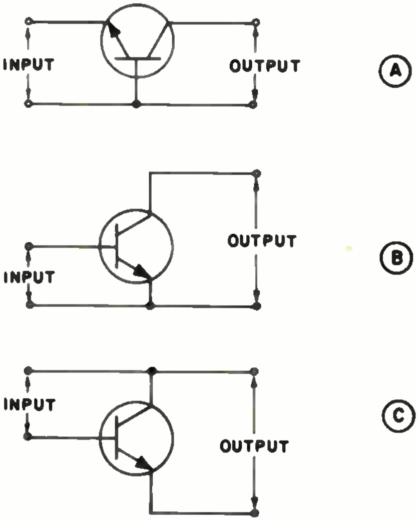

Fig. 46-1. The signal input and output terminals for the (A) common base, (B) common emitter and (C) common collector transistor amplifier configurations.

emitter circuit, the input is applied between the base and emitter and the output is taken between the collector and emitter. In the common collector circuit, the input is applied between the base and collector and the output is taken between the emitter and collector.

The connections shown in Fig. 46-1 refer to the ac signal connections. Due to the forward and reverse bias requirements, the common element may be at some dc level other than ground. However, the common element is held at signal ground by a bypass capacitor or by the low impedance of the dc source.

In this experiment, you will apply ac signals to the amplifier configurations and measure the voltage and current gain of each to compare the circuit characteristics.

Experimental Procedure: In order to carry out this experiment you will need the experimental chassis, your tvom, and the following parts:

1 10-ohm resistor
2 1K-ohm resistors
1 4.7K-ohm resistor
2 10K-ohm resistors
1 47K-ohm resistor
2 100K-ohm resistors
1 100-mfd electrolytic capacitor
1 Alligator clip

You will begin by constructing the circuit shown in the schematic diagram in Fig. 46-2. This is an adjustable voltage divider for supplying the proper level of ac signal voltage to the amplifier and the common base amplifier circuit which you will use for Step 1. The adjustable voltage divider will be used in all of the steps.

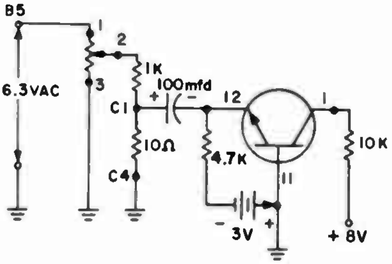

Fig. 46-2. The voltage divider and common base amplifier circuit you use for Step 1.

Loosen the screw at hole U and turn terminal strip C around so that terminal C1 is toward the front of the chassis. Retighten the screw. This will make the wiring easier.

Construct the voltage divider portion of the circuit first. Connect and solder lengths of hookup wire between terminal B5 and terminal 1 of the 1K-ohm potentiometer and between terminal C4 and terminal 3 of the potentiometer. Connect a 1K-ohm resistor from terminal 2 of the potentiometer to terminal C1. Connect a 10-ohm resistor between terminals C1 and C4. Solder the positive lead of a 100-mfd capacitor to terminal C1. Solder the negative lead of the capacitor to lug 12 of circuit board EC25.

Next, wire the amplifier. Move the short ground wire from lug 12 to lug 11 on EC25. Solder a 10K-ohm resistor between lug 1 of EC25 and lug 5 of EC24. Solder a 4.7K-ohm resistor to lug 12 of EC25. Leave the other lead free.

You should still have two flashlight cells connected in series, forming a 3-volt battery. Solder a test clip to the positive battery lead. This will simplify your work a little later. Solder the negative battery lead to the free lead of the 4.7K-ohm resistor soldered to lug 12.

Check your wiring against the schematic and be sure all connections are soldered. To complete the 3-volt battery circuit, you will clip the positive battery lead to the chassis.

Step 1: To show that the common base amplifier has voltage gain.

Energize the circuit, connect the clip from the 3-volt battery to the chassis, and set your tvom to measure ac voltage. Measure the voltage between terminal 2 (the center terminal) of the 1K-ohm potentiometer and the chassis. Adjust the potentiometer for a reading of 2.5 volts. Use the 3-volt range. The 1K-ohm resistor and 10-ohm resistor connected between potentiometer terminal 2 and ground form a 100:1 voltage divider. With the potentiometer set for 2.5 volts, about .025 volts is being applied to the transistor amplifier circuit at terminal C1.

After you have adjusted the input voltage, measure the ac output voltage between ground and the collector of the transistor. Record this value as the output voltage for Step 1 on the first line of the chart in Fig. 46-3. Note that the input voltage has been written in.

Now that you have both the input and output voltage levels, compute the amplifier voltage gain using the formula:

$$V_G = \frac{V_{out}}{V_{in}}$$

STEP	INPUT	OUTPUT	GAIN
1	.025V	2[illegible] V	≃ 100
2	.285h	.25 ma	≃ <1

Fig. 46-3. Record your results for Steps 1 and 2 here.

and record the gain for Step 1 in the chart.

Turn the circuit off. Be sure to disconnect the battery clip.

Step 2: To show that the common base amplifier has a current gain of less than 1.

Modify your circuit as shown in Fig. 46-4. Solder a 10K-ohm resistor to terminal 2 of the potentiometer. Unsolder the capacitor lead from terminal C1 and solder it to the free lead of the 10K-ohm resistor.

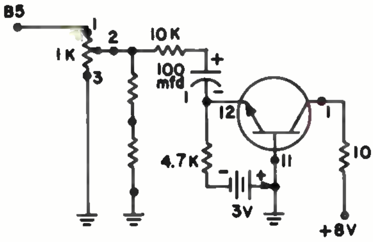

Fig. 46-4. The circuit for Step 2.

To determine the current gain, you will use the following procedure: First set the potentiometer for a given amplifier output voltage. This will give you the output signal current through the load resistor. Then measure the signal voltage drop across a resistor in series with the amplifier input. Use this value to compute the input signal current. Finally, divide the output current by the input current to find the current gain.

Now you can proceed with this step. Energize the circuit and connect the 3-volt battery clip. Set the 1K-ohm potentiometer for an output of 2.5 volts between the collector, lug 1, and ground. This corresponds to the output current of .25 ma, as recorded in the chart in Fig. 46-3.

Measure the ac voltage between ground and the resistor lead connected to the potentiometer. Jot down the value for reference. Now measure the signal voltage between ground and the resistor lead connected to the coupling capacitor. The difference between these two readings is the signal voltage across the 10K-ohm series resistor.

2,85

0V

.285

10K) 2.85

Now that you know the voltage across the resistor, you can find the input signal current. Divide the voltage reading by 10,000. You can do this simply if you remember that the current through the resistor in ma is 1/10 the voltage across the resistor in volts. Record the input current in the space provided in the chart in Fig. 46-3.

Compute the current gain of the amplifier. Use the formula:

$$I_G = \frac{I_{out}}{I_{in}}$$

Your answer should be some number between .7 and 1. Record the value in the chart in Fig. 46-3 and turn the circuit off.

Step 3: To show that the common emitter amplifier has voltage gain.

Construct the circuit shown in Fig. 46-5. Unsolder and disconnect the leads from lug 12 of the circuit board. Unsolder the ground wire from lug 11. Solder the free end of this wire to lug 12.

Unsolder and remove the 4.7K-ohm resistor. Solder the negative lead of the 3-volt battery to a convenient ground point. Solder one lead of a 47K-ohm resistor and the positive lead of the 100-mfd capacitor to lug 11. Solder the negative capacitor lead to terminal C1. Check your wiring and be sure all connections are soldered.

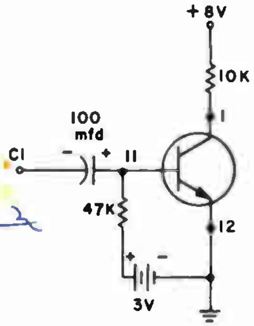

Fig. 46-5. The common emitter amplifier circuit for Step 3.

To produce an input of .025V ac between the base and emitter of the transistor, energize the circuit, clip the positive battery lead to the 47K-ohm resistor and set the potentiometer for 2.5V ac across the voltage divider.

Move the tvom probe to lug 1 and measure the output signal between the collector of the transistor and ground. Record the output voltage in the space provided in Fig. 46-6. Compute the voltage gain of the circuit by dividing the output voltage you just recorded by the input voltage of .025V. Record the voltage gain in the chart.

Turn your circuit off.

Step 4: To show that the common emitter amplifier has current gain.

Connect two 100K-ohm resistors in parallel. Solder one end of this parallel

combination to terminal 2 of the potentiometer. Unsolder the capacitor lead from terminal C1 and solder it to the free leads of the two 100K-ohm resistors.

Turn your circuit on and adjust the potentiometer for an output of 2.5 volts between ground and the collector of the transistor at lug 1. This corresponds to a collector output signal current of .25 ma, as shown in the chart in Fig. 46-6. Without readjusting the potentiometer, determine the input current. Measure the ac voltage across the 50K-ohm input series resistance formed by the two parallel-connected 100K-ohm resistors. Use the technique described earlier: measure the voltage between ground and each end of the resistance and take the difference. Divide this difference voltage by 50 to find the input signal current in ma. Record the current value in the space provided in Fig. 46-6.

To find the current gain, divide the output signal current by the input current recorded in Fig. 46-6. Record the current gain in the space provided in the chart.

Construct the circuit shown in the schematic diagram in Fig. 46-7. Remove the length of hookup wire connected between lug 12 and ground and replace it with a 1K-ohm resistor. Unsolder and remove the 10K-ohm resistor connected to lug 1. Solder a length of hookup wire between lug 1 of EC25 and lug 5 of EC24. Unsolder and remove the two 100K-ohm resistors from the circuit. Unsolder the capacitor lead from the 50K-ohm resistance and solder it to terminal 2 of the potentiometer.

Turn the circuit on and adjust the 1K-ohm potentiometer for .25V ac between the base of the transistor (lug 11) and ground. Move the probe of the tvom to lug 12 and measure the ac output voltage across the 1K-ohm emitter load resistor. Record this value for the output voltage in Fig. 46-8. We have already indicated the input voltage of .25V.

Separate the leads of the 100K-ohm resistors and connect the capacitor in series with one of the 100K-ohm resistors.

Turn the circuit on, connect the battery, and adjust the potentiometer for an output of .25V ac across the 1K-ohm emitter load resistor. This corresponds to an output signal current of .25 ma or 250 μa. Now determine the input current flowing into the base circuit. Measure the ac voltage across the 100K-ohm series resistor using the technique outlined in Steps 2 and 4. Divide the voltage across the resistor by 100,000 to find the input current. The current in μa is equal to 10 times the voltage across the resistor in volts. For example, a voltage of .8V corresponds to 8 μa. Record the input current in the chart in Fig. 46-8.

Compute the current gain by dividing the output signal current by the input signal current as you have done previously. Record the current gain in the chart in Fig. 46-8.

Discussion: In this experiment, you demonstrated the voltage and current gain characteristics of the three basic transistor amplifier configurations. In all three, the base, emitter and collector currents are fixed largely by the characteristics of the transistor: a small current flowing across the forward biased base-emitter junction causes a much larger current to flow from the emitter across the base to the reverse biased base-collector junction. The levels of the input and output currents are primarily due to whether they are the emitter, base or collector current or a combination.

The voltage gain of any amplifier configuration is generally determined by the current gain of the transistor and the input and output resistances.

The important facts of this experiment are summarized in Fig. 46-3, Fig. 46-6, and Fig. 46-8. You can see that the common base amplifier has the highest voltage gain but the lowest current "gain." A voltage gain of 100 and a current gain of .8 are typical. The common collector stage has the lowest voltage gain and the highest current gain. Typical values are a voltage gain of .95 and a current gain of 30. The common emitter amplifier has medium voltage and current gains. Typical values are a voltage gain of 90 and a current gain of 4.

From basic transistor theory, you know that the emitter current is the sum of the base and collector currents. You also know that the collector current is many times the value of the base current. You know that normally the base-emitter junction is forward biased and that it acts like a forward biased diode and has a low resistance. Conversely, the base-collector junction is reverse biased and hence has a much higher resistance.

With this information you can see that each amplifier configuration has different input and output impedances. The common base circuit has low input impedance and high output impedance. The input signal is applied to the emitter-base junction and the emitter current flows in the input signal circuit. On the other hand, the output impedance is roughly equal to the load resistance.

The common emitter circuit used in Steps 3 and 4 has moderate input impedance and high output impedance. The input is applied to the base-emitter junction, but only the base current flows in the input signal circuit. The output, taken across the emitter-base and base-collector junctions connected in series, is nearly equal to the resistance of the load resistor.

The common collector circuit, which you used for the last two steps, has very high input impedance. The input signal is applied across the base-collector junction, which is reverse biased and acts somewhat like an open circuit. Even with an input voltage of .25V, the input current was probably less than 10 μa (.01 ma).

From the work in this experiment you can see that the choice of an amplifier configuration must be based on the voltage and current gain requirements and input and output impedances. You will learn more about these configurations in your regular lessons.

One of the characteristics of the common base amplifier is that it does not reverse the phase of the applied signal: a positive-going change in the input signal produces a positive-going change in the output. For this Report Statement, you will determine whether or not the other amplifier configurations reverse the phase of the signal.

Instructions for Statement No. 46: Unsolder and remove the 100-mfd capacitor and the 100K-ohm resistor from the circuit and lay them aside. Solder a 100K-ohm resistor to lug 5 of EC24 and position the resistor so you can touch the other lead to lug 11 of EC25. You should now have the common collector circuit shown in Fig. 46-7, but without the ac input circuit.

Turn your circuit on, connect the battery clip, and measure the dc voltage
1.65 across the 1K-ohm output load resistor.
Touch the 100K-ohm resistor lead to the
+ transistor base to represent a positive dc signal voltage and note the direction of the change in dc output voltage. (The direction of the change depends on whether the emitter voltage increases or decreases when a positive signal is applied to the base.)

When you have made this measurement, turn the circuit off and change the amplifier to a common emitter configuration. Replace the 1K-ohm resistor with a length of wire and replace the wire connected between lug 1 and lug 5 of EC24 with a 10K-ohm resistor. The circuit will then be similar to the circuit shown in Fig. 46-5.

Connect the 3-volt battery, energize the circuit and measure the output voltage between the collector at lug 1 and ground. Touch the lead of the 100K-ohm resistor to the transistor base circuit and note the direction in which the collector voltage changes. You now have enough data to answer the Report Statement. Turn your equipment off.

EXPERIMENT 47

Purpose: To demonstrate and compare several methods of biasing a transistor using a single source of dc voltage.

Introductory Discussion: You already know that transistors are normally operated with forward bias on the base-emitter junction and reverse bias on the base-collector junction. Now you will see how both of these bias requirements can be obtained from a single source of dc voltage.

A simple bias arrangement using one dc source is shown in Fig. 47-1. A relatively high positive voltage is applied to the collector through a load resistor. This is an NPN transistor, so the collector voltage is positive with respect to the emitter. The base resistor is connected between the base and the collector supply voltage, thereby making the base positive. This causes a current to flow from the emitter across the base-emitter junction and through the base resistor to the positive source. Most of the voltage is dropped across the resistor, making the base slightly positive with respect to the emitter, and the collector highly positive with respect to the base. The bias requirements, therefore, are satisfied.

The base bias current in the circuit in Fig. 47-1 is totally dependent on the value of the bias resistor and the resistance of the base-emitter junction of the transistor. Any change in either will shift the transistor from the desired point on its characteristic curve. This may cause distortion in the output signal (if it is used as an amplifier) or damage to the transistor due to excessive current.

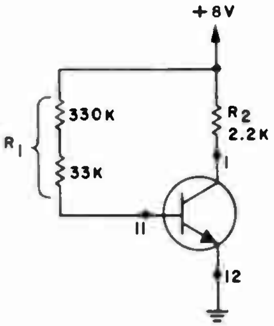

Fig. 47-1. The circuit for Step 1.

The basic bias circuit can be modified to make it more stable. By stable, we mean the transistor can be made to operate satisfactorily despite normal variations in resistor values, transistor characteristics, ambient temperature, etc. You will demonstrate this by reducing the value of a resistor and observing the effect on the output voltage.

Experimental Procedure: For this experiment, you will need the chassis, your tvom and the following parts:

- **1 1K-ohm resistor**
- **2 2.2K-ohm resistors**
- **1 4.7K-ohm resistor**
- **1 22K-ohm resistor**
- **1 33K-ohm resistor**
- **1 47K-ohm resistor**
- **1 220K-ohm resistor**
- **1 330K-ohm resistor**
- **1 10-mfd capacitor**
- **1 100-mfd capacitor**

Begin by constructing the circuit shown in Fig. 47-1. Unsolder and remove all parts and hookup wires from lugs 1, 11 and 12 of circuit board EC25. Do not remove the ac voltage divider wired on terminal strip C and the 1K-ohm potentiometer.

Connect a 2.2K-ohm resistor from lug 1 of EC25 to lug 5 of EC24. Connect together a 330K-ohm resistor and a 33K-ohm resistor and solder this resistor combination between lug 5 of EC24 and lug 11 of EC25. Connect a length of hookup wire between lug 12 of EC25 and any convenient ground point. Check over your work and solder all connections.

Your circuit is a common emitter amplifier stage having base bias supplied by a dropping resistor, R_1, of approximately 360K-ohms. Changes in collector current will be reflected in a variation in the voltage drop across the collector load resistor, R_2.

Set your tvom to measure positive dc voltage on the 12V range and energize your circuit. Measure the voltage between ground and the collector of the transistor at lug 1. Record the reading in the space for V_C on the top line of the chart in Fig. 47-2. This is the output voltage. Note that the voltage you just measured is also the voltage across the transistor (between the collector and emitter). Then record the same reading for V_{CE} in the chart.

17.8
uA

Determine the base current by the indirect method. Measure the dc voltage across the base resistance, R_1, and divide the voltage reading by 360K. Jot down the base current in the margin. The current should be about 20 μa (.02 ma).

Measure the bias voltage between the emitter and the base. About .6V is typical. Record this value in the margin also.

52

To check for stability, short out the 33K-ohm resistor with a piece of wire or a screwdriver and measure the collector voltage again. The voltage should be noticeably lower. Record the new value for V_C and V_{CE} on the second line in the chart.

Now that you have the output voltages for base bias resistances of 360K and 330K-ohms, you can determine the change in collector voltage, ΔV_C. This is equal to the difference in the V_C readings. Record the change in the space provided in the last column. Turn the circuit off.

	22K	4.85	2.8	

Fig. 47-2. Chart for this experiment.

Step 2: To demonstrate simple bias with emitter stabilization.

Modify your circuit to that shown in Fig. 47-3. Replace the series-connected base resistors with a 220K-ohm resistor and a 22K-ohm resistor connected in series. Also, replace the ground wire in the emitter circuit with a 1K-ohm resistor.

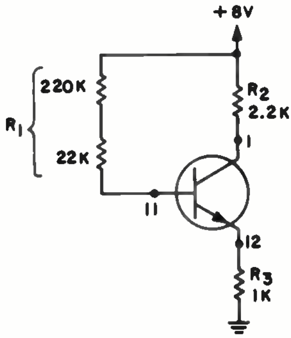

Fig. 47-3. The circuit used in Step 2.

Energize the circuit and measure the collector voltage, V_C. It should be close to the value you measured in Step 1. Record this voltage on the third line of the chart in Fig. 47-2. Move the ground clip of your tvom to lug 12 and measure the voltage across the transistor, V_{CE}. Record this voltage in the chart also.

Next, measure the voltage across the .81 emitter resistor, R_3. The voltage drop across this resistor is equal to the difference between the collector voltage and the collector-emitter voltage.

Test the circuit for stability. Short out the 22K-ohm resistor and measure the collector and collector emitter voltages again. Record your readings on the fourth line of the chart. Determine the change in the output voltage and record it in the last column.

Connect your tvom across the emitter resistor again and open and close the short across the 22K-ohm resistor. Note that when you short the resistor, the emitter voltage increases, thus counteracting the change in base current. Turn the circuit off.

Step 3: To show a bias method which uses base stabilization.

Wire the circuit shown in Fig. 47-4. Connect a 47K-ohm resistor and a 4.7K-ohm resistor in place of the base bias resistors used in the last step. Also, connect a 33K-ohm resistor between lug 11 and a ground point. Check your wiring against the schematic.

Energize the circuit and measure and record the collector and collector emitter voltages on the fifth line of the chart in Fig. 47-2. Check for stability by shorting out the 4.7K-ohm resistor and taking these voltage readings again. Record the values and determine the change in collector voltage. Record this value also.

Now, find the base current in the circuit. Note that part of the current through R_1 flows through R_4. Therefore, the base current is the difference between the R_1 and R_4 currents. First measure the voltage across R_1 and divide the voltage reading by the resistance value. Use 52K for the resistance of R_1 to make the computations easier. Next, measure the voltage across R_4 and find the current I_{R_4}. When you have found the currents, use the formula:

$$I_b = I_{R_1} - I_{R_4} = 33\mu$$

137.0 µ
13.9 µ
123.1 µ = I_b

The value should be in the vicinity of 20 µa. Turn the circuit off.

Step 4: To show a bias network using voltage feedback.

Unsolder and remove the 47K and 4.7K-ohm resistors. Connect a 2.2K-ohm resistor and a 22K-ohm resistor in series between lug 1 and lug 11 of the circuit board. The wiring of the circuit in Fig. 47-5 should now be complete.

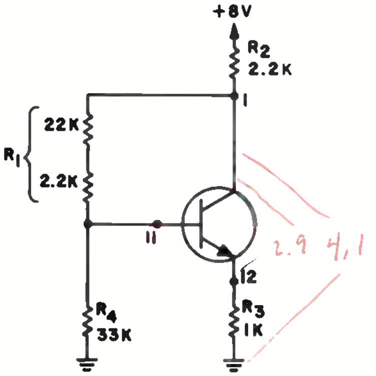

Fig. 47-5. The circuit used in Step 4.

Turn the circuit on and measure and record the voltages for V_C and V_{CE} with a bias resistance of 24K-ohms. Record your results in Fig. 47-2. Short out the 2.2K-ohm resistor and repeat the test to demonstrate the stability of this circuit. Record the change in collector voltage, ΔV_C, for this step. The change may be too small to observe on your meter. If it is, mark a dash in Fig. 47-2 for ΔV_C.

Turn the equipment off.

Discussion: You have demonstrated the four principal transistor biasing arrangements. In all four, forward bias for the base-emitter junction was obtained from the collector supply voltage. This eliminates the need for a second power source.

In Step 1, you used simple bias, which has the poorest stability. As you saw, the change in collector voltage was proportional to the change in the base resistor value. The change in the resistor value increased the base current and collector current by about 10 per cent.

In Step 2, emitter stabilization was used. Emitter current produced a voltage drop across the emitter resistor. This is reverse bias voltage for the base-emitter junction which opposes the forward bias and tends to decrease the base and collector currents. Thus, the base-emitter bias voltage was equal to the voltage directly across the terminals rather than between ground and the base. The stability of this circuit is better than the circuit shown in Fig. 47-1, as you found out.

The circuit in Step 3 combined emitter stabilization and base stabilization. As such, it was more stable than the preceding circuits. In addition to the emitter stabilization, the change in the base bias resistor value was offset by the bleeder resistor action of resistor R_4 in Fig. 47-4. Since part of the current through the forward bias resistor flowed through the bleeder resistor, the bias voltage at the base varied very little when the resistor value was decreased.

When you computed the bias current, you should have found a current of about 100 μa through R_1 and about 80 μa through R_4. Thus, the base current was approximately 20 μa.

The circuit used in Step 4 has the best stability. It uses the stabilization methods discussed earlier plus voltage feedback. Because the base bias network is supplied from the collector voltage, any change in collector voltage is reflected in a corresponding change in base voltage. Due to the 180° phase shift between the input and output, this minimizes the effect of the initial change, which was a reduction in the forward bias resistor value. You should have found that the collector emitter voltage varied by less than .1V.

Instructions for Statement No. 47: For this Report Statement, you will compare the amplification and collector voltages of the circuit in Fig. 47-5 with and without a bypass capacitor across the emitter resistor.

Use the ac voltage divider from Experiment 46 as a signal source. Connect a 100-mfd electrolytic capacitor between terminal C1 and lug 11 of the circuit board with the positive lead to lug 11 to form the circuit of Fig. 47-6. Energize the circuit and adjust the 1K-ohm potentiometer for 3V ac across the 100:1 voltage divider made up of the 1K-ohm and 10-ohm resistors. This voltage reading corresponds to an input signal of .03V ac.

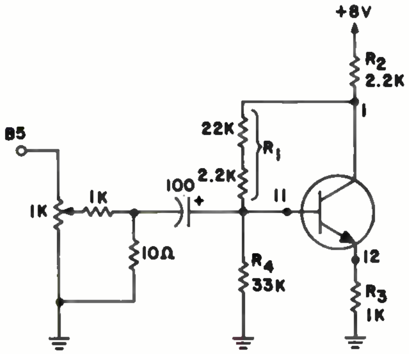

Fig. 47-6. The circuit used for the Report Statement.

Measure the ac voltage between the collector and ground. Also measure the dc collector voltage. Jot down the readings in the margin. Now, connect a 10-mfd capacitor across the 1K-ohm emitter resistor with the positive lead to lug 12 and measure the ac and dc output voltages again. Turn the equipment off and answer the Statement.

EXPERIMENT 48

Purpose: To demonstrate L-C oscillator circuits.

Introductory Discussion: Oscillator circuits are used in nearly all types of electronic apparatus to generate ac signals. These oscillator circuits can be divided according to the frequency of operation (audio or rf) and according to what is used to establish the frequency. In an L-C oscillator, a resonant circuit made up of inductance and capacitance determines the output frequency. In an R-C oscillator of the type you will study later, the frequency is determined by R-C time constants.

All oscillator circuits are basically amplifier circuits in which some of the energy from the output of the stage is fed back to the input. If we place a resonant circuit between the output and the input of an amplifier stage, and the circuit is excited by the amplifier, an ac signal will be produced across the resonant circuit. If some path is provided so that a portion of the output energy can be fed back to the input of the amplifier stage, oscillation will be produced. The stage will continue to oscillate because the energy in the resonant circuit will be constantly reinforced by the amplified output voltage variations. This is illustrated in Fig. 48-1. Fig. 48-1A shows an rf amplifier. The signal across the resonant circuit is fed to the base and the amplified current

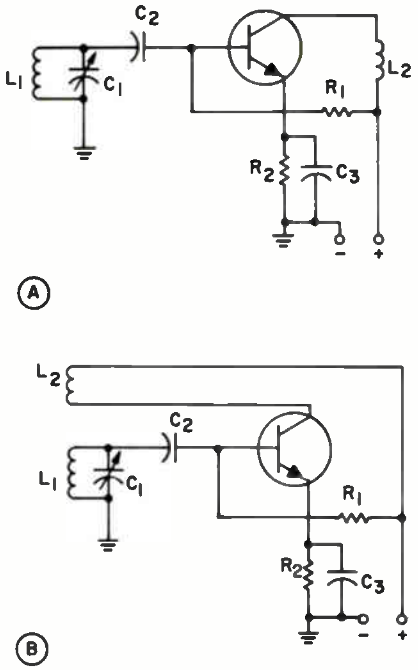

Fig. 48-1. An rf amplifier with coil L_1 in the base circuit and coil L_2 in the collector circuit, (A); an rf oscillator obtained by coupling the collector coil to the base coil, (B).

produces a larger signal voltage across the collector load inductance L_2. If no signal is present across the resonant circuit there will be no variation in collector current and no signal voltage across the collector load.

If, however, the collector load inductance is placed so its magnetic field cuts the turns in the tank inductance, the tank circuit will be shock-excited and will go into oscillation at its resonant frequency. A voltage at this frequency will be set up across the tank. Ordinarily, only a few cycles of voltage would be produced and the oscillation would quickly die out. But in this case the signal is applied to the transistor and the amplified signal current flowing in the collector load induces more voltage into the tank and the circuit continues to oscillate. Fig. 48-1B shows a practical oscillator circuit such as we have described.

As you already know and will prove in this experiment, the feedback must be of the correct phase to reinforce the signal in the tank circuit. If the feedback connections are reversed, oscillation will cease.

In this experiment you will build and test several widely used rf oscillator circuits. You will begin with circuits using inductive feedback and then work with circuits using capacitive feedback.

Experimental Procedure: For this experiment, you will need the experimental chassis, your tvom and the following parts:

1	**Oscillator coil (CO43)**
1	**470-ohm resistor**
1	**1K-ohm resistor**
1	**2.2K-ohm resistor**
1	**100K-ohm resistor**
2	**.001-mfd disc capacitors**
1	**.002-mfd disc capacitor**
1	**250-pf mica capacitor**

Prepare the chassis for this experiment by removing the resistors and capacitors attached to circuit board EC25. Also, disassemble the ac voltage divider connected to terminal strip C. Loosen the screw at hole U, turn the terminal strip around to its previous position and retighten the screw. Remove the 1K-ohm potentiometer and mounting bracket from the chassis.

Mount the oscillator coil on top of the front chassis rail at holes AG and AH as

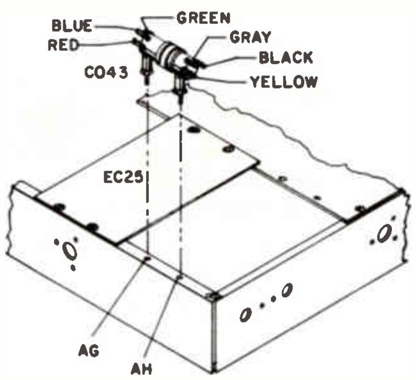

Fig. 48-2. Mounting the oscillator coil.

shown in Fig. 48-2. Remove one nut from each mounting screw on the coil, position the coil so that the terminals color-coded green, blue and red are toward the circuit board and slip the mounting screws through the holes. Attach and tighten the nuts you just removed.

When making connections to the coil, be careful to avoid touching the windings with your soldering iron, as the coil will be damaged.

Construct the circuit shown in the schematic in Fig. 48-3. Connect a 2.2K-ohm resistor from lug 12 of the circuit board to a convenient ground point. Connect a 100K-ohm resistor from lug 11 of EC25 to lug 5 of EC24. Connect a length of hookup wire from lug 1 of EC25 to the terminal color-coded blue on the oscillator coil. Connect a length of hookup wire from the red terminal of the oscillator coil to lug 5 of EC24. Connect a .001-mfd disc capacitor from the green terminal of the oscillator coil to lug 11. Connect a 250-pf mica capacitor between the green and black terminals of the coil. Connect a length of hookup wire from the black terminal of the oscillator coil to ground. Check your wiring against the schematic and make sure all connections are soldered.

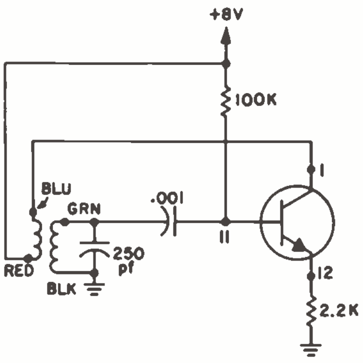

Fig. 48-3. An oscillator circuit using a tickler coil for feedback.

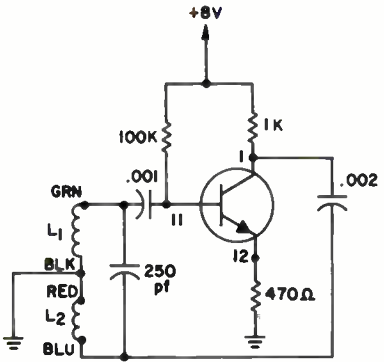
Step 1: To demonstrate a simple L-C oscillator circuit.

Energize the circuit and check to see if it is oscillating. To do this, measure the ac voltage between the collector of the transistor, lug 1, and ground. Any reading greater than about .5V is a pretty good indication that the circuit is oscillating.

Move the probe of your tvom to the green terminal of the oscillator coil and read the ac voltage across the resonant circuit. A reading of 4 to 6 volts ac is normal. Note that this is the voltage across the resonant circuit formed by the green-black winding and the 250-pf capacitor.

Step 2: To prove that in-phase feedback is necessary to sustain oscillations.

Turn the circuit off and unsolder and reverse the connections to the red and blue terminals of the oscillator coil. This change will reverse the phase of the voltage induced into the base circuit



Hartley

winding from the collector. Energize the circuit and check for ac voltage between the collector and ground. Your reading should be zero. Turn the circuit off.

Step 3: To demonstrate an oscillator circuit having feedback through a tapped inductance.

For this step, you will construct a Hartley oscillator circuit. Wire the circuit shown in Fig. 48-4. Unsolder and disconnect the lengths of wire from the red and blue terminals of the oscillator coil. Unsolder and remove the 2.2K-ohm resistor and replace it with a 470-ohm resistor. Connect a 1K-ohm resistor between lug 1 of EC25 and lug 5 of EC24. Connect the red and black terminals of the coil together using a short length of wire.

Move the lead of the 250-pf capacitor from the black terminal to the blue terminal of the coil. Solder a .002-mfd capacitor between lug 1 of EC25 and the blue coil terminal. If necessary, connect a piece of wire to the capacitor lead. Check over your wiring to be sure it is correct.

Energize the circuit and measure the ac output voltage at the collector. Record the value in the chart in Fig. 48-5. You should read 1 volt or more, indicating that the circuit is oscillating.

Next, measure the voltage across the resonant circuit, L_1 and L_2: clip the tvom ground lead to the blue terminal and touch the probe to the green lead of the oscillator coil. Record your reading in the chart. Measure and record the feedback voltage. This is the voltage across the blue-red winding, L_2, of the rf transformer. Then measure and record the voltage across L_1, the green-black winding. Note that the two voltages add, producing approximately 4 volts across the entire resonant circuit which consists of the two windings and the 250-pf capacitor.

Turn the circuit off.

ACROSS L_1 AND L_2	3.5
ACROSS L_2	.38
ACROSS L_1	3.0

Fig. 48-5. Chart for Step 3.

Step 4: To demonstrate an oscillator circuit using capacitive feedback.

You will now construct the Colpitts oscillator circuit shown in the schematic in Fig. 48-6. Unsolder and remove the .002-mfd and 250-pf capacitors and the lengths of wire connected to the red, blue and black terminals of the oscillator coil. Connect a .002-mfd capacitor between the green terminal of the coil and ground. Connect a .001-mfd capacitor between

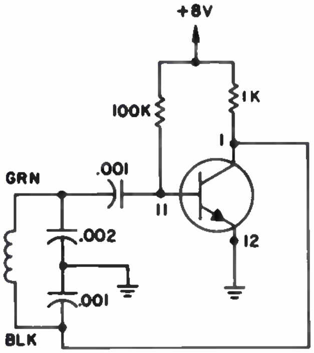

Fig. 48-6. The Colpitts oscillator for Step 4.

the black terminal of the coil and ground. Complete the wiring according to the schematic. Check your work carefully and solder all connections.

Energize the circuit and check for oscillation. You should measure about 1V ac between the collector and ground. Measure the ac voltage across the oscillator coil. A reading of 4V is normal. Now measure the ac voltage at the input to the transistor, between lug 11 and ground. Notice that it is lower than the signal at the collector.

Turn the equipment off.

Discussion: When you reversed the connections to the feedback coil, you found that the oscillator did not work. The feedback was out-of-phase with the voltage across the resonant circuit and cancellation occurred. In-phase feedback is necessary for any oscillator to work.

In Step 3, you built and tested a Hartley oscillator which uses a "tapped" inductance for feedback. By connecting the two windings of the coil in series, you simulated a single-tapped coil. The feedback signal was developed across the blue-red winding. This induced a larger voltage in the green-black winding. The two voltages are in series and add, as you can see in your chart in Fig. 48-5. The total voltage was applied to the base of the transistor.

The circuit in Fig. 48-4 is called a shunt-fed Hartley oscillator. This simply means that the ac and dc circuits of the oscillator are separated so that no dc flows in the oscillator coil, L_1 and L_2.

In Step 4, you experimented with a conventional Colpitts oscillator. The circuit uses "tapped" capacitance in its feedback path. The tapped capacitance consists of two capacitors connected in series, with the center point grounded. The feedback signal is applied through the coil and series capacitors to the base circuit to sustain oscillations. The capacitors are series-connected, and, as you already know, the net value of series-connected capacitors is less than the value of the smaller capacitor. This equivalent capacitance resonates with the coil to establish the oscillator frequency.

You can expect to find variations of these oscillator circuits in electronic equipment. For example, here we used common emitter amplifier configurations. You are sure to find both common base and common collector circuits.

Instructions for Statement No. 48: For this Report Statement, you will take dc voltage readings in the circuit you used in Step 4, first with the oscillator operating and then with it stopped. No additional wiring will be needed.

Turn the circuit on and measure the dc collector voltage and the dc base voltage. Note your readings in the margin. Then, turn the circuit off and unsolder one lead of the .001-mfd capacitor from the green terminal of the coil. Energize the circuit and repeat the voltage measurements.

EXPERIMENT 49

Purpose: To show that two amplifier stages can be connected to form an R-C oscillator; to show how feedback controls the stages and to observe the voltage variations.

Introductory Discussion: In the previous experiments, we examined current flow in transistors and examined bias arrangements in amplifier stages. We also demonstrated the operation of L-C oscillator circuits. We will now construct two amplifier stages and connect them to form an oscillator circuit called an "astable" or "free running" multivibrator. The two amplifiers are connected so that they conduct alternately and each one controls the other. As one transistor cuts off, it turns on the other so that the second transistor conducts heavily.

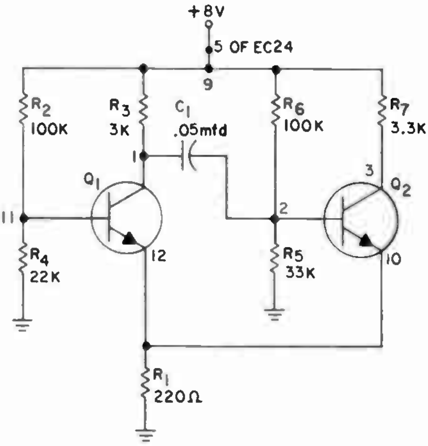

Fig. 49-1. The emitter-coupled multivibrator circuit used in Step 1.

The circuit you will use is the emitter-coupled multivibrator circuit shown in the schematic in Fig. 49-1. Let's briefly describe how the circuit works. When power is first applied to the circuit, both transistors begin to conduct. Initially, however, one will always conduct more heavily than the other.

Let's assume that transistor Q_2 conducts more heavily. Current flows from ground through resistor R_1 to both emitters. In each transistor, the current divides, with part going to the base and through the base bias resistor (R_2 or R_6) and the remainder flowing into the collector circuit and through the collector load resistor (R_3 or R_7) to the positive voltage supply. The current through R_1 produces a voltage drop which makes the emitters positive and tends to reverse bias the base-emitter junctions of both transistors. As the total current increases, the emitter voltage increases. The emitter voltage reaches a level where transistor Q_1 begins to cut off as its base becomes less positive with respect to its emitter. The Q_1 collector voltage rises toward the supply voltage, causing capacitor C_1 to charge.

The charge path is through the Q_2 base circuit, causing current flow from ground up through resistor R_5. This makes the base of Q_2 more positive and Q_2 conducts even more. As C_1 becomes fully charged, the current through R_5 decreases and the voltage drop across R_5 decreases. Therefore, the bias on Q_2 decreases and it conducts less, producing a smaller voltage drop across R_1.

When the R_1 voltage drop falls below a certain level, Q_1 will begin to conduct and its collector voltage will begin to drop. C_1, which has charged to the high Q_1 collector voltage, will then begin to discharge. It discharges through R_5 and R_6 to ground and +8, through R_1 and the emitter-collector path of Q_1. Note that now the current through R_5 and R_6 makes the base of Q_2 negative. Hence, Q_2 is cut off.

After C_1 has discharged enough, the reduced discharge current will allow Q_2 to conduct again. As before, the forward bias is supplied by R_6. Q_2 will begin to conduct and the next cycle will begin.

The multivibrator is one of the most useful circuits in electronics. It is used in the horizontal and vertical deflection circuits of TV receivers, in transmitter control equipment, in test equipment and in computers. Frequency of operation can be as low as a few Hertz or as high as several megahertz. The circuits you will build have a maximum frequency of slightly less than 1 kHz.

Experimental Procedure: For this experiment you will need your tvom, the experimental chassis and the following parts:

1	220-ohm resistor
1	470-ohm resistor
1	3K-ohm resistor
1	3.3K-ohm resistor
1	22K-ohm resistor
1	33K-ohm resistor
2	100K-ohm resistors
1	.05-mfd capacitor
1	100-mfd, 10V elect. capacitor

Before proceeding with this experiment, you will construct the multivibrator circuit shown in Fig. 49-1. First unwire the circuit used in Experiment 48 but leave the transistor on the circuit board. Remove the coil from the chassis.

You will need two transistors for this experiment. Locate a second NPN transistor among the parts you received in this kit and identify the leads. Refer to the sketch in Fig. 49-2. Mount the transistor on the circuit board (EC25) at the location shown in Fig. 49-2. Mount it in the same manner as the transistor already on the board. Melt a little solder for each connection, use your pliers as a heat sink and solder each lead carefully. Check carefully to see that the collector con-

nects to lug 3, the base connects to lug 2, and the emitter connects to lug 10.

In wiring the multivibrator circuit, the leads of the component parts can either be soldered to the terminal lugs or to the copper foil strips, as mentioned earlier. Do not cut the leads of the components, but bend the leads as necessary to make the connections.

Wire the circuit shown in Fig. 49-1. You can use lug 9 of EC25 as a tie point for some of the connections to the +8V source. Connect a 22K-ohm resistor between lug 11 and ground; connect a 220-ohm resistor between lug 12 and ground; and connect a 33K-ohm resistor between lug 2 and ground.

Connect a 100K-ohm resistor between lugs 9 and 11; connect a 3.3K-ohm resistor between lugs 3 and 9; connect a 100K-ohm resistor between lug 2 of EC25 and lug 5 of EC24; and connect a 3K-ohm resistor between lug 1 of EC25 and lug 5 of EC24.

Connect a .05-mfd disc capacitor between lugs 1 and 2; connect a length of hookup wire between lugs 10 and 12; and connect a length of wire between lug 9 of EC25 and lug 5 of EC24. Check your wiring and solder all connections. Bend the leads of the parts so that there are no short circuits.

Step 1: To show that the multivibrator circuit produces oscillations.

Set your tvom to measure 3 volts ac and turn the circuit on. Connect the tvom ground clip to the chassis, touch the probe to lug 3 and measure the ac voltage at the collector of transistor Q_2. Record the value in the space provided for Q_2 in the chart in Fig. 49-3. If you read no ac voltage, recheck your circuit to be sure it is wired correctly.

	AC	DC
Q_1 COLLECTOR	.5V	5.4
Q_1 BASE	.14V	.95
Q_2 COLLECTOR	2.65V	5.2
Q_2 BASE	.44V	.63
EMITTERS	.15V	.32

Fig. 49-3. The chart for use in Step 1.

Move the tvom probe to lug 1 and measure the ac voltage at the collector of Q_1. Record this value in the chart also. Measure and record the ac voltages at each of the points listed in the chart in Fig. 49-3.

When you complete your ac readings, go back and take the dc voltage readings at each of the 5 points in the circuit and record your readings.

Step 2: To show voltage variations in the multivibrator circuit.

Turn the circuit off and connect a 100-mfd, 10V electrolytic capacitor in place of the .05-mfd capacitor in your circuit. Connect the positive lead to lug 1 and the negative lead to lug 2. Turn the circuit on and measure the dc voltage at the collector of transistor Q_2.

You will notice first that the voltage varies from the supply voltage of about +8 volts to 0 and back again. By increasing the value of the coupling capacitor (C_1 in Fig. 49-1), you have slowed down the operation of the oscillator to the point where the dc voltmeter is nearly able to follow the voltage variations.

Note that the voltage rises sharply, remains at its maximum value for a time, falls sharply and stays near zero for a while. If you were to graph this voltage variation with respect to time, you would have a voltage waveform similar to the one shown in Fig. 49-4A.

Move the probe to the collector of Q_1 and observe the dc voltage there. You will see that this voltage varies at the same rate as the Q_2 collector voltage, but over a very narrow range. The nominal variation is from 3.5 to 5.5 volts. The transitions are not as sharp as those at the collector of Q_2. However, the waveform is said to be a rectangular wave. It is shown in Fig. 49-4B.

Set the range switch to 3V and touch the probe to the base of Q_2 (lug 2). You will see that the voltage varies by about 1 volt. Actually, it swings positive and negative. The voltage goes slightly negative and becomes positive again so quickly that the meter may not show it. Consequently you may not see the pointer move to the left of zero. The Q_2 base waveform is shown in Fig. 49-4C.

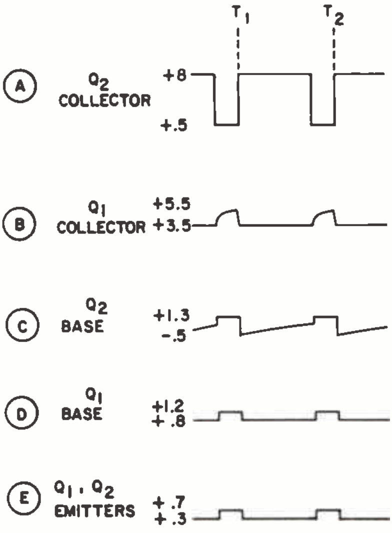

Fig. 49-4. Waveforms in the multivibrator circuit.

With your voltmeter, verify that the waveforms shown in Figs. 49-4D and E occur at the base of transistor Q_1 and at the emitters at both transistors. Note that these voltages vary over a very narrow range and that they are in step with the other voltages.

Step 3: To demonstrate the feedback paths in the multivibrator circuit.

Turn the circuit off and replace the 100-mfd capacitor with the .05-mfd capacitor shown in Fig. 49-1. Turn the circuit on and check for ac voltage at lug 3. The ac voltage will tell you that the circuit is oscillating.

Solder the negative lead of the 100-mfd electrolytic capacitor to a ground point near lug 12. While observing the ac voltage at lug 3, touch the positive lead of the electrolytic capacitor to lug 12. The capacitor places lug 12 at ac ground. Note its effect on the oscillation. Remove the 100-mfd capacitor.

Turn the circuit off and unsolder one lead of the .05-mfd coupling capacitor. Energize the circuit and measure the ac voltage at lug 3. There should be none, indicating that the circuit is not oscillating. Turn the circuit off. Replace the .05-mfd capacitor with the 100-mfd capacitor. Be sure to connect the positive lead to lug 1.

Discussion: In this experiment you demonstrated that two transistor amplifiers can be coupled together to form an oscillator. This is termed an R-C oscillator to distinguish its general type from the L-C oscillators you used in the previous experiment.

In Step 1 you proved that the circuit was oscillating by the fact that you were able to measure ac voltages in the circuit.

The ac voltages are actually the ac components of pulsating dc voltages, with the exception of the voltage at the base of transistor Q_2 which goes negative during each cycle.

Refer to your chart in Fig. 49-3. The ac voltage at the collector of Q_2 should be higher than the ac voltage anywhere else in the circuit. The ac at the collector of Q_1 should be between one third and one half of the Q_2 collector ac voltage. Typically, the ac at the base of Q_2 is under .5V and the ac at the base of Q_1 and at the emitters was too low to measure.

Now look at the dc voltages. The Q_1 collector voltage should be about 6V and the Q_2 collector voltage should be about 4V. The average conduction of Q_1 is higher than that of Q_2. Thus the average voltage drop across its collector load resistor (R_3) is higher. Similarly, the Q_1 base voltage should be more positive than the Q_2 base voltage. Both should be between .5V and 1V. It may appear that there is insufficient forward bias on the transistors. This is an illusion created by the fact that the meter gives average voltage indications.

In Step 2 you observed the wave shapes in the circuit with the oscillator operating at a very low frequency. Your observations should be very similar to the waveforms shown in the graph in Fig. 49-4.

You should have found that transistor Q_2 is alternately cut off and saturated. Cutoff is indicated by high collector voltage when there is hardly any voltage drop across the collector load resistor. When the transistor is saturated, the collector voltage is nearly zero due to the large current through the collector load and the large voltage drop across it.

This variation in collector voltage is caused primarily by the base voltage. You saw that the base was reversed biased during part of the cycle and highly forward biased during the remainder of the cycle. Thus the transistor conduction varied widely.

Transistor Q_1 acted basically as a common base amplifier as the input signal was applied to its emitter and the output was taken from its collector. As you saw, the Q_1 collector voltage varied by only 2 volts or so. This, however, was sufficient to initiate the charging and discharging of the coupling capacitor.

As we mentioned earlier, the charging and discharging of the coupling capacitor establishes the voltage drop across resistors $\mathbf{R_5}$ and $\mathbf{R_6}$ and, consequently, the voltage at the base of Q_2. Thus when we increased the amount of capacity, we increased the period of each cycle proportionately.

From earlier studies you know that the frequency of a signal is equal to the reciprocal of its period: $F = 1/P$. Then, if we increase the time required for the capacitor to charge and discharge, we decrease the frequency. To determine the frequency, count the number of complete cycles which occur in a given unit of time. If each cycle takes longer than a second, it is most convenient to express the frequency in cycles-per-minute.

In Step 3 you should have found that the oscillations stopped when you placed the capacitor across the emitter resistor and when you disconnected the coupling capacitor. In both cases you disabled the feedback. It is necessary for both feedback loops to pass signals so that each amplifier will be controlled and will be able to control the other.

In connecting the capacitor across the

emitter resistor, you placed the emitters at signal or ac ground potential. Thus variations in the conduction of Q_2 were not applied to the emitter of Q_1 so Q_1 could not cause C_1 to charge and discharge. When you opened the coupling capacitor, you prevented any voltage variations at the Q_1 collector from reaching the base of Q_2.

Instructions for Statement No. 49: For this Statement you will increase the value of the emitter resistor and note its effect on the oscillator frequency. With the 100-mfd coupling capacitor in the circuit, observe the Q_2 collector voltage and determine the frequency of the oscillations. To do this, count the number of oscillations taking place in 1 minute. One cycle is the period, for example, between T_1 and T_2 of the collector waveform in Fig. 49-4A. Watch your voltmeter and note the number of times the collector voltage jumps to +8 volts (T_1). The voltage will then drop. Use a watch or clock having a sweep second hand to measure the time accurately.

Turn the circuit off, disconnect the 220-ohm resistor from lug 12 and connect a 470-ohm resistor in its place.

14 Turn the circuit on, connect the voltmeter to lug 3 and again determine the frequency of oscillation. Compare this frequency with the frequency produced with the 220-ohm emitter resistor. Answer the Statement here and on the Report Sheet and turn your equipment off. 11

Statement No. 49: When I increased the emitter resistor value from 220 ohms to 470 ohms, the oscillator frequency:

(3) remained the same.

EXPERIMENT 50

Purpose: To show that the gain of a cascade amplifier is greater than the gain of a single amplifier stage and to compare AC and DC coupling in cascade amplifier stages.

Introductory Discussion: There are very few applications where a single stage of amplification is used. Usually amplifier stages are connected in cascade to increase the overall gain or amplification which the signal receives. Typical examples are the audio, i-f and video sections of a TV receiver and the audio section of a radio receiver. Each of these amplifier sections consists of from 2 to 4 stages cascaded together.

Amplifier stages may be coupled together by several different methods. In this experiment, we will concern ourselves with common emitter stages, resistance-capacitance (R-C) coupling and direct current (DC) coupling. As the names imply, R-C coupling consists of a coupling capacitor connected between the stages in such a way that only the ac component signal is transferred. In DC coupling, usually a direct wire or a resistor is connected between the two stages. However, diodes can also be used. As such, the dc reference level, as well as the signal, is coupled from the first stage to the second. Of the two methods, R-C coupling is more widely used, and DC coupling is used for special purposes.

In this experiment, you will first construct a two-stage amplifier with R-C coupling. After measuring gain and dc voltages, you will rewire the circuit for DC coupling and carry out additional steps.

Experimental Procedure: For this experiment, you will need the experimental chassis with the two circuit boards mounted, your tvom, and the following parts:

- 1 10-ohm resistor
- 1 220-ohm resistor
- 1 330-ohm resistor
- 1 470-ohm resistor
- 1 2.2K-ohm resistor
- 1 3.3K-ohm resistor
- 1 4.7K-ohm resistor
- 1 15K-ohm resistor
- 1 18K-ohm resistor
- 2 100K-ohm resistors
- 1 10-mfd electrolytic capacitor
- 1 6-mfd electrolytic capacitor
- 2 HV silicon diodes

The HV diodes are in the HV power supply circuit. Temporarily remove them from terminal strip A on your chassis.

Dismantle the circuit used for Statement 49, but leave the two transistors on the circuit board. Also leave the 3.3K-ohm resistor connected between lugs 3 and 9, leave the 100K-ohm resistors in place, and leave the length of hookup wire between lug 9 and lug 5 of EC24.

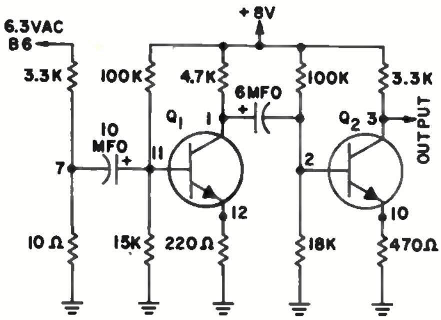

Fig. 50-1. The ac voltage divider and R-C coupled amplifier.

Wire the ac voltage divider and 2-stage amplifier circuit shown in the schematic diagram in Fig. 50-1. Connect a 3.3K-ohm resistor between terminal B6 and lug 7 of EC25. Connect a 10-ohm resistor from lug 7 to ground. Connect a 10-mfd electrolytic capacitor from lug 7 to lug 11. The positive lead connects to lug 11. Connect a 15K-ohm resistor between lug 11 and ground. Connect a 220-ohm resistor from lug 12 to ground. Connect a 470-ohm resistor from lug 10 to ground. Connect an 18K-ohm resistor between lug 2 and ground.

Connect a 4.7K-ohm resistor from lug 1 of EC25 to lug 5 of EC24. Connect a 6-mfd electrolytic from lug 1 to lug 2, with the positive lead going to lug 1.

Your circuit should now be wired according to the schematic in Fig. 50-1. Check your work and make sure all connections are soldered.

Step 1: To measure the voltage gains in an R-C coupled amplifier circuit.

As in previous work, you will use the 60 Hz ac filament voltage as your signal. The voltage divider, consisting of the 3300-ohm resistor and the 10-ohm resistor, gives an output of approximately .02V. We will use the value .02V in the discussion as the input signal voltage throughout this experiment.

With your tvom set to read ac voltage, touch the probe to lug 11 and note that the input voltage is too low to read on your meter. Move the probe to lug 1 and read the ac output voltage of the first stage at the collector. Record your reading in the space for the "stage 1 output" in the chart in Fig. 50-2.

.24

Now measure the input to stage 2 at the base connection, lug 2. The reading

should be very close to the previous reading, as the large coupling capacitor has extremely low impedance at the signal frequency. Record this value in the space for the "stage 2 input" in Fig. 50-2.

Using the information in the chart, compute the voltage gain of each stage and record it in the proper place in the chart. Use the formula,

$$\text{voltage gain} = \frac{\text{output voltage}}{\text{input voltage}}$$

Now compute the overall gain of the two-stage amplifier. Use the same formula, but divide the Q_2 output by the Q_1 input of .02 volts. Jot down the results of this computation in the margin and compare it with the individual stage gains. You can readily see that the overall gain is the product of the individual stage gains.

Step 2: To show that the amplifier does not provide DC coupling.

Measure the dc voltage at the base of transistor Q_1 and record it in the chart in Fig. 50-3A. In a similar manner, measure and record the dc voltages at the other three points listed in Fig. 50-3A.

Solder a length of wire between ground and lug 11 and repeat the dc voltage measurements. Record the reading in Fig.50-3B. The short-circuited input represents a negative change in the dc voltage at the input to the amplifier. You should find that some of the voltage readings change very little if at all. Remove the short from the input.

Step 3: To measure the gain of a DC coupled cascade amplifier.

Turn the circuit off and wire the circuit shown in the schematic in Fig. 50-4. Remove the 6-mfd capacitor. Remove the 18K-ohm and 100K-ohm resis-

tors connected to lug 2. Connect a 2.2K-ohm resistor between lug 2 and ground.

Connect the 2 HV silicon diodes with the anode lead of one soldered to the cathode lead of the other. Now solder the free *anode* lead to lug 1 and solder the free *cathode* lead to lug 2. Connect a 330-ohm resistor between lug 8 and ground. Connect the 6 mfd capacitor from lug 10 to lug 8 with the polarity shown in Fig. 50-4. Note in Fig. 50-4 that the forward bias as well as the signal for the base of Q_2 comes from the Q_1 collector circuit.

Energize the circuit and measure the ac voltages at the collector of Q_1 and at the base and collector of Q_2. Record your readings in the chart in Fig. 50-5. The input signal voltage remains unchanged at .02V.

Fig. 50-6. The chart for dc voltages in Step 4 (A) with signal and (B) with input shorted.

As you did in Step 2, measure the dc voltages at the points in the circuit listed in the chart in Fig. 50-6A, and record them. Then short the input, lug 11, to ground and repeat the measurements with the input shorted. Record your voltage readings in Fig. 50-6B. Turn the equipment off and remove the short from lug 11.

Discussion: The essential facts demonstrated in this experiment are (1) the gain of a cascade amplifier is equal to the product of the individual stage gain, and (2) a DC amplifier passes the dc as well as the ac component of the input signal.

In the first two steps, you used conventional RC coupling between the stages. The voltage variations at the collector of transistor Q_1 caused the coupling capacitor to charge and discharge through the Q_2 base circuit. This caused the current through the 18K-ohm resistor in the Q_2 base circuit to vary, and thus a varying voltage was applied to Q_2. Q_2 amplified this signal voltage.

The diodes provided the coupling in Steps 3 and 4. As you have learned, a forward biased silicon diode has a voltage drop of about .6V across itself. The two series connected diodes, therefore, have a net voltage drop of slightly more than 1V. The diodes, therefore, couple both ac and dc voltage from the collector of Q_1

to the base of Q_2. The resistor between the base of Q_2 and ground helps provide the proper bias for the transistor.

In the NRI Laboratory, we realized stage gains of 10 for Q_1 and 8 for Q_2 in Step 1. The product of the two is 80. Our overall gain measurement was equal to 1.6V/.02V which is also 80. In Step 3, the stage 1 gain was 5 and the stage 2 gain was 15, giving a computed overall amplification of about 75. The overall gain was approximately 1.5/.02 or 75.

You saw how both amplifier circuits responded to changes in dc level at the input in Steps 2 and 4. With R-C coupling, only the ac component of the signal is transferred through the amplifier circuit. This is because the coupling capacitor provides dc isolation between stages. In Step 4, however, you found that both stages were affected when you removed the forward bias on Q_1 by shorting its base to ground. The reduction in forward bias cut off Q_1 and caused its collector voltage to rise. This appeared to Q_2 as a positive-going signal, increasing the forward bias on Q_2. The resulting increase in Q_2 collector current produced a greater voltage drop across the Q_2 collector load resistor. Thus, it reduced the output dc level.

Instructions for Statement No. 50: For this Statement, you will simulate a defect in the coupling between the two amplifier stages and note its effect on the gain of the first stage.

Energize the circuit, measure the ac voltage at the collector of Q_1 and compute the gain of the stage. (The input is approximately .02V.) Then turn the circuit off and unsolder the anode lead of D_1 from lug 1.

Turn the circuit on again and measure the ac voltage at the collector of Q_1. Again compute the gain, compare it with the gain before you disconnected the diode, and answer the Statement here and on the Report Sheet.

Turn all equipment off. Remove the HV diodes from the circuit board and reinstall them in the HV power supply circuit as shown in Figs. 5 and 6.

Statement No. 50: When I opened the circuit between the two amplifier stages, I found that the gain of the first amplifier stage:

(1) remained the same.
(2) decreased.
[✓ *(3) increased.*]

CONCLUSION

You have completed the final experiment in this Training Kit. Let's review the important points which you have learned. In the first four experiments, you studied vacuum tubes and vacuum-tube circuits. You learned that a Class A vacuum-tube amplifier requires a bias voltage applied between the grid and cathode. The bias voltage makes the grid negative with respect to the cathode so that both the negative and positive portions of the input signal will control the tube current and be amplified. You also saw that bias voltage can be supplied by a separate bias source, or it can be derived from the signal or from the B+ supply by one of several methods. Finally, you compared the three vacuum-tube amplifier configurations: common cathode, common plate and common grid.

In the latter part of the kit, you worked with transistor circuits. You began with bias and biasing methods and amplifier configurations. Then you constructed and performed experiments on L-C and R-C oscillators and cascade amplifiers.

You learned that in a transistor, the base-emitter junction must be forward biased in order for current to flow from the emitter across both junctions to the collector. Also, the bias voltage can be obtained from an external bias source or from the collector supply voltage in the circuit. In the experiment on transistor amplifier configurations, you constructed and compared the gain and impedance characteristics of the three amplifier configurations: common emitter, common base and common collector.

L-C and R-C oscillators were taken up after the work with amplifier fundamentals. You learned that an oscillator must have amplification and feedback. Also, you learned that in an L-C oscillator, the frequency is established by the resonant frequency of a resonant circuit while in an R-C oscillator, the frequency is set by the time constant of an R-C network.

In the final experiment, you built a cascade amplifier and saw that its overall gain is the product of the individual stage gains and that either R-C or DC coupling can be used.

WHEN YOU WORK FOR A MAN

Here are some words of advice written by Elbert Hubbard. Whether you are an employer or employee, I believe you'll want to read this over several times:

"If you work for a man, in heavens's name work for him. If he pays wages that supply you your bread and butter, work for him, speak well of him, think well of him, stand by him, and stand by the institution he represents. I think if I worked for a man, I would work for him, I would not work for him a part of his time, but all of his time. I would give an undivided service or none. If put to a pinch, an ounce of loyalty is worth a pound of cleverness. If you must vilify, condemn, and eternally disparage, why, resign your position, and when you are outside, damn to your heart's content. But, I pray you, so long as you are a part of an institution, do not condemn it. Not that you will injure the institution – not that – but when you disparage the concern of which you are a part, you disparage yourself."

INSTRUCTIONS FOR PERFORMING EXPERIMENTS 51 THROUGH 60

In your last series of experiments, you conducted experiments with transistor and vacuum tube amplifiers and oscillators. You are now ready to conduct experiments on typical circuits which you will encounter in future training kits and in your work as a technician. You will continue work with amplifiers and oscillators and we will show you how these circuits are used in electronic equipment for home entertainment.

This kit is divided basically into two parts: Audio Frequency and Radio Frequency. In the Audio Frequency section, you will begin with loudspeakers and audio amplifiers. In these experiments, you will learn how loudspeakers work and you will study typical audio amplifier circuits. Then you will perform an experiment using the field-effect transistor. Following this, you will perform an experiment on a stereo indicator circuit.

In the rf section of the kit, you will construct an rf oscillator circuit and use it to demonstrate i-f amplifier and limiter stages and AM and FM demodulator circuits.

Be careful as you construct the circuits for these experiments to avoid short-circuits and wiring errors. Locating such troubles can be time-consuming and it is usually unnecessary. Extra care is needed because the circuits are more complex, containing many parts and wires.

Wiring from the schematic diagrams usually works best. However, some help is given in the form of sketches and written instructions. Use the extra help if you need it. Remember, however, a good technician should be able to work from the schematic diagram alone.

If you have trouble with any experiment, look the circuit over carefully to make sure there are no poorly soldered connections or wiring errors. Make voltage and resistance measurements and, if you need help, write, telling us what tests you have made and your test results. Use the special kit consultation blank enclosed for all questions concerning the experiments in your practical demonstration course.

CONTENTS OF THIS KIT

The contents of this kit are shown in Fig. 1 and listed below the figure. Check the parts you received against this list to be sure you have all the listed parts. Do not discard any of these parts or the parts from previous kits until you have finished your NRI course.

IMPORTANT: If any part in this kit seems to be missing, look for a substitute. If any part is obviously defective, or has been damaged in shipment, return it immediately to NRI as directed on the "Packing and Returned Material" slip included with this kit.

PARTS DATA

The following information should help you to understand some of the special characteristics of certain parts supplied in this kit.

PNP Transistor. You received three small PNP transistors (TS22) in this kit. These are small signal silicon transistors which have high gain and are designed for amplifying weak signals. As you already know, the polarities of the voltages applied to the elements of a PNP transistor are the reverse of those for an NPN transistor. With respect to the emitter, the collector is operated highly negative and the base is slightly negative.

The schematic symbol for the transistor is shown in Fig. 2A. This symbol is different from the NPN symbol only in the direction of the arrow representing the emitter. Fig. 2A also shows the lead identification for the PNP transistor.

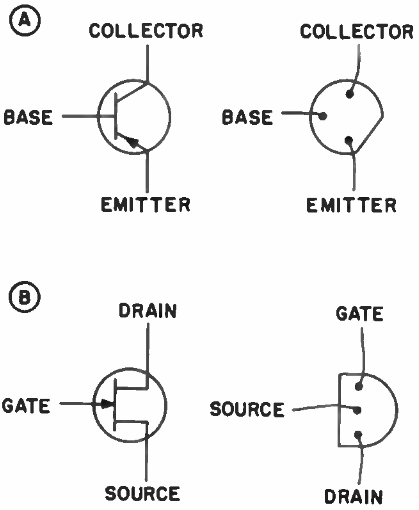

Fig. 2. Schematic symbols and lead identification for (A), the PNP transistor, and (B), the field-effect transistor you will use in this kit.

Field Effect Transistor. This transistor is a silicon N-channel type, solid-state device which physically resembles a transistor, but behaves more nearly like a vacuum tube. You will work with this transistor to discover some of its characteristics. The schematic symbol and lead identification are given in Fig. 2B.

The Tuning Capacitor. The tuning capacitor you received in this kit is a standard receiver type. It has two sets of multiple plates and uses an air-dielectric. The stator plates connect to the insulated terminals on the capacitor and the rotor is grounded to the capacitor frame.

As the shaft is turned counterclockwise, the plates mesh. This increases the total surface area between the two sets of plates and increases the total capacity.

When handling the capacitor, care must be taken to keep from bending the plates. The capacitor is shorted if any adjacent plates touch each other. Similarly, all four terminals on the capacitor are connected to the stator. Thus, if any of the terminals is shorted to the frame, the capacitor is shorted.

As you will see in the following experiments, the tuning capacitor will be connected into the resonant circuit of an rf oscillator. You will be able to change the total capacity in the circuit by rotating the shaft of the tuning capacitor. Therefore, the tuning capacitor will vary the frequency of the oscillator output signal.

Trimmer Capacitor. The trimmer capacitor also has multiple plates. It is called a compression type since the capacity is adjusted by turning the screw which changes the spacing between the plates. Tightening the screw squeezes the plates closer, thereby increasing the capacity.

RF Transformer. Transformer TR31 is an rf transformer with one tapped winding. The inductances of the two windings are about the same, so either winding can be tuned to the frequency of the rf oscillator by using the trimmer capacitor.

Physically, the rf transformer resembles the oscillator coil you used in the last kit. The rf transformer also has its own mounting hardware and mounts on top of the chassis.

I-F Transformer. As you will learn in the sixth experiment of this kit, the degree of coupling between the primary and secondary windings of an i-f transformer has a marked effect on the frequency response of the transformer, as well as on the rf voltage output. So that you can demonstrate the effects of different degrees of coupling, one coil of the i-f transformer supplied in this kit has been constructed so that it can be moved back and forth along the coil form.

This transformer was designed especially for NRI. If you should damage it in carrying out the experiments, you can get a replacement only from NRI. Do not write to the manufacturer or try to buy one from a parts jobber.

In other respects, the i-f transformer is just like any other standard 456 kHz interstage or output i-f transformer that is tuned by compression trimmers. Although output voltage will be maximum when the frequency is between 425 and 485 kHz, there will be a certain amount of output throughout the range from approximately 390 kHz with the trimmers tight to nearly 600 kHz with the trimmers at minimum capacity.

Output Transformer. The audio output transformer is used to couple and match the output of an amplifier to a loudspeaker. The transformer matches the high impedance of the amplifier, which is frequently several thousand ohms, to the four-to-eight ohms impedance of a loudspeaker. Be careful not to pull on any of the transformer leads; you might rip the paper wrapped around the coil windings and pull the leads loose from the windings.

Loudspeaker. The loudspeaker which you received is a PM or permanent magnet type. It is typical of those used in table model radio and TV receivers. The audio frequency signal is applied to the terminals, which connect to the voice coil. Signal current through the speaker causes the speaker to reproduce the signal.

Circuit Boards. Two printed circuit boards are included in this kit. These boards are labeled EC26. The boards are laid out in a pattern of squares which are numbered as shown in Fig. 3. The squares are located by a number and letter. For example, square 5H is at the intersection of the fifth column and row H.

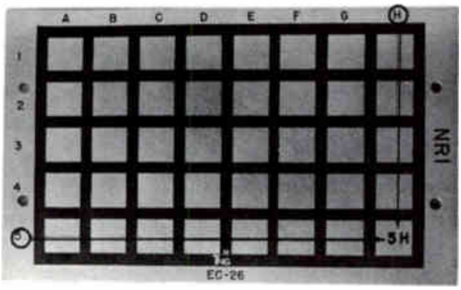

Fig. 3. Circuit board EC26.

When soldering leads to the squares on these boards, use the following technique: Melt a small pool of solder on the foil. Place the leads on top of the solder and heat until the lead penetrates the solder to the foil.

Preliminary Construction

In this section, you will prepare the experimental chassis for the following experiments. You will modify your low voltage power supply, build an audio oscillator, and build part of an audio frequency amplifier. First, you will mount the parts on the chassis. You will then wire and test your circuits.

MOUNTING THE PARTS

Gather the following parts:

2	**Circuit boards (EC26)**
1	**2-lug terminal strip**
1	**Audio output transformer**
3	**Potentiometer mounting brackets**
1	**1k-ohm potentiometer**
1	**3-position rotary switch**
2	**3/8" X 8-32 screws**
2	**8-32 hex nuts**
5	**3/8" X 4-40 screws**
8	**4-40 hex nuts**

Fig. 4 shows the parts mounted on top of the chassis. Refer to this figure as you perform the following steps.

Remove circuit board EC25 and the

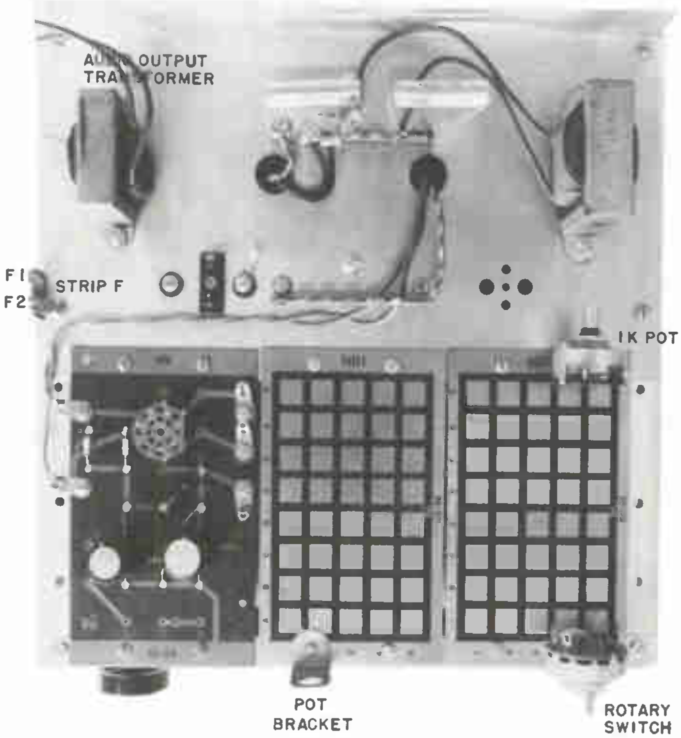

Fig. 4. Refer to this diagram as you install the parts on the chassis.

solder lug from the experimental chassis. Lay the circuit board aside, but keep the 4-40 screws and nuts handy.

Prepare a new circuit board, EC26, for mounting as follows: Secure potentiometer mounting brackets (BR1) to the board at the holes near squares 4A and 4H, using 3/8" X 4-40 screws and nuts. Position the brackets so they are facing away from the circuit board, and tighten the nuts. Place 3/8" X 4-40 screws in the remaining two mounting holes in the board and attach nuts and tighten.

Position the board over the chassis so that the potentiometer mounting brackets are over holes V and AH. (The numbers inscribed along the end of the circuit board should be over the front chassis rail.)

Mount a 1k-ohm potentiometer in the bracket at hole V. Place a lockwasher over the bushing, slip the potentiometer bushing through the hole and attach a control nut. Position the terminals upward and tighten the nut.

Next you will mount the rotary switch in the potentiometer mounting bracket at hole AH. First rotate the shaft of the switch fully clockwise. Slip a knob on the shaft temporarily or use a pair of pliers to grasp the shaft. Slip a control lockwasher over the shaft and bushing of the switch. Slip the bushing through the mounting hole in the bracket and rotate the switch so that the flat on the shaft is downward, pointing toward the circuit board.

Attach a nut and tighten.

Mount another circuit board, EC26, on the chassis at holes AE, AF, S, and T. Turn the board so that the numbers are over the front edge of the chassis rail. Secure with three 1/4" X 4-40 screws through holes AF, S, and T. Attach nuts and tighten.

Attach a potentiometer mounting bracket at hole AE, using a 3/8" X 4-40 screw and nut.

Install the audio output transformer on top of the chassis at holes A and B. Position the transformer so that the blue and red leads are toward the right and secure with 8-32 screws, lockwashers, and nuts. Position these leads so they will not touch any of the circuitry, as you will not use the transformer immediately.

Mount a two-lug terminal strip (strip F) at hole P. Secure the strip using the hardware in hole P. Position the strip as shown in Fig. 4 and tighten the screw.

One of the thin secondary leads of the audio output transformer is tinned with solder throughout its length. Solder this lead to terminal F2. Solder the enamel-covered secondary lead of the transformer to terminal F1.

WIRING THE CIRCUITS

You are now ready to construct the circuits for Experiment 51. The circuits will be constructed on the boards you just installed on your chassis.

Low Voltage Power Supply. You will convert your low voltage power supply on EC24 into a bridge rectifier circuit, using an L-C filter which will supply about +12V to your experimental circuits. You will need the following:

2 LV silicon diodes (SR12)

The schematic diagram of the power supply is shown in Fig. 5. Unsolder and disconnect the green/yellow lead of the power transformer from terminal B7. Push the lead aside and tape it to be sure it does not make contact with the chassis, terminals or other leads.

Solder the cathode lead of a silicon diode to lug 1 of circuit board EC24. Solder the cathode lead of the other

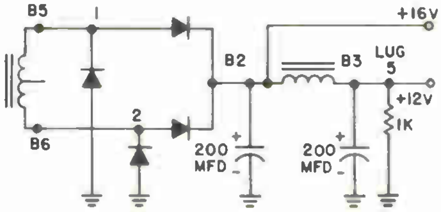

Fig. 5. The low voltage power supply circuit.

diode to lug 2 of EC24. Solder the free (anode) lead of each diode to the ground foil near the end of the circuit board.

Unsolder and disconnect the leads of the filter choke from terminals A4 and A6. Unsolder and disconnect one lead of the 100-ohm resistor from circuit board EC24. Connect the filter choke in place of the 100-ohm resistor as follows. Connect the choke leads to terminals B2 and B3. Connect a length of hookup wire from terminal B2 to the foil connecting the diodes to the input filter capacitor of the power supply circuit. Connect another length of hookup wire from terminal B3 to the foil which connects to lug 5 of EC24.

Your +12V output terminal will be lug 5 of circuit board EC24.

Audio Frequency Oscillator. You will construct a three-frequency phase-shift oscillator circuit on the circuit board on the right side of your chassis. This is the board with the switch and potentiometer attached to it.

The circuit is shown in the schematic diagram in Fig. 6. As you can see, three separate phase shift networks are used

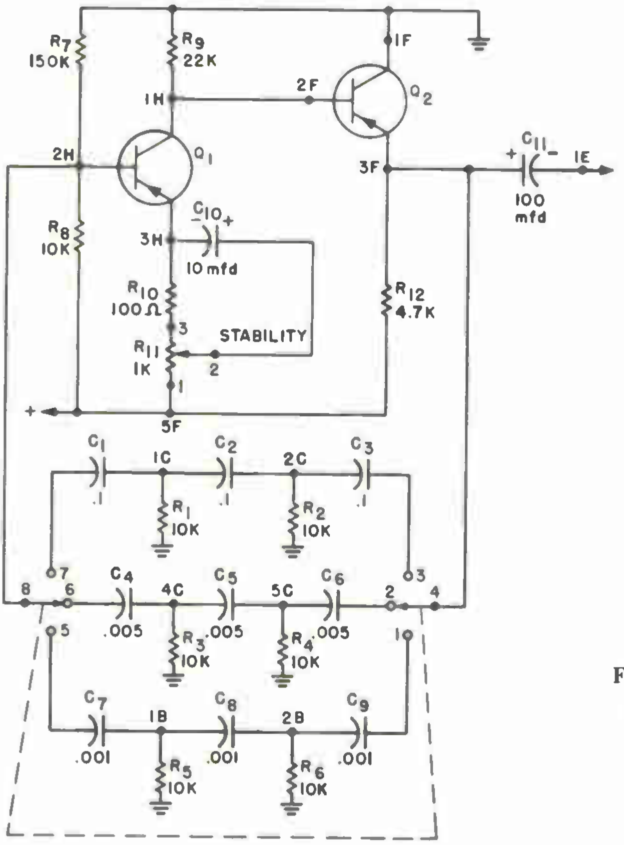

Fig. 6. Schematic diagram of the audio oscillator circuit.

and you select the desired frequency by switching in the appropriate feedback network. Capacitors C_1, C_2 and C_3 and resistors R_1 and R_2 are used in switch position 1 to produce 100 Hz. In position 2, C_4, C_5, C_6, R_3 and R_4 are used for 1 kHz. When the switch is in position 3, the R-C network made up of C_7, C_8, C_9, R_5 and R_6 is used and the oscillator frequency is 10 kHz.

To wire the oscillator circuit, you will need the following parts:

1 100-ohm resistor
1 4.7k-ohm resistor
7 10k-ohm resistors
1 22k-ohm resistor
1 150k-ohm resistor
3 .001-mfd disc capacitors
3 .005-mfd disc capacitors
3 .1-mfd disc capacitors
1 10-mfd electrolytic capacitor
1 100-mfd electrolytic capacitor
2 PNP transistors (TS22), 2N5138
1 Pointer knob

All wiring except for the connections to the 1k-ohm potentiometer will be permanent. Therefore, you will cut off the excess lead lengths as you solder the parts in the circuit.

The connections will be made by soldering the component leads to the squares of copper foil on the circuit board. In each case, you will have two or more leads soldered to a square. To avoid having one lead pull loose while you solder the next, do not leave the soldering iron on the connections too long. You may find it worthwhile to solder each lead to a different corner of the square. Cut the leads and bend them so they will stay in place even if the solder is melted.

You will build the oscillator in two parts. First you will wire the R-C phase shift network. Then you will construct the transistor amplifier section.

Begin by soldering the 10k-ohm resistors to the board near the rotary switch. Shorten one lead of six 10k-ohm resistors to 1/2-inch and bend the short lead downward slightly. Lay a resistor on the circuit board with the short lead on square 4C, as shown in Fig. 7A. Solder the lead to square 4C. Bend the free lead of the resistor so it is touching the ground foil at the end of the board. Solder the

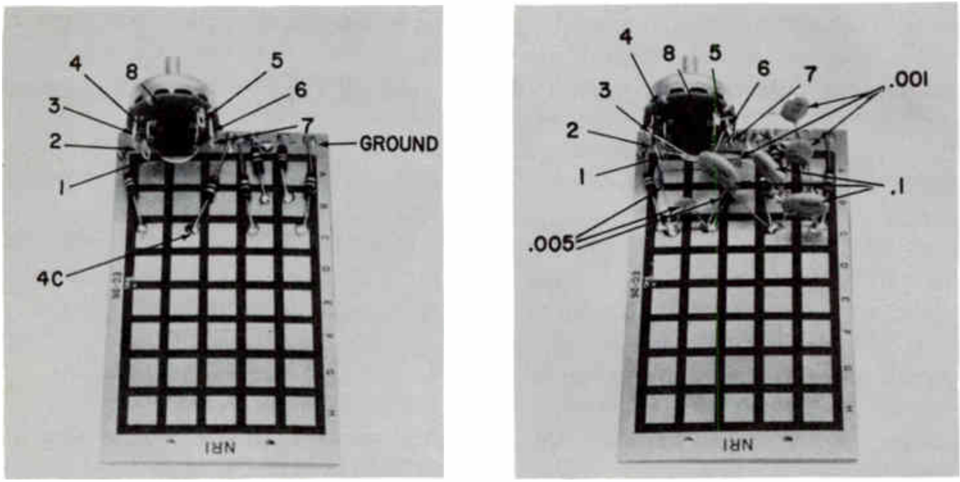

Fig. 7. (A) Mounting the resistors; (B) mounting the capacitors in the oscillator phase-shift network.

free lead to the foil and cut off the excess lead length.

In a similar manner, solder the short lead of another 10k-ohm resistor to square 5C, bend the leads so the free lead touches the ground foil and solder it at the end of the board.

Use the same procedure to install and solder the four remaining 10k-ohm resistors between squares 1C, 2C, 1B and 2B and the ground foil at the end of the board.

Now install the nine disc capacitors at the same end of the circuit board. When making connections to the switch, push each lead about 1/16 to 1/8-inch through the hole of the switch terminal and solder. The switch terminals are numbered in Figs. 7A and 7B.

Proceed as follows: Shorten both leads of two .001-mfd capacitors to 1 inch. Refer to Fig. 7B. Solder one lead of a .001-mfd capacitor to terminal 5 of the switch. Bend the leads so the free lead touches square 1B and solder. Solder another .001-mfd capacitor to terminal 1, bend the leads as necessary and solder the free lead to square 2B. Shorten the leads of the remaining .001-mfd capacitor to 1/2-inch and solder this capacitor between squares 1B and 2B.

Shorten the leads of two .1-mfd capacitors to 1 inch. Solder one capacitor between terminal 7 and square 1C. Solder the other .1-mfd capacitor between terminal 3 and square 2C. Shorten the leads of the third .1-mfd capacitor to 1/2-inch and solder it between squares 1C and 2C.

Shorten the leads of two .005-mfd capacitors to 3/4". Solder one capacitor between terminal 6 of the switch and square 4C. Solder the other capacitor between terminal 2 and square 5C. Shorten the leads of the remaining .005-mfd capacitor to 1/2-inch and solder it between squares 4C and 5C.

Take a break and check over your work. You should have six 10k-ohm resistors, three .001-mfd capacitors, three .005-mfd capacitors and three .1-mfd capacitors installed on your circuit board. All leads should be soldered. You will next wire the transistor amplifier section.

Refer to Fig. 7C as you perform the

following steps. Shorten the leads of a 22k-ohm resistor and a 150k-ohm resistor to 3/8-inch and bend the leads of each resistor downward at right angles. Solder the 22k-ohm resistor between square 1H and the ground foil at the end of the board. Similarly, solder the 150k-ohm resistor between square 2H and the ground foil.

Shorten the leads of a 100-ohm resistor to 1/2-inch and solder the resistor from square 3H to terminal 3 of the 1k-ohm potentiometer. Shorten the leads of a 10k-ohm resistor to 3/4-inch and solder the resistor between squares 2H and 5F.

Shorten the leads of a 4.7k-ohm resistor to 1/2-inch. Solder the resistor between squares 3F and 5F.

Shorten the leads of a 10-mfd electrolytic capacitor to 3/4-inch. Solder the positive lead to terminal 2 (the center terminal) of the 1k-ohm potentiometer. Solder the negative lead of the capacitor to square 3H.

Solder a short length of wire between terminal 1 of the 1k-ohm potentiometer and square 5F.

Solder a short length of hookup wire between squares 1H and 2F. Solder a short length of bare wire from square 1F to the ground foil at the edge of the board.

Shorten the leads of a 100-mfd electrolytic capacitor to 1/2-inch. Solder the positive lead to square 3F and solder the negative lead to square 1E.

Connect and solder a length of hookup wire from terminal 4 of the switch to square 3F. Connect and solder another length of hookup wire from terminal 8 of the switch to square 2H.

Identify the leads on the two PNP transistors (2N5138), by referring to Fig. 2A. Spread the leads of one transistor and mount it on the board. Solder the collector, base and emitter leads to squares 1H, 2H and 3H, respectively. Be careful to keep the other leads from coming loose.

In a similar manner, solder the collector, base and emitter leads of the other PNP transistor to squares 1F, 2F and 3F, respectively.

Inspect the board for short circuits and wiring errors. You can check it against Figs. 6 and 7. Also, test each solder connection by pulling each wire gently.

Finally, solder a length of hookup wire between terminal 1 of the 1k-ohm potentiometer and terminal B3 on the chassis.

Install a pointer knob on the switch shaft. Loosen the setscrew in the knob with a small screwdriver, slip the knob on the shaft and tighten the screw against the flat on the shaft.

When you complete the work, test the oscillator. Rotate the 1k-ohm stability control potentiometer fully counterclockwise and energize your circuit. Connect your tvom to measure the ac voltage between the chassis and square 1E. Adjust the 1k-ohm stability control for a reading. You should read 1.5V ac or more. Try all three switch positions and readjust the stability control slightly, as necessary. The ac output voltage at 1E should be approximately the same on all three frequencies.

If your oscillator does not work, check your wiring carefully and trace out each connection. Measure the dc bias voltage on both transistors. You should measure about –.6V between the emitter and base of each transistor. If the voltages are incorrect, look for an open in the ground or collector circuit or for trouble in the positive supply voltage. If you have trouble which you cannot locate, write for help before you attempt to perform the experiments.

WIRING THE AUDIO AMPLIFIER

You will now wire the audio amplifier circuit shown on the schematic in Fig. 8.

You will need the following:

- 1 47-ohm resistor
- 1 100-ohm resistor
- 1 10K-ohm resistor
- 1 6-mfd electrolytic capacitor
- 1 100-mfd electrolytic capacitor
- 1 NPN transistor (TS21), 2N5134

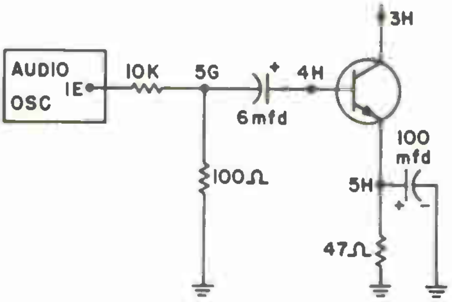

Fig. 8. The voltage divider and amplifier wiring.

The amplifier and voltage divider circuit will be assembled mainly on the center circuit board, which we will call the "experimental circuit board".

To wire the voltage divider, solder a 10k-ohm resistor between square 1E of the oscillator circuit board and square 5G of the experimental circuit board. Solder a 100-ohm resistor between square 5G of the experimental board and the ground foil at the outer edge of the board.

Solder a 6-mfd electrolytic capacitor between squares 4H and 5G of the experimental board, with the positive lead to 4H.

Solder a 47-ohm resistor and a 100-mfd capacitor in parallel between square 5H and the ground foil of the experimental board. The positive lead of the capacitor goes to square 5H.

Solder an NPN transistor to the experimental board. Be sure you can identify the leads and solder the emitter, base and collector leads to squares 5H, 4H and 3H, respectively.

As shown in Fig. 8, your amplifier is not complete. You will add parts in performing the following experiment.

EXPERIMENT 51

Purpose: To show how a loudspeaker converts electrical signals into sound and to show how a loudspeaker can be coupled to an audio amplifier.

Introductory Discussion: In this experiment, you will learn something about how the loudspeaker is constructed and how it works. You will then connect the loudspeaker to an audio amplifier and use it to reproduce a signal. You will also experiment with various methods of driving the loudspeaker. For Steps 2, 3, and 4 you will use your audio frequency oscillator as a signal source and you will use a single stage amplifier to drive the speaker. The amplifier consists of an NPN transistor. Initially, it will be operated in the common emitter mode, with the signal applied to the base and taken from the collector.

Experimental Procedure: For this experiment, you will need the experimental chassis with the oscillator and amplifier circuits wired, your tvom and the following:

- 1 Loudspeaker
- 1 1k-ohm resistor
- 1 3.3k-ohm resistor
- 1 4.7k-ohm resistor
- 1 10k-ohm resistor
- 1 150k-ohm resistor
- 1 6-mfd electrolytic capacitor
- 1 Test clip

Step 1: To demonstrate how the permanent magnet loudspeaker works.

Place the loudspeaker on your work surface so that you can reach its terminals. Set your tvom to measure resistance on the R X 1 range, and measure the resistance between the terminals of the loudspeaker. You should read quite a low resistance, probably less than 3 ohms.

Note that as you make the connection to the terminals, you hear a cracking noise in the loudspeaker. This is due to a sudden change in current passing through the coil and it causes the cone of the speaker to move. Touch the speaker cone with your fingers while you make and break the ohmmeter connection to the speaker terminals. You should feel the cone move slightly as the connection is opened. Move the polarity switch on the tvom to reverse and repeat the test. This time the cone of the speaker should move in the opposite direction.

Prepare two lengths of hookup wire about 12 inches long. Connect them between the speaker terminals and terminals 1 and 2 of strip F, the two-lug terminal strip near the audio output transformer.

Slip the test clip on the tvom probe. Switch the tvom to read ac voltage on the 1.2V range and clip the ground lead and probe to the blue and red leads of the audio output transformer. This will leave both hands free. Move the cone of the loudspeaker in and out rapidly with your fingers while observing the meter. You should see an indication on the meter.

Place the speaker near the speaker of a radio or whistle into it and observe that the tvom indicates an ac voltage.

Discussion: As you can see, the loudspeaker is made of a paper cone, a voice coil and a permanent magnet which are held together by a metal frame. The voice coil is physically attached to, and drives the cone. The permanent magnet is placed behind the voice coil. A pole piece conducts the magnetic field to the voice coil.

The voice coil is energized by a signal applied to the loudspeaker terminals. Current passes through the voice coil and sets up a magnetic field. This field interacts with the field of the permanent magnet. When current passes in one direction, the voice coil and the permanent magnet attract each other. Thus, the voice coil and the cone move in one direction. When the current is reversed, the two fields repel each other and the cone moves in the opposite direction. The frequency and strength of the signal current control the rate and the distance that the cone moves.

The voice coil in your speaker has a nominal impedance of 3 to 4 ohms. This was confirmed by your dc resistance measurement. When you connected your ohmmeter across the voice coil a current of about 100 ma flowed and caused the voice coil to move, producing the sound in the speaker. The current, produced by the 1.5-volt cell in the ohmmeter, was limited by the 10-ohm resistor in the ohmmeter circuit and the impedance of the speaker. The click in the loudspeaker was due to the sudden change in current.

You were able to reverse the direction of current through the voice coil simply by moving the polarity switch on the tvom. As you know, the polarity switch reverses the connections to the probe and ground lead.

In the latter part of this step, you found that the speaker can act as an ac generator. By moving the cone, you caused the voice coil to move within the field of the permanent magnet. The winding of the voice coil cut the magnetic lines of force and a voltage was generated in the coil. With suitable coupling, a loudspeaker can be used as a microphone to convert sound waves into an electrical signal.

Step 2: To show the loudspeaker transformer-coupled to the output of an audio amplifier.

You will use the circuit shown in the schematic in Fig. 51-1. Solder the red lead of the audio output transformer to lug 5 of EC24 and solder the blue lead to square 3H on your circuit board. Solder a 150k-ohm resistor between square 4H and lug 5 of EC24. Solder a 10k-ohm resistor between square 4H and the outer ground foil on the circuit board.

Set the frequency selector switch on your oscillator to position 2, turn the power on and listen for a tone in the loudspeaker. The tone, which is produced by a phase-shift oscillator, has a frequency of about 1000 Hz. This is one of the standard audio test frequencies.

Set your tvom to measure ac voltage on the 12-volt range and measure the voltage across the primary winding of the audio output transformer. Clip the ground lead to the chassis and touch the probe to the blue transformer lead. Read the ac voltage and record the value in the space provided on the first line on the chart in Fig. 51-2.

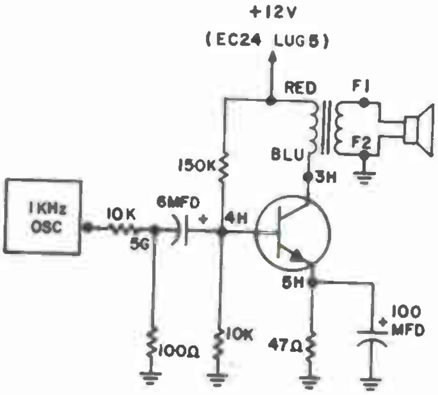

Fig. 51-1. The circuit used for Step 2.

STEP NO.	MEASUREMENT	VALUE
2	Voltage across primary	2V

	Voltage across speaker	—
3	Voltage across speaker	—
	Voltage at collector	—

Fig. 51-2. Use this chart for recording data in Steps 2, 3 and 4.

Next find the signal current through the collector and the transformer primary circuit. You can assume that the impedance of the transformer winding is 5000 ohms. Thus, you can use the Ohm's Law formula, I = E/Z, where Z is the primary impedance value of 5000 ohms. Compute the current and record it in the space provided in Fig. 51-2.

Now measure and record the voltage across the speaker terminals. The voltage may be too low to measure. If so, place a dash (–) in the space provided in the chart. Turn the circuit off.

Step 3: To show the speaker shunt-connected to the amplifier. Next, you will use the circuit shown in the schematic in Fig. 51-3.

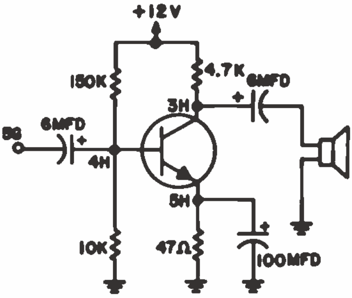

Fig. 51-3. The loudspeaker connected in shunt with the amplifier.

Unsolder and disconnect the blue and red audio output transformer leads. Connect a 4.7k-ohm resistor between square 3H and lug 5 of EC24. Solder the positive lead of a 6-mfd electrolytic capacitor to square 3H. Unsolder the speaker lead from terminal F1 and solder it to the free lead of the 6-mfd capacitor. Check your wiring carefully against the schematic.

Turn the circuit on and note the level of the sound from the speaker. Measure the ac voltage across the speaker terminals. The voltage should be less than .1V. Record the value in Fig. 51-2. Move the probe to the collector side of the 6-mfd coupling capacitor at square 3H and note that the voltage is low there also. Unsolder the speaker lead from the capacitor and note the large increase in the ac voltage at the collector of the transistor. Record the value in the chart. The increase in voltage indicates that the speaker was severely loading the transistor amplifier.

Step 4: To show that power amplification is necessary to drive the speaker.

Construct the power amplifier circuit shown in Fig. 51-4. Connect a length of hookup wire from the collector terminal (the solder lug) of the power transistor mounted at hole C to a ground terminal. Connect a 3.3k-ohm resistor between the base and emitter terminals of the transistor. The emitter terminal is nearest to circuit board EC24. Solder the free speaker lead to the emitter terminal. Replace the 4.7k-ohm resistor with a 1k-ohm resistor. Disconnect the capacitor lead from square 3H. Solder the positive lead of the 6-mfd capacitor to the base terminal of the power transistor and solder the negative lead of the capacitor to square 3H. Unsolder the other speaker lead from terminal F2 and connect it to terminal B2.

Check your wiring very carefully against the schematic diagram and be sure all connections are soldered.

Energize the circuit and note that the volume has increased significantly. Now measure the ac voltage between ground and the collector of transistor Q_1 at square 3H. Record the value in Fig. 51-5. Similarly, measure and record the ac voltages between ground and the base of Q_2 and across the speaker terminals.

Turn the equipment off.

Discussion: Typically, a loudspeaker is

a low impedance current-operated device. Therefore, a stepdown transformer is frequently used with a speaker operated from a high impedance source, as was the case in Step 2. The amplifier output impedance was several thousand ohms and the speaker impedance was about 4 ohms. The transformer has a step-down ratio (turns-ratio) of approximately 40 to 1. The impedance ratio of a transformer is the square of the turns-ratio, or about 1,600 to 1 for the transformer you are using. Thus the transformer can match the low impedance speaker to the high impedance amplifier circuit.

You should be able to see the transformer action from the data for Step 2 in Fig. 51-2. The ac voltage across the speaker was much less than the voltage across the primary of the transformer. You should have found that the signal current in the primary was quite low, on the order of .5 to .6 ma. Because the transformer steps up the current in the same proportion as it steps down the voltage, the speaker current was about 40 X .6 ma or about 24 ma.

The speaker loaded the amplifier badly in Step 3. The coupling capacitor acted as a short circuit at the signal frequency and the speaker impedance is quite low. Thus, the transistor had approximately 4 ohms shunted across it. The amplification of the transistor was held to a minimum and little output was obtained. As you saw, when the speaker was disconnected, the ac voltage at the collector increased sharply.

In Step 4, you used the power transistor as a power amplifier stage. The transistor was connected as an emitter follower, with the speaker as the emitter load. You should have noticed the increase in sound volume and the increase in the values of ac voltages at each of the three test points listed in Fig. 51-5.

The power amplifier presented a relatively light load to transistor Q_1, while acting as a low impedance source for the speaker. You will note that the signal voltage at the emitter of the power transistor was lower than the signal voltage at the base. Thus, the stage provided an increase in the signal current, with no signal voltage gain. There are cases, however, where a power amplifier provides voltage amplification as well.

Instructions for Statement 51: For this Statement, you will connect the speaker into the collector circuit of transistor Q_2 through the audio output transformer. You will then take measurements and determine whether or not the output stage is amplifying the signal voltage.

Use the circuit shown in Fig. 51-6.

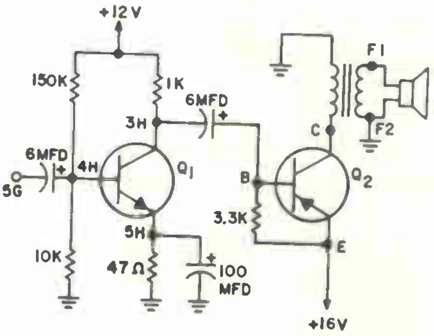

Fig. 51-6. The circuit for Statement 51.

Disconnect the speaker leads from the emitter terminal of the power transistor and terminal B2. Solder a length of hookup wire between these two points. Solder one speaker lead to terminal 1, and solder the other speaker lead to terminal 2 of strip F. Unsolder and disconnect the length of hookup wire between the collector terminal and the power transistor and ground. Solder the blue lead of the audio output transformer to the collector terminal and solder the red lead of the transformer to a ground terminal. Check your work against the schematic.

Energize the circuit and listen to the sound to be sure the circuit is working. Measure the ac voltage across the primary winding of the audio output transformer. Jot down the readings in the margin and answer the Statement.

EXPERIMENT 52

Purpose: To demonstrate how tone controls work.

Introductory Discussion: Tone controls are provided on an audio amplifier to enable the listener to adjust for the most pleasing sound. This is done by varying the relative amplification which the low, middle and high frequencies receive. As an example, for heavy or strong bass, the low frequencies are amplified more than the middle and high frequencies; for more brilliant sound, the highs are amplified more than the middle and low frequencies.

You will use three audio frequencies to demonstrate how tone controls work. You will apply each frequency to the input of your amplifier separately and observe their relative output levels. Then, you will see how the controls affect the amplifier frequency response.

Experimental Procedure: For this experiment, you will need your chassis, your tvom and the following parts:

1 .01-mfd disc capacitor
1 .1-mfd tubular capacitor
1 .25-mfd tubular capacitor
1 50k-ohm potentiometer (PO100)
1 Pointer knob

Mount a 50k-ohm potentiometer in the potentiometer mounting bracket at hole AE. Place a control lockwasher over the bushing. Position the potentiometer in the bracket so the terminals are upward, attach a control nut and tighten. Install a pointer knob on the shaft of the potentiometer.

You will use the phase-shift oscillator, which is wired on one of your circuit boards, and the two-stage amplifier from the last experiment. The circuit is shown in Fig. 52-1. If you find that the sound is too loud or too weak, you may substitute a 22k or 4.7k-ohm resistor for the 10k-ohm resistor connected to square 5G.

Step 1: To determine the frequency response of the amplifier.

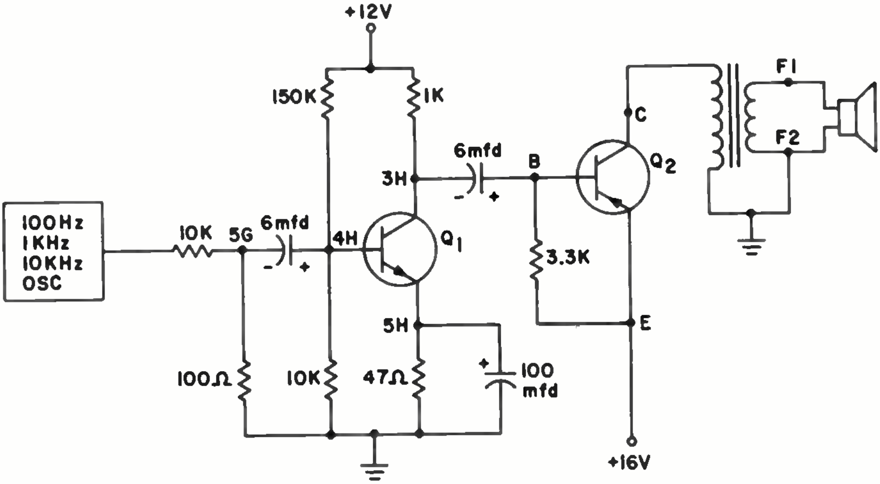

Fig. 52-1. The circuit used in Step 1.

Energize your circuit and set the frequency selector switch on the oscillator circuit board fully counterclockwise to position 1. In this position, your oscillator produces a 100 Hz tone, which should sound like a low rumble in the loudspeaker. Measure the ac voltage between the chassis and square 1E of the oscillator board. This is the oscillator output signal voltage which is applied to the amplifier through the 100:1 voltage divider. Therefore, divide your reading by 100 and record the result as the input signal in Fig. 52-2. Similarly, measure and record the signal voltage at the collector of transistor Q_1 (square 3H), the collector of transistor Q_2 and across the speaker.

Switch the frequency selector to position 2 for a 1 kHz signal. Repeat the four voltage measurements and record your readings in Fig. 52-2.

Switch the oscillator switch to the 10 kHz position (position 3) and take the measurements at this frequency to complete the chart for Step 1, in Fig. 52-2.

Step 2: To show the effect of reducing the value of the capacitor coupling the signal between stages.

Turn off the equipment and disconnect the electrolytic capacitor connected between square 3H and the base terminal

of the power transistor and replace it with a .1-mfd tubular capacitor. Connect the tvom across the speaker terminals (terminals F1 and F2) and turn the circuit on.

Turn the frequency selector switch to positions 1, 2 and 3 and measure the output voltages for 100, 1,000 and 10,000 Hz. You should find that the output increases as you switch to higher frequencies. Record your readings in the chart in Fig. 52-3.

Replace the .1-mfd capacitor with a .01-mfd disc capacitor. Repeat the test, measuring the output at each frequency. Record your results in Fig. 52-3 and turn off the equipment.

Step 3: To show the effect of connecting an R-C feedback network between the input and output of the first amplifier stage.

Make the circuit changes shown in Fig. 52-4. Remove the .01-mfd capacitor used in Step 2 and replace it with the 6-mfd electrolytic capacitor you used originally. Now, connect one lead of a .25-mfd tubular capacitor to terminal 2 (the center terminal) of the 50k-ohm potentiometer. Connect the free lead of the capacitor to the collector of transistor Q_1 at square 3H. Prepare about an 8-inch length of hookup wire and connect it to terminal 3 (the right terminal) of the 50k-ohm potentiometer. Solder the other lead to the Q_1 base terminal, square 4H.

Turn the circuit on and measure the output voltage across the speaker terminals at 100 Hz. Rotate the potentiometer

throughout its range and notice how the sound level varies. Record both the voltage levels with the potentiometer fully counterclockwise and fully clockwise in the chart in Fig. 52-5. Similarly, measure and record the output for frequencies of 1000 Hz and 10 kHz with the potentiometer fully counterclockwise and fully clockwise.

Step 4: **To show how low-frequency response can be varied by shunting a small coupling capacitor with an R-C network.**

Change your wiring to the circuit shown in Fig. 52-6. Unsolder and remove the .25-mfd capacitor. Remove the 6-mfd coupling capacitor lead from the base terminal of the power transistor and solder it to terminal 2 of the 50k-ohm potentiometer. Solder a .01-mfd capacitor between square 3H and the power transistor base terminal. Connect the series-connected 6-mfd capacitor and 50k-ohm potentiometer across the .01-mfd coupling capacitor. Unsolder the potentiometer lead from square 4H and solder it to the power transistor base terminal.

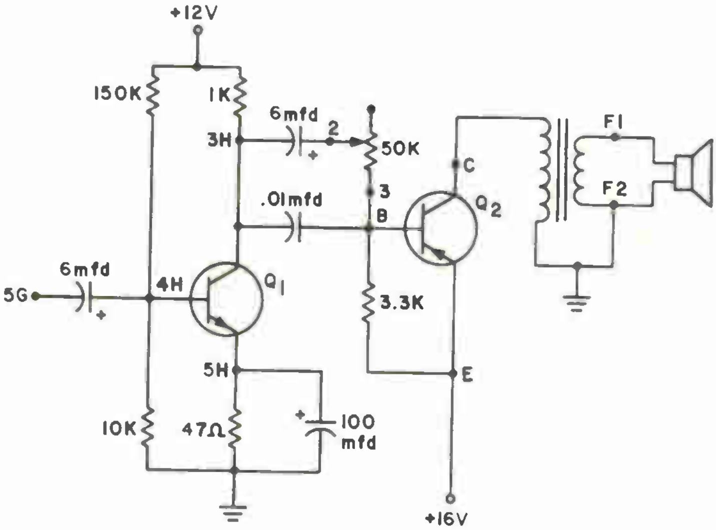

Fig. 52-6. The circuit for Step 4.

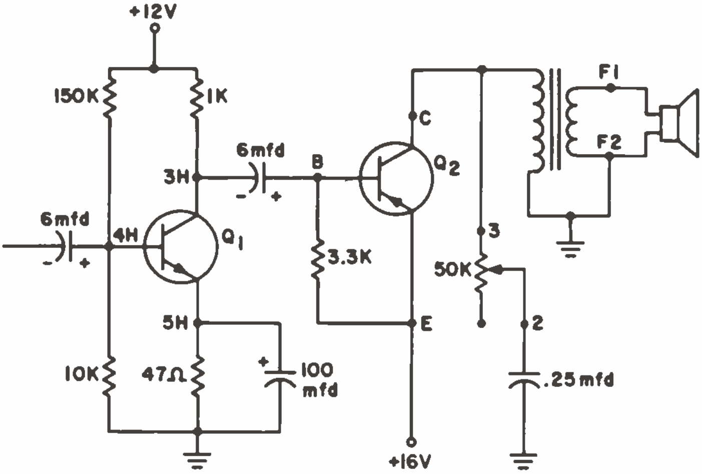

Fig. 52-7. The circuit used for Step 5.

Energize the circuit and vary the potentiometer while listening to each of the three tones. Note that the low tone is affected more than the high when you rotate the potentiometer. Measure the output level for each frequency with the potentiometer fully counterclockwise and fully clockwise, and record the values in the chart in Fig. 52-5.

Step 5: To show the effect of shunting the primary winding of the output transformer with an R-C network.

Change the circuit as shown in Fig. 52-7. Remove the .01-mfd capacitor and reconnect the 6-mfd capacitor between the base of the power transistor and square 3H. Be sure to connect the positive capacitor lead to the power transistor base. Connect the .25-mfd capacitor between terminal 2 of the potentiometer and the ground foil. Unsolder the potentiometer lead from the base terminal of the power transistor and solder it to the collector terminal of the power transistor.

Turn the circuit on and note how the 50k-ohm potentiometer affects the output sound at each of the three frequencies. Record the voltage levels for each frequency in Fig. 52-5 with the potentiometer at each extreme. Turn the equipment off.

Discussion: In this experiment, you measured the signal levels in an audio amplifier and demonstrated several methods of changing the amplifier frequency response. In Step 1, you measured the signal levels at various points in the amplifier to determine the normal amplifier response. You should have found that the three frequencies were amplified nearly equally by each of the amplifier stages. Thus, we can say that the amplifier frequency response is nearly "flat" over the range of 100 to 10,000 Hz.

Capacitance was used in each of the following steps to alter the frequency response of the amplifier. The reactance of a capacitor is inversely proportional to frequency. This can be seen from the formula for capacitive reactance:

$$X_C = \frac{1}{2\pi FC}$$

In Step 2, lower values of coupling capacitor were connected between the two stages. The smaller capacitor passed the high frequencies with less attenuation than the low frequencies. Thus, in the output, the high frequencies were emphasized. In any R-C coupling network, the coupling capacitor and the input resistance of the following stage form a signal voltage divider.

Normally the capacitance value is chosen so that it has negligible reactance at the signal frequency. Therefore, little or no signal voltage is dropped across the coupling capacitor. However, if the capacitance is small and has appreciable reactance at the signal frequency, reduced signal will be available at the input of the following stage. In this step, the capacitors were small enough so that the middle and low frequencies were highly attenuated. However, the 10 kHz signal was passed readily.

Inverse feedback was used in Step 3. The capacitor was used to couple the signal from the collector of Q_1 back to the base. This is degenerative feedback, which is 180° out-of-phase with the input, and it was used to reduce the effective input signal level. The capacitive reactance to the high frequencies was low. Thus, it coupled back more of the high frequency signal voltage. As a result, the overall gain of the stage was highest at the lowest frequency.

The 50k-ohm potentiometer varied the effect of the capacitive feedback. Increasing the resistance decreased the amount of signal coupled through the network at each frequency. Thus it reduced the difference in gain for the various frequencies.

For Step 4, you used an R-C network in parallel with a small coupling capacitor. The small coupling capacitor attenuates middle and low frequencies severely, as you saw in Step 2. The 6-mfd capacitor passed the low frequencies more readily. Therefore, as the resistance of the potentiometer was decreased, the low and middle frequencies were attenuated less and, consequently, received more overall amplification.

An R-C network was connected in

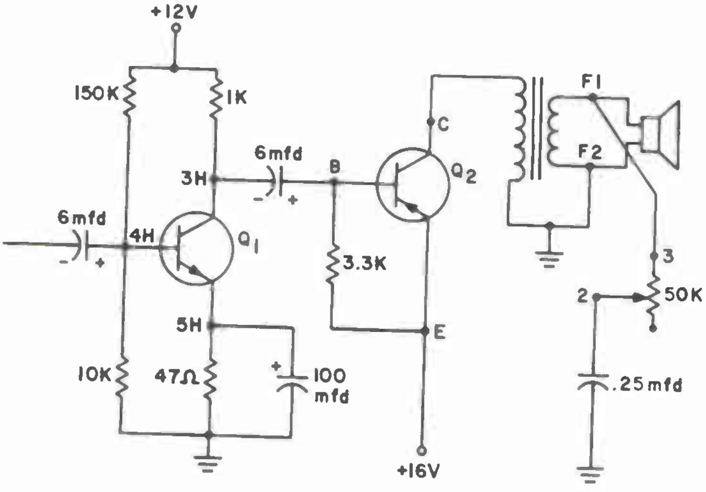

Fig. 52-8. The circuit for Statement 52.

parallel with the output of transistor Q_2 in Step 5. The capacitor filtered out the high frequencies, just as any filter capacitor would do. It has a high reactance to low frequencies. Therefore, the low frequencies were affected very little by the filtering action. The 50k-ohm potentiometer varied the amount of filtering which the capacitor could produce. Thus it varied the attenuation of the high and middle frequencies. As a result, the low frequencies would seem to be emphasized.

In Steps 2 through 5, you saw several methods of altering the amplifier frequency response. All of the methods employ R-C filtering and they either emphasize or attenuate a band of frequencies. As a general rule, 1,000 Hz is taken as the center frequency. Then the lows are frequencies less than 1,000 Hz and the highs are frequencies greater than 1,000 Hz. The effect of tone controls is gradual: The higher or lower the frequency, the more it is affected by the control.

Instructions for Statement 52: For this Report Statement, you will connect the series-connected potentiometer and the .25-mfd capacitor across the speaker terminals and determine the effect. Unsolder the lead of the 50k-ohm potentiometer from the collector terminal of power transistor and solder it to terminal F1. You now have the circuit shown in Fig. 52-8.

Energize the circuit and observe the amplifier output level at each frequency with the potentiometer set at each extreme. Answer the Statement here and on the Report Sheet and turn your equipment off.

Statement No. 52: When I varied the resistance in series with the capacitor across the speaker, I found that:

(1) the low frequencies were most affected.

(2) the middle frequencies were most affected.

[✓ (3)] there was no noticeable effect.

EXPERIMENT 53

Purpose: To show some of the techniques used to control audio volume and to compare their advantages and disadvantages.

Introductory Discussion: The volume control in a radio or television receiver enables the user to vary the audio output level without changing the tone or distorting the output signal. Many different systems are used. The volume control device itself is almost always a potentiometer and it can be connected to vary either the gain of an amplifier stage or the attenuation of the signal. In rare cases the gain of two or more stages is adjusted by the volume control.

In this experiment, you will demonstrate several volume control methods. You will use your audio frequency oscillator set to 1 kHz as a signal source and, by observing the ac output voltage on your tvom and listening to the sound, you will be able to see how the volume control methods affect the sound output.

Experimental Procedure: You will need the experimental chassis with the audio oscillator and amplifier circuits and the 50k-ohm potentiometer, your tvom and the following:

1 3.3k-ohm resistor

You will begin the experiment with the

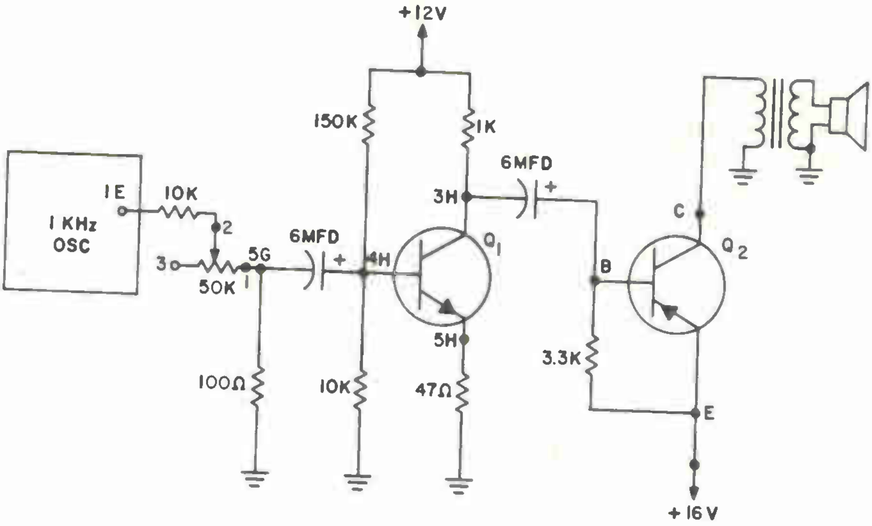

Fig. 53-1. The circuit for Step 1.

circuit shown in the schematic diagram in Fig. 53-1. To prepare for the experiment, unsolder and remove the 100-mfd capacitor from the Q_1 emitter circuit.

Unsolder the .25-mfd capacitor connected to the 50k-ohm potentiometer, and lay it aside; also, disconnect the hookup wire attached to the potentiometer.

Unsolder the 10k-ohm resistor lead from square 5G of the experimental circuit board and connect it to terminal 2 (the center terminal) of the 50k-ohm potentiometer. (You will have to solder a short length of hookup wire to the resistor lead.) Solder a length of hookup wire between terminal 1 (the left terminal) of the 50k-ohm potentiometer and square 5G. Check your wiring against the schematic and be sure all connections are soldered.

Step 1: To show that increasing or decreasing a resistance in series with a signal source will vary the signal amplitude.

Connect your tvom between ground and the collector terminal of the power transistor. Set the meter to read 12 volts ac and turn the circuit on. Set the oscillator for 1 kHz (position 2). Adjust the volume control (the 50k-ohm potentiometer) until maximum signal is indicated on the tvom.

Turn the volume control throughout its range while listening to the sound from the speaker. Also, observe the meter. The volume and the meter indication should vary. Note that the potentiometer cannot completely cut off the sound. Turn off the power.

Step 2: To show that the volume can be controlled by varying the amplifier load impedance.

You will place the potentiometer across the primary winding of the audio output transformer in the collector circuit of the power transistor. Disconnect the potentiometer lead from square 5G. Unsolder the 10k-ohm resistor lead from the center

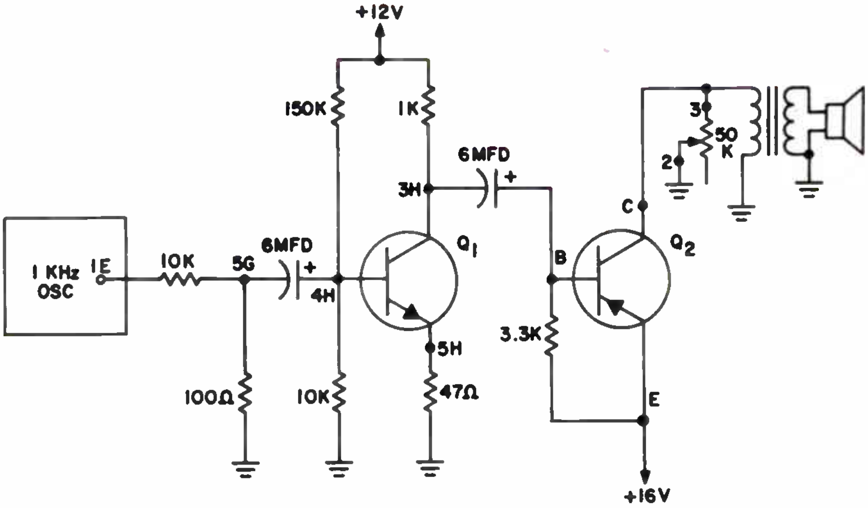

Fig. 53-2. The circuit for Step 2.

terminal of the potentiometer and solder it to square 5G. Now connect terminal 2 of the potentiometer to ground.

Connect a length of hookup wire from terminal 3 of the potentiometer to the collector of the power transistor. You should now have the potentiometer connected as shown in the schematic in Fig. 53-2.

Turn on the power and rotate the volume control. Observe the meter indication while listening to the sound. The output should vary smoothly from one extreme of the volume control setting to the other.

Step 3: To show that volume can be controlled by varying the bias on an amplifier stage.

Disconnect the potentiometer lead

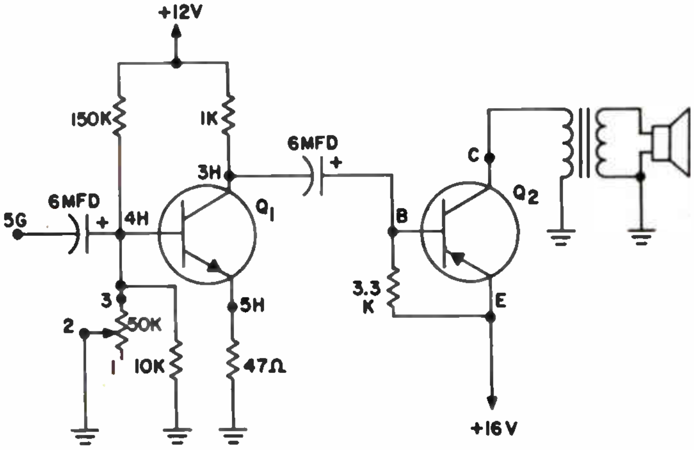

Fig. 53-3. The circuit for Step 3.

from the collector of transistor Q_2 and connect it to square 4H. You now have the circuit shown in Fig. 53-3.

Turn on the power and vary the potentiometer throughout its range while listening to the sound and observing the meter indication. Note that as the resistance is decreased, the volume decreases.

Step 4: To demonstrate a volume control method using a potentiometer as a signal voltage divider.

The circuit for this step is shown in Fig. 53-4. Note that the potentiometer is connected in shunt with the 100-ohm resistor. Wire the circuit as shown. Unsolder the lead of the 6-mfd capacitor from square 5G. Disconnect both potentiometer leads from the circuit. Connect a length of hookup wire from terminal 1 of the potentiometer to square 5G. Solder the lead from terminal 2 of the potentiometer to the free lead of the 6-mfd capacitor. Solder the lead from terminal 3 of the potentiometer to ground. Check over your work.

Turn the equipment on and vary the setting of the volume control while observing the output voltage reading on your tvom and listening for the sound. You should have full output at one extreme and no volume at the other extreme of the volume control rotation. Further, the variation in output level should be smooth. Turn the equipment off.

Discussion: In volume controls, three factors are important: The control should operate smoothly, it should not introduce distortion and the control should dissipate little if any power. The first two factors are fairly obvious. It is annoying to have the volume change suddenly from low to high as the volume control knob is rotated. You expect and prefer that the level be continuously variable from one extreme to the other.

From the preceding experiment, you know that the volume can be varied by varying the level of the high or low tones in the audio frequency output. This is a form of distortion, however. Varying the highs or the lows only would make the reproduction of the speech or music less pleasing.

Most potentiometers used in volume

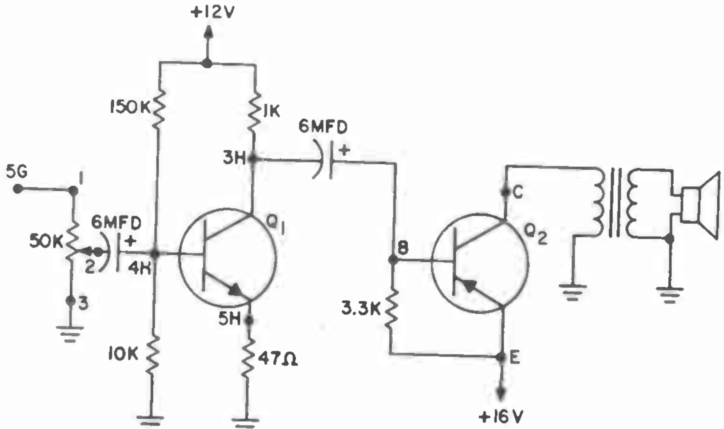

Fig. 53-4. The circuit for Step 4.

control circuits have low wattage ratings. Like fixed resistors, they become overheated and damaged by excessive current. Carbon potentiometers, such as those you have on your experimental chassis, consist of a circular resistive element connected to the end terminals and a sliding contact connected to the center terminal. As the shaft is rotated, the contact slides along the surface of the resistive element. Excessive current will frequently cause the surface of the resistive element to burn where it contacts the slider. This produces intermittent connections and popping or cracking noises in the audio.

Now let us look at the results of the experiment. In Step 1, you connected the potentiometer as a variable resistor between the source and the amplifier circuit. The potentiometer varied the attenuation of the signal applied to the amplifier input stage.

You know from previous experiments that the 10k-ohm resistor and the 100-ohm resistor form a signal voltage divider. By placing the 50k-ohm potentiometer in series with the 10k-ohm resistor, you were able to vary the voltage divider ratio. Consequently the potentiometer made it possible to reduce by approximately 80% the signal voltage applied to the amplifier circuit.

In Step 2, you connected the potentiometer across the primary winding of the audio output transformer. The primary winding and the associated impedances reflected from the secondary and the loudspeaker form the load for this stage.

Changing the resistance parallel with the primary winding altered the impedance and the path of the collector current. With the volume control set for maximum volume, the resistance was high when compared to the impedance of the primary winding. Therefore, most of the current flows through the primary winding and the loudspeaker and produced normal volume.

The volume control was connected so that rotating the shaft counterclockwise reduced the total resistance in shunt with the primary. This reduced the amplifier load resistance, and also reduced the amount of signal coupled into the speaker. At any setting except maximum volume, a heavy current flows through the volume control. Under some circumstances, the current would be great enough to require a higher wattage (and more expensive) potentiometer. Over a long period of time, the current can cause potentiometers of the type you are using to become noisy.

The volume control in this step is able to cut off the sound, or at least reduce it to inaudibility. This is because the minimum resistance of the potentiometer is quite low when compared to the impedance of the primary winding.

In Step 3, you used a volume control arrangement which varied the bias on the first amplifier stage. The potentiometer was connected between the base of the transistor and ground. Note that forward bias on the stage is developed by the voltage drop across the 150k-ohm resistor connected between the positive supply voltage and the base. The potentiometer was connected so that it affected the forward bias.

As the resistance of the potentiometer was reduced, the forward bias on the base of the transistor was lowered. Eventually, a point was reached where the transistor was cut off. Within limits, the gain of the transistor is proportional to the collector current. Thus, with this arrangement you were able to vary the output signal and amplitude.

The primary drawback of this volume

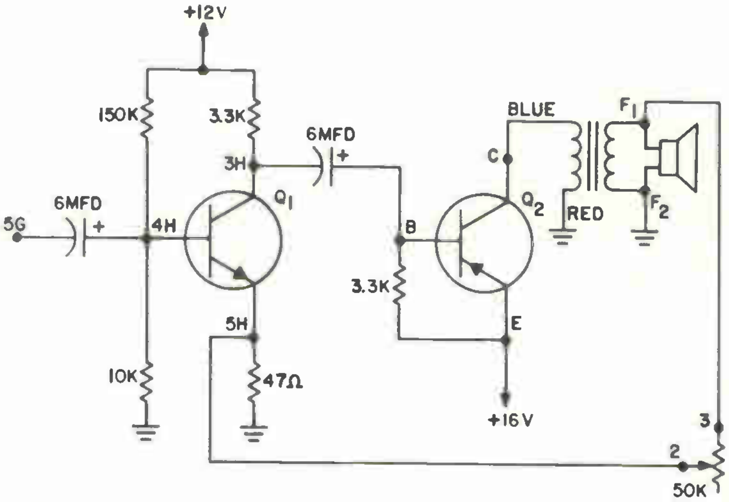

Fig. 53-5. The circuit for Statement 53.

control is the fact that it is prone to produce amplitude distortion. When the control is set for low levels, the bias is very low and negative excursions of the signal can drive the transistor into cutoff. Similarly, high positive peaks would receive more amplification than lower positive peaks. Thus the gain varies with the signal level.

In Step 4 you demonstrated one of the most common volume control circuits. In your circuit, the junction of the 10k-ohm and 100-ohm resistors was for all practical purposes the source of a low level signal. The volume control, then, was across the low level signal source.

For maximum volume, the resistance between the source (square 5G) and the slider on the volume control is at minimum. The full 50,000-ohms is between the slider and ground. As the volume is decreased, the resistance between square 5G and the slider increases while the resistance between the slider and ground decreases. As you already know, the resistance of the transistor input circuit is quite low. Therefore, the signal voltage will be dropped across the portion of the potentiometer between the slider and square 5G.

Further rotation of the potentiometer increases the resistance between the source and the slider and the voltage actually reaching the transistor becomes too low to drive the stage. This, of course, results in no audible output.

Note in Fig. 53-4 that the volume control is connected on the input side of the coupling capacitor. This arrangement prevents the volume control from affecting the bias voltage on the transistor. If the potentiometer were placed so that the slider was connected to the base, the signal reaching the transistor as well as the transistor forward bias would be reduced whenever you turned the volume down. Depending on the level of the input signal, this may produce distortion in the audio, as mentioned earlier.

Instructions for Statement 53: For this Statement, you will connect the potentiometer between the Q_1 emitter circuit and the secondary winding of the audio output transformer and determine the effect of varying the resistance. Change your circuit according to the schematic diagram shown in Fig. 53-5.

Unsolder and remove the length of wire connected between square 5G and terminal 1 of the potentiometer. Unsolder the potentiometer lead connected to ground and solder it to terminal F1. Unsolder the lead of the 6-mfd capacitor from the center potentiometer lead and solder the capacitor lead to square 5G. Solder the free end of the center potentiometer lead to square 5H. Replace the 1k-ohm resistor in the Q_1 collector circuit with a 3.3k-ohm resistor. Check your circuit against the schematic diagram.

Turn your circuit on and vary the setting of the volume control while listening to the sound and observing the output on the tvom. Observe the effect of rotating the volume control in the counterclockwise direction. If your circuit is wired correctly, this will decrease the resistance between the leads of the potentiometer. Make whatever tests are necessary and answer the Statement here and on the Report Sheet.

Statement No. 53: **When I decreased the resistance by rotating the volume control counterclockwise, the overall amplifier gain:**

(1) increased.
[✓ *(2) decreased.*]
(3) remained the same.

EXPERIMENT 54

Purpose: To show how the field effect transistor works and to show that it can be used as an audio frequency amplifier.

Introductory Discussion: The field effect transistor (or FET) is a solid-state device with characteristics very similar to those of a vacuum tube. Some of its characteristics, however, are unique. An understanding of the FET is important to the service technician because FET's are being more widely used in radio and TV receivers. Thus, you will be faced with troubleshooting circuits containing them.

An FET has three terminals called the drain, source, and gate. The schematic symbol shown in Fig. 2B should be familiar to you, as FET's are used in your tvom. A resistive current path or channel exists between the drain and source terminals.

In the FET supplied with this kit, this path consists of a small bar of N-type silicon material. Thus, the device is called an N-channel FET. The gate consists of a piece of P-type material surrounding the N channel. The application of the negative voltage to the gate causes the channel to become less conductive, thus exhibiting a higher resistance.

In this experiment, you will see how the gate voltage affects the current through the channel, you will see how bias voltage is obtained and you will construct and demonstrate a basic amplifier using your FET.

Experimental Procedure: For this experiment, you will need the experimental chassis with the oscillator, power supply and experimental circuit boards, your tvom and the following:

2	1.5V flashlight cells
1	FET (TS20)
1	470-ohm resistor
1	1k-ohm resistor
1	10k-ohm resistor
1	47k-ohm resistor
1	100k-ohm resistor
1	.1-mfd tubular capacitor
1	6-mfd electrolytic capacitor

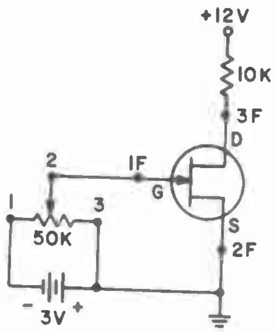

Fig. 54-1. The circuit for Step 1.

You will use the circuit shown in Fig. 54-1. Before wiring the circuit, dismantle the circuit from the previous experiment. Remove the resistors and capacitors connected to squares 3H, 4H and 5H. Leave the signal voltage divider connected to square 5G and ground and leave the transistors in place. Remove the resistor and the emitter lead from the power transistor.

Unsolder and disconnect all 4 leads and remove the audio output transformer.

To wire the battery and potentiometer, prepare two lengths of hookup wire about 8 inches long. Your two flashlight cells should still be connected in series, forming a 3-volt battery. Solder lengths of wire to the positive and negative terminals of the 3-volt battery. Solder the negative battery lead to terminal 1 (the left terminal) of the 50k-ohm bias potentiometer. Solder the positive battery lead to terminal 3 (the right terminal) of the potentiometer. Solder a short length of wire between terminal 3 of the potentiometer and ground (the chassis).

Connect a 10k-ohm resistor between square 3F and lug 5 of circuit board EC24. Connect a short length of hookup wire between ground and square 2F. Connect another length of hookup wire from the center terminal of the 50k-ohm bias potentiometer to square 1F.

Be sure you can identify the leads of the FET. This information is given in Fig. 2B. Then solder the gate, source, and drain leads to squares 1F, 2F and 3F, respectively. Use the same precautions as instructed for handling your other transistors: do not apply excessive heat or physical strain to the leads.

This completes your wiring. Check your work to be sure the circuit is wired according to the schematic diagram.

Step 1: To show that the channel current in an FET can be controlled by applying a negative voltage to the gate.

Turn the circuit on and measure the dc voltage across the 10k-ohm resistor connected between the drain terminal of the FET at square 3F and the positive supply voltage. Vary the 50k-ohm bias control potentiometer and note that the meter reading varies.

Set your tvom to measure negative voltage on the 3-volt range. Move the ground clip to the chassis and measure the voltage between ground and the gate of the FET. Adjust the bias control for 0V. Then switch the tvom to the 12-volt range and move the ground clip to the positive terminal, lug 5 of EC24. Measure the voltage across the 10k-ohm resistor and record it on the first line in Fig. 54-2.

In a similar manner, set the gate voltage to −1V, −2V, and −3V and measure and record the corresponding voltage drops across the 10k-ohm drain resistor.

When you complete these readings, compute the drain current for each entry. The current in ma is equal to 1/10th the voltage across the 10k-ohm resistor in volts. For example, a voltage of 12V corresponds to 1.2 ma.

Step 2: To show that the source and drain are interchangeable.

Turn the circuit off and unsolder and interchange the resistor lead and the ground lead to squares 2F and 3F.

Connect the tvom across the 10k-ohm resistor, turn the circuit on and vary the potentiometer. Note that the voltage drop across the 10k-ohm resistor varies just as it did in Step 1, although the current now flows through the FET from drain to source.

Step 3: To show another method of biasing an FET.

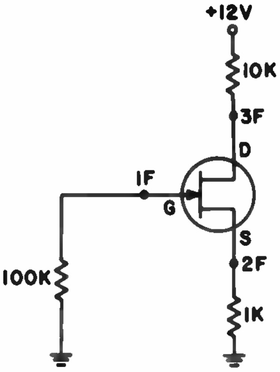

Fig. 54-3. The circuit for Step 3.

You have already used negative fixed bias applied to the gate. Now you will demonstrate self-bias. Turn the circuit off and change it to that shown in the schematic in Fig. 54-3. Disconnect the leads from the battery and the 50k-ohm potentiometer. Unsolder and remove the hookup wire from square 3F. Solder a 100k-ohm resistor between square 1F and the ground foil. Unsolder the 10k-ohm resistor lead from square 2F and solder it to 3F. Solder a 1k-ohm resistor between the ground foil and square 2F. You now have the gate grounded through a 100k-ohm resistor, the 10k-ohm resistor connected in the drain circuit and the 1k-ohm resistor connected between ground and the source.

Turn the circuit on and measure the voltage between ground and the gate terminal at square 1F. You should read zero. Now measure the voltage across the 1k-ohm source resistor. This is the gate bias voltage, as it is equal to the voltage between the gate and source.

0.5

Turn the circuit off and replace the 1k-ohm source resistor with a 47k-ohm resistor. Energize the circuit and determine the bias voltage, as before. Also, measure the voltage across the 10k-ohm resistor and determine the drain current. Jot down the current in the margin.

Step 4: To show that the FET can be used to amplify ac signals.

Wire the circuit shown in Fig. 54-4. Replace the 10k-ohm drain resistor with a 100k-ohm resistor. Connect a .1 mfd-tubular capacitor between squares 5G and 1F. Replace the 100-ohm resistor connected between square 5G and ground with a 470-ohm resistor. Check your wiring.

lator switch to position 2 and measure the ac voltage between ground and square 1E of the oscillator board. This is the oscillator output applied to the voltage divider. The voltage divider has a ratio of about 20 to 1. Thus the signal applied to the FET is about 1/20th of the voltage reading at the oscillator output.

Perform this computation and record the input voltage in the first column of Fig. 54-5. Move the probe of your tvom to square 3F and measure and record the output voltage. Compute the stage gain, using the formula,

$$\text{gain} = \frac{E_{out}}{E_{in}}$$

and record it in Fig. 54-5.

(B) Solder a 6-mfd capacitor between ground and the source terminal at square 2F. Note that the positive capacitor lead goes to square 2F. Turn the circuit on and measure and again record the output voltage at 3F. The input voltage has not changed. Therefore, you can use the same value as in Step 4A. Compute and record the stage gain for this step. Turn the equipment off.

Discussion: The field effect transistor you used is called a junction FET which is sometimes abbreviated JFET. This means that the gate is in physical and electrical contact with the channel. The P-type gate material must never be made positive with respect to the channel or it will act as a forward-biased diode and will pass excessive current and become damaged.

In Step 1, you recorded the gate input voltage and the resulting drain current. From the data you recorded in Fig. 54-2, you can see that the current was highest when the gate voltage was at zero and the current decreased as you made the gate more negative. This is very similar to what happens to the plate current in a vacuum tube as the grid voltage is varied. In an FET, if you continue to make the gate more negative, you reach a point known as "pinch-off", which corresponds to plate current cutoff in a vacuum tube or collector current cutoff in a bipolar transistor.

The voltage drop across the load resistor in the drain circuit varied with drain current. Therefore, the variation in the voltage at the gate produced larger changes in the voltage across the FET itself.

As stated earlier, the channel in an FET is simply a resistive current path. Thus, like a resistor, it will pass current in either direction. You should have found that the FET acted in exactly the same manner in Step 2 when you interchanged the source and drain connections as in Step 1.

In Step 3, you demonstrated the most common method of biasing an FET. The gate is returned to the negative side of the power supply and a resistor is placed between the negative supply and the source terminal of the transistor. Current flow through the source resistor makes the source positive with respect to ground. The gate, therefore, is negative with respect to the source. This method eliminates the need of a separate bias supply and also makes it possible to use FET's with widely varying internal resistances in an amplifier circuit.

You constructed an amplifier stage in Step 4. This circuit is called a common source amplifier. In Step 4A, the gain was about 2 and the output level was too low to measure accurately. The unbypassed source resistance was responsible for the low gain. Input signal variations caused variations in the source as well as drain current. The voltage drop across the source resistor opposed the signal variations and reduced the effective input signal to an extremely low level.

When you bypassed the source resistor, you found that the gain increased significantly. The bias was held stable so that the input signal variations produced proportional changes in channel current and in the voltage drop across the load resistor.

The signal across the drain resistor is 180° out-of-phase with the input signal; a positive going excursion of the signal increases the source-drain current and produces an increase in the voltage drop across the drain resistor. If the source resistor is left unbypassed, the voltage across it will be in-phase with the applied signal voltage.

Any JFET such as the one you used in this experiment can be handled safely if you heed the same precautions that you do for regular bipolar transistors. Take care not to subject the device to excessive heat, voltage or physical strain.

Another type of FET, called the insulated gate FET, (IGFET, or MOSFET) requires much more care in handling. Although it resembles the JFET, this type of FET has a thin layer of insulation between the gate and channel. This insulation can be broken down by ac voltage pickup on the leads. Therefore, the leads must be kept grounded until the FET is installed in a circuit.

Instructions for Statement 54: For this Report Statement, you will convert your FET stage to a source-follower amplifier, in which the signal is applied to the gate and the output is taken at the source.

Wire the circuit shown in Fig. 54-6. Unsolder and remove the 100k-ohm drain resistor, which is connected between square 3F and lug 5 of EC24. Connect a length of hookup wire in its place. Unsolder and remove the electrolytic capacitor in parallel with the 47k-ohm source resistor. Remove the 470-ohm resistor in the signal voltage divider.

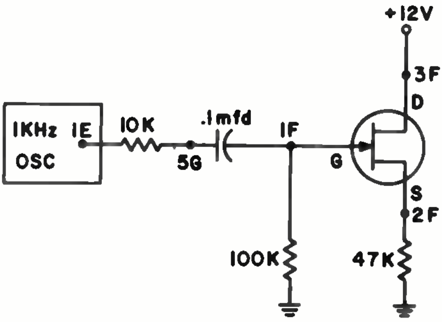

Fig. 54-6. The circuit for Statement 54.

Energize the circuit and measure the input signal voltage at the gate and at the output, which is the source terminal. Turn the equipment off. Compare the two voltage readings and answer the Statement.

EXPERIMENT 55

Purpose: To demonstrate how the stereo indicator on an FM receiver works and to show the effects of common circuit defects in stereo indicator circuits.

Introductory Discussion: Many FM receivers feature an indicator light which glows whenever a stereo transmission is being received. In some receivers, the circuit which operates the light also switches in the stereo detector circuitry. Otherwise, the signal passes through the simpler monophonic circuitry only.

The stereo indicator consists of a sensing circuit in addition to the indicator device. In most sets, the 19 kHz pilot carrier, which is part of the stereo multiplex signal, is monitored. When the pilot carrier is present with sufficient strength, the circuit is actuated. In order to discriminate against other signals, such as audio, a tuned circuit is often placed in the indicator circuit to pass the 19 kHz signal only.

In this experiment, you will use the 10 kHz output of your phase-shift oscillator to represent the 19 kHz pilot carrier. As an indicator, you will use an incandescent pilot lamp. This lamp requires 2V at 60 ma for full brilliance. Therefore, you will operate the lamp from the +16V supply at the input to the L-C filter in the power supply.

Experimental Procedure: For this experiment, you will need the experimental chassis, your tvom, and the following:

1 PNP transistor (TS22)
1 No. 49 pilot lamp
1 Lamp socket
1 1-megohm resistor
1 6.8k-ohm resistor
1 4.7k-ohm resistor
1 220-ohm resistor
1 150-ohm resistor
1 250 pf mica capacitor
1 Signal diode (CR10)

You will begin the experiment with the circuit shown in the schematic diagram in Fig. 55-1. First, disassemble the circuitry on the center circuit board. Leave the

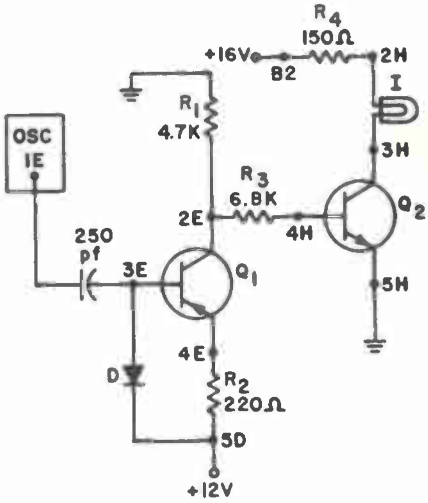

Fig. 55-1. The circuit you use for Step 1.

NPN transistor used in Experiment 53.

Connect square 5H to the outer ground foil, using a short length of wire. Solder a 150-ohm resistor between square 2H and terminal B2. Prepare the lamp socket for mounting as follows: Bend each terminal outward at a 90° angle about 1/8 inch from the end. Also, tin each terminal with solder. Solder the terminals of the lamp socket to squares 2H and 3H. Insert the lamp into the socket.

Solder a 6.8k-ohm resistor between squares 4H and 2E. Solder a 4.7k-ohm resistor between the ground foil and square 2E.

Solder a 220-ohm resistor between squares 5D and 4E. Solder a signal diode between square 3E and square 5D, with the cathode lead to 5D.

Solder a 250 pf capacitor between square 3E of the experimental board and square 1E of the oscillator board. Solder a length of hookup wire from square 5D to lug 5 of circuit board EC24.

Mount the PNP transistor on the experimental circuit board, using Fig. 2A as a guide. Identify the leads and bend them to fit. Solder the collector to square 2E, the base to square 3E, and the emitter to square 4E. Check your work carefully, making sure there are no unsoldered connections, no short-circuits, and that the circuit is wired according to the schematic.

Step 1: To demonstrate the basic circuit operation.

Set the frequency selector switch to position 3 (10 kHz) and energize the circuit. The lamp should light. If necessary, readjust the 1k-ohm potentiometer on the oscillator circuit board slightly. Switch the oscillator frequency to 1 kHz and 100 Hz and observe the lamp. Note that it glows only on the high frequency signal.

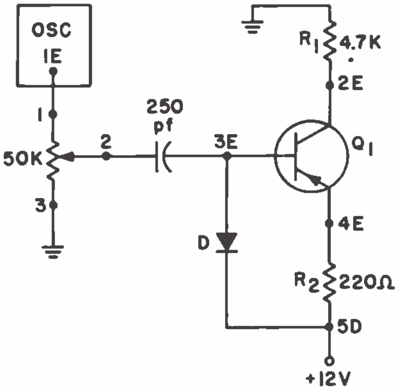

Fig. 55-2. Input circuit using the 50k-ohm pot.

Turn the circuit off and wire the 50k-ohm potentiometer, which is mounted on the front of your circuit board, into the circuit as shown on the schematic in Fig. 55-2. The terminals of the potentiometer are numbered clockwise when looking at the shaft end.

Unsolder the lead of the 250 pf capacitor from the oscillator board and solder it to terminal 2 of the potentiometer. Solder a length of hookup wire from terminal 3 of the potentiometer to ground. Solder a length of wire between terminal 1 of the potentiometer and square 1E of the oscillator circuit board.

Step 2: To show that the circuit responds to variations in signal strength.

Turn the circuit on, set the frequency to 10 kHz and vary the 50k-ohm potentiometer. Note that the brilliance of the lamp varies with the potentiometer adjustment.

Connect the ground clip of your tvom to lug 5 of EC24 and set the tvom to measure ac voltage on the 3-volt range. Touch the probe to square 3E to measure

the ac voltage applied to the base of transistor Q_1. Notice the voltage variation as you rotate the potentiometer. Record the maximum value of ac voltage in Fig. 55-3. Reduce the signal strength with the potentiometer as you observe the lamp's brilliance. When the lamp just goes out, read the value of ac voltage at the base of Q_1. Record this as the minimum value of ac in Fig. 55-3.

Set your tvom to measure negative dc on the 3V range and measure the dc voltage corresponding to the minimum and maximum values of ac voltage. Record these values in the chart in Fig. 55-3.

Set the polarity switch on the tvom to normal, move the ground clip to the chassis and measure the Q_1 dc base voltage again. Record your reading in the chart in Fig. 55-4. Measure and record the voltages (with respect to the chassis) at the collector of Q_1 at square 2E; the base of Q_2 at square 4H; and the collector of Q_2 at square 3H with the minimum and maximum ac signal voltages applied.

Step 3: To show the effect of typical circuit defects. You will simulate defects

(A) To simulate a shorted diode, carefully short the signal diode lead with a screwdriver or a length of wire. Energize the circuit, vary the potentiometer and note that the bulb does not light. Measure the dc voltage at the base of transistor Q_1. The voltage should be approximately +12V. Remove the short circuit across the diode. 14.1

(B) To show the effect of a shorted transistor, Q_1. Connect a 1-megohm resistor between the ground foil and square 3E. When you energize the circuit, the lamp should light. Vary the signal level and change frequencies. The lamp should remain lighted and steady. Measure the voltages at the collector of Q_1 and the base and collector of Q_2 and compare them with the values recorded in the chart in Fig. 55-4. Remove the 1-megohm resistor.

(C) To show how a defective lamp affects the circuit voltages. Check to see that the lamp lights, and remove the lamp

from the socket. Measure the voltage at the collector of Q_1 and at the base and collector of Q_2. You should find that the Q_2 collector voltage falls to zero while the Q_1 collector and Q_2 base voltages rise slightly. Turn the circuit off and replace the lamp.

(D) To show the effect of a base-emitter short-circuit in transistor Q_2. Connect a short length of hookup wire from ground to the base of transistor Q_2 at square 4H. Energize the circuit, vary the signal level and switch frequencies, and notice that the lamp remains off. Measure the Q_1 and Q_2 collector voltages. The Q_2 voltage should be abnormally high while the Q_1 voltage is normal.

Turn your equipment off and remove the short between the base of Q_2 and ground.

Discussion: In this experiment, you demonstrated a simple stereo indicator circuit. The circuit lighted the lamp whenever the proper signal voltage was applied to it.

The circuit consists of a shunt detector, diode D, and a two-stage direct-coupled amplifier with a lamp as part of the collector load of the output transistor. Transistor Q_1 is a PNP type while Q_2 is an NPN type. Normally, both transistors are turned off and little current flows through the lamp. When a signal is applied, Q_1 conducts and turns on Q_2, which causes current to flow through the lamp.

Diode D rectifies the ac signal voltage applied to it and makes the base of Q_1 negative with respect to the emitter. Because Q_1 is a PNP transistor, this negative voltage causes it to conduct. Current flows from ground through R_1 to the collector and from the emitter through resistor R_2, to the positive supply voltage terminal.

The collector of Q_1 becomes positive with respect to ground and this voltage is coupled through resistor R_3 and applied to the base of Q_2. Q_2 is an NPN transistor and the positive voltage fed to the base makes it conduct heavily. A large collector current flows through the lamp and the 150-ohm resistor to the positive supply voltage.

The information which you recorded in the chart in Fig. 55-4 confirms the preceding discussion of how the circuit works.

In Steps 1 and 2, you found that the circuit responds only to a moderately high amplitude 10 kHz signal. It does not work on 1 kHz or 100 Hz because the value of the coupling capacitor is too small to pass these frequencies without severe attenuation. The threshold or minimum required signal level is established primarily by the base cutoff characteristic of the input transistor, the reverse bias developed across the emitter resistor and the impedance of the coupling capacitor at the signal frequency. The threshold level of your circuit should be about .45V ac at the base of transistor Q_1.

In Step 3, you saw the effects of several common circuit defects. A shorted diode will not rectify the applied ac signal. Therefore, Q_1 will not become forward-biased and the lamp will not light. The circuit becomes completely inoperative.

A short in transistor Q_1, which you represented by applying a high forward bias, will keep the lamp turned on in the absence of signal. Q_1 will conduct continuously and the positive voltage dropped across the 4.7k-ohm collector load resistor, R_1, will keep Q_2 conducting heavily.

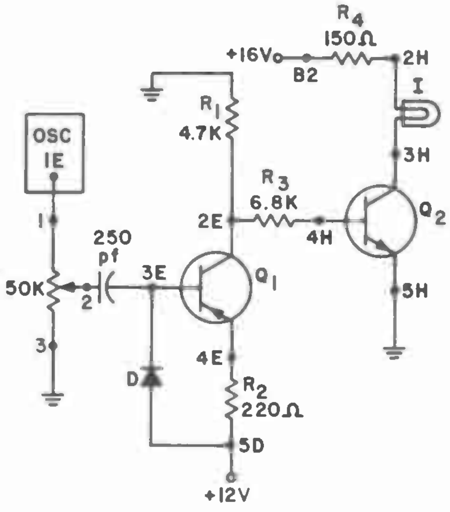

Fig. 55-5. The circuit for Statement 55.

In Step 3C, you found that a burned-out bulb will result in normal voltages throughout the circuit except at the collector of Q_2. The lamp is in series with the supply voltage and any break in that circuit removes the Q_2 collector voltage.

A shorted base-emitter in transistor Q_2 cuts Q_2 off and causes the lamp to remain turned off. The Q_2 collector voltage increases. Q_2 does not conduct so there is not enough collector current to light the lamp.

Instructions for Statement 55: For this Report Statement, you will reverse the connections of the diode as shown in Fig. 55-5 and determine how it affects the circuit operation.

Remove diode D from the circuit and reinstall it with the cathode lead to the base of Q_1 and the anode lead to the emitter supply voltage at square 5D. Turn the circuit on, test its operation on all three frequencies and answer the Statement. Be sure to place your answer on the answer sheet.

Turn your equipment off.

Statement No. 55: When I reversed the connections to the diode, I found that the circuit:

(1) worked normally.
(2) responded to all frequencies.
[✓ *(3)*] *did not respond to signals.*

This concludes the experiments on audio circuits. Dismantle your circuits to prepare for the new circuits which you will build for the next group of experiments.

Unsolder and disconnect the hookup wire connecting the 1k-ohm potentiometer and terminal B3. Also, unsolder and remove the 250 pf mica capacitor. Remove the oscillator circuit board along with the three-position switch and the potentiometer brackets from the top of the chassis.

Unsolder and remove all parts and leads (including the transistors) from the center circuit board. Remove the 50k-ohm potentiometer. Remove the board and the potentiometer mounting bracket.

Unsolder and remove both leads connecting terminals B2 and B3 to the low voltage supply.

Building An RF Oscillator And I-F Amplifier

In the next group of experiments, you will work with rf and i-f circuits. Thus, you will need a source of rf voltage. You will also work with a vacuum tube amplifier so you will need a circuit board having a tube socket mounted on it.

At this time, you should have terminal strips A, B, and F mounted on your chassis. The low voltage power supply is wired on circuit board EC24 and the high voltage supply is wired on terminal strip A. The green filament leads of the power transformer are connected to terminals B5 and B6. You will install one circuit board, modify your power supplies and wire the rf oscillator and i-f amplifier circuit for the next experiment.

MOUNTING THE PARTS

Refer to Fig. 9 as you carry out the following assembly steps. First, gather the following parts:

1	Oscillator coil with mtg. hardware (C043)
1	I-F transformer with mtg. hardware (TR13)
1	Tuning capacitor
1	1k-ohm potentiometer with mtg. hardware
1	Paper dial scale
1	Terminal lug
2	Knobs
4	No. 6 lockwashers
3	3/16″ 6-32 screws
4	4-40 screws
4	4-40 nuts
1	Circuit Board (EC25)

First, remove the 1k-ohm potentiometer from the audio oscillator board.

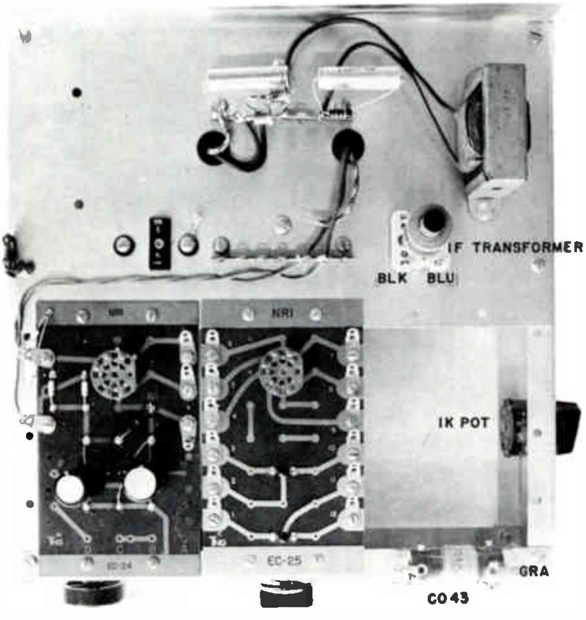

Fig. 9. The parts mounted on the chassis.

Unsolder the connections carefully. Also, remove the knob from the rotary switch on the oscillator board.

Mount circuit board EC25 on the chassis. Mount the board over holes S, T, AE, and AF, using four 4-40 screws and nuts.

Mount the rf oscillator coil, CO43, on top of the chassis at holes AG and AH. Position the coil so that the terminals color-coded yellow, gray and black are toward the right. Place a terminal lug over the screw at hole AH. Attach 4-40 nuts and tighten.

Mount the 1k-ohm potentiometer in hole AZ from the inside of the chassis. Use a control lockwasher and nut. Position the potentiometer so that the terminals are toward the top of the chassis rail.

Mount the i-f transformer on top of the chassis at hole L. Remove one of the nuts from the mounting screw of the transformer. Slip the mounting screw through the hole and rotate the transformer so that the terminals color-coded blue and black are toward the front rail of the chassis. Attach a lockwasher and the nut you removed from the screw and tighten securely.

Install the tuning capacitor at the front on the inside of the chassis at hole AV. At the same time, install the paper dial scale outside the chassis, using the same mounting screws. Refer to Fig. 10. Place No. 6 lockwashers over three 3/16" X 6-32 screws. Push the screws through the small holes in the dial scale and the three holes in the front of the chassis. Run these screws into the threaded holes in the front of the frame of the tuning capacitor. Rotate the shaft of the capacitor fully counterclockwise and place a pointer knob on the shaft. Position the knob so it points to zero on the scale and tighten the setscrew.

In a similar manner, install a pointer knob on the shaft of the 1k-ohm potentiometer. Rotate the shaft fully counter-

clockwise and install the knob in the 7 o'clock position.

WIRING THE CIRCUITS

You will begin your wiring by modifying the high and low voltage power supplies. Then you will wire the i-f oscillator and i-f amplifier circuits.

Gather the following parts:

1	**12BA6 tube**
1	**1-megohm resistor**
2	**10k-ohm resistors**
1	**3.3k-ohm resistor**
1	**470-ohm resistor**
1	**.1-mfd tubular capacitor**
2	**.01-mfd disc capacitors**
1	**.001-mfd disc capacitor**
1	**470 pf disc capacitor**

Power Supplies. The power supply circuits are shown in the schematic diagram in Fig. 11. First short terminal A4 to ground with a screwdriver to discharge the filter capacitor. Then unsolder and disconnect the red and red/yellow power transformer leads from terminals A1 and A2. Also disconnect and remove the rectifier connected between terminals A2 and A4. Solder the red transformer lead to terminal A1 and the red/yellow lead to terminal A2.

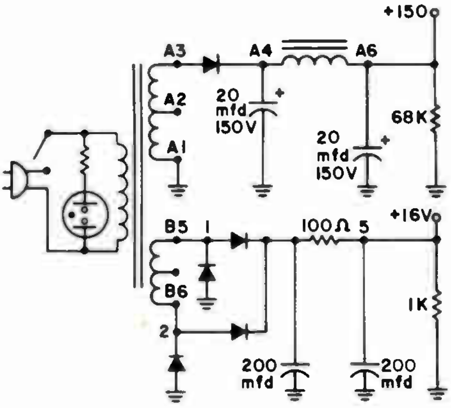

Fig. 11. High and low voltage power supplies.

Next, unsolder and disconnect the leads of the filter choke from terminals B2 and B3 and reconnect them to terminals A4 and A6. Terminal A6 is the +150V source (B+).

Reconnect the 100-ohm resistor between the positive leads of the input and output filter capacitors on circuit board EC24. Lug 5 of EC24 is the +16V terminal.

RF Circuits. To wire the rf oscillator and i-f amplifier circuits follow the schematic diagram in Fig. 12. The terminals are identified in the parts layout diagram in Fig. 9. The tuning capacitor is grounded through its frame and mounting to the chassis. The coil windings shown in the transistor circuit are windings of the oscillator coil on the front of the chassis. The windings shown in the plate circuit of the tube are the windings of the i-f transformer mounted at hole L.

All wiring, unless otherwise indicated, is on circuit board EC25. Where a ground is indicated, use a grounded terminal or solder directly to the foil at the end of the printed circuit board.

To wire the circuit, proceed as follows:

Connect a 10k-ohm resistor and a .01-mfd capacitor in parallel between lug 11 and ground. Connect a 10k-ohm resistor between lug 11 of EC25 and lug 5 of EC24.

Connect a 3.3k-ohm resistor and a .001-mfd capacitor in parallel between lug 12 and ground. Connect a 470 pf capacitor between lugs 1 and 12.

Connect a length of hookup wire from lug 1 to the green terminal of the oscillator coil.

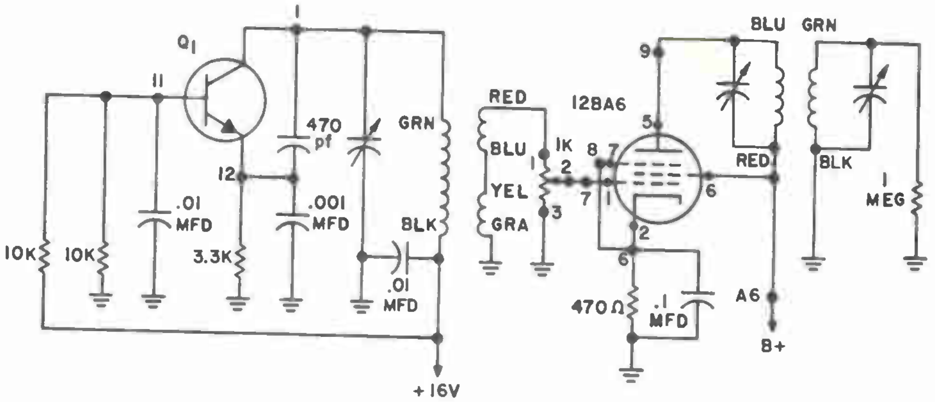

Fig. 12. The rf oscillator and amplifier circuit.

Prepare a 3-inch length of hookup wire. Push one end through the hole near lug 1 of the circuit board from the phenolic side of the board and solder. Solder the other end to the terminal at the lower rear corner of the tuning capacitor.

Connect a length of hookup wire from the black terminal of the oscillator coil, CO43, to lug 5 of EC24. Solder a .01-mfd capacitor between the black terminal and the ground lug. Connect a short length of wire between the gray terminal and the ground lug.

Solder a length of wire between the blue and yellow terminals of the oscillator coil. Solder a length of wire between the red terminal of the coil and terminal 1 of the 1k-ohm potentiometer mounted on the right side of the chassis. (The terminals are numbered clockwise from the shaft end of the potentiometer.) Solder a length of wire between terminal 2 of the potentiometer and lug 7 of the EC25 circuit board. Connect and solder a wire from terminal 3 of the potentiometer to ground.

Connect a length of wire between lugs 6 and 8 of EC25. Connect a 470-ohm resistor and a .1-mfd tubular capacitor in parallel between lug 6 and ground.

Connect a length of wire from the red terminal of the i-f transformer to terminal A6. Notice that pin 6 of the tube does not connect to any of the lugs on EC25. There are two holes in the foil instead. Solder a length of wire from one of these holes to the red terminal of the i-f transformer. Connect a wire from lug 9 to the blue terminal of the i-f transformer.

Connect a short length of wire from the black terminal of the i-f transformer to ground. Connect a 1-megohm resistor from the green terminal of the transformer to ground.

To wire the filament circuit, solder a length of wire from terminal B5 to lug 4 and solder a length of hookup wire from terminal B6 to lug 5. Be sure the wires already connected do not come loose from terminals B5 and B6. Insert the 12BA6 tube in the socket on the experimental circuit board.

When you complete the wiring, check your work carefully, then energize the circuit and observe that the filament in the tube lights up.

To test your circuit, measure the oscillator output voltage. Set your tvom to measure 3V ac and measure the voltage between the red terminal of the oscillator coil and the chassis. You should read

1V or more. If not, check for +16V at lug 5 of EC24 and check the oscillator wiring. Assuming that the oscillator is working, measure the ac voltage at the plate of the amplifier. Turn the shaft of the 1k-ohm potentiometer fully clockwise. While measuring the voltage, rotate the shaft of the tuning capacitor throughout its range. If you get a reading of over 5 volts, you can assume that the oscillator and amplifier are both working correctly.

Turn your equipment off.

HOW THE CIRCUITS WORK

At present you have a high voltage power supply supplying about +150V dc to the plate and screen circuits of the vacuum tube. From the schematic in Fig. 11, you can see that it is a half-wave supply with a pi-type filter network. The full HV secondary winding of the power transformer is used for maximum output voltage.

The low voltage supply is also a bridge type with a pi-filter network. The filter uses two capacitors and a small series resistor instead of a choke.

The rf oscillator is a Colpitts, using an NPN transistor. The transistor is connected in a grounded base configuration. The base is held at ac ground by the .01-mfd capacitor in shunt with the base bias resistors.

The resonant circuit for the oscillator consists of the primary winding of the oscillator coil in parallel with the 470 pf and .001-mfd capacitors and the tuning capacitor. The .01-mfd capacitor at the black transformer terminal has such a low reactance at the signal frequency that this end of the coil winding is at signal ground. The 470 pf and the .001-mfd capacitors form a capacitive voltage divider. This divider taps off and feeds back part of the collector output signal voltage to the emitter to sustain oscillations.

Combination bias is used. Forward bias voltage is supplied by the voltage divider across the base circuit and the resistor connected between ground and the emitter provides reverse bias.

The tuning capacitor varies the frequency of the oscillator by varying the total capacitance in shunt with the oscillator coil. The output signal is coupled inductively from the primary to the secondary winding. Note that the two secondary windings are series-connected for greatest output. This voltage is developed across the 1k-ohm potentiometer which will serve as an oscillator output level control.

The rf amplifier uses the 12BA6 tube connected as a pentode. The amplifier uses cathode bias, developed by cathode current flowing through the 470-ohm resistor. The i-f transformer in the plate circuit can be tuned to resonance by the trimmer capacitors connected across the windings.

EXPERIMENT 56

Purpose: To show that in a double-tuned circuit: (a) loose coupling gives low output and a sharp response; (b) there is a degree of coupling – called critical coupling – that gives maximum output voltage; and (c) overcoupling gives a broad double-peaked response; and to show that loading the secondary of a double-tuned transformer reduces the output and flattens the response.

Introductory Discussion: The output of an amplifier stage is of no practical use unless it can be effectively coupled to a load. This coupling can be accomplished in a variety of ways, as you have learned in your regular lessons and in previous experiments.

The i-f amplifier stages of almost all superheterodyne AM and FM sound receivers are coupled through a transformer having both the primary and secondary windings tuned to resonance at the intermediate frequency. A winding can be tuned by changing the setting of a variable capacitor connected across it, or by varying the position of a powdered-iron slug inside the winding, thus varying its inductance.

When a given voltage is applied across the primary winding of a coupling transformer, the amount of voltage developed across the secondary winding depends upon a number of factors, the most important of which are: (a) the degree of coupling between the two coils; (b) the Q of the transformer; and (c) the accuracy with which the primary and secondary coils are adjusted to resonance with the frequency of the input voltage.

In this experiment, you will vary the degree of coupling between the coils and note the effect upon the output voltage and upon the response over a wide range of frequencies.

The i-f transformer is designed to operate most effectively within the frequency range from 400 to 500 kHz.

The tuning range of the rf oscillator is from about 380 kHz to about 570 kHz, as shown in the graph in Fig. 56-1. From this graph, you can see that if you set the variable capacitor to 50 on its reference dial scale, the frequency produced by the oscillator will be very close to the 456 kHz frequency at which the i-f transformer was intended to be operated.

The response curve of a circuit is a graph in which output voltage is plotted against frequency. Normally, the frequency is varied in even steps and the voltage is plotted at each point. A smooth curve is then drawn connecting these points.

To get the response curves for a given degree of coupling, you will set the pointer knob on the tuning capacitor shaft to 50 on the dial scale, and adjust both i-f transformer trimmers for maximum output voltage at that frequency. Then, without touching the settings of

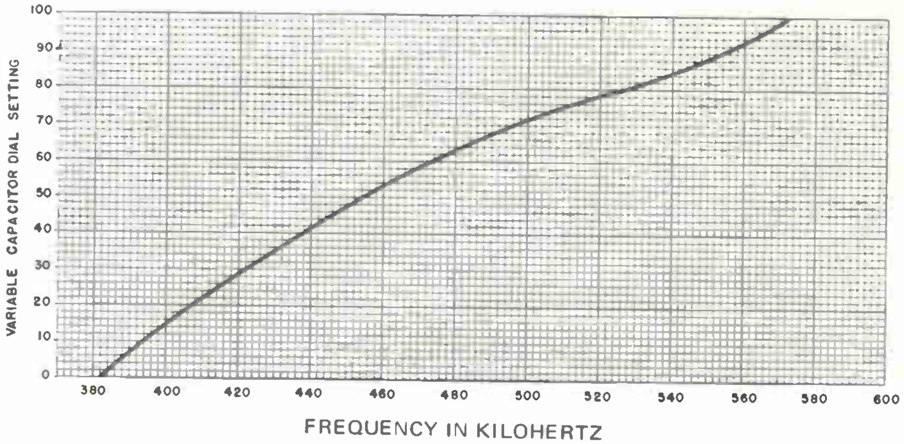

Fig. 56-1. Tuning range of the rf oscillator with .001-mfd capacitor and 470 pf capacitor across oscillator coil and tuning capacitor.

the i-f trimmers, you will tune the oscillator throughout its range and measure the rf output voltage as you do so. To show the effect of loading on the circuit response, you will connect a smaller resistor across the transformer output winding. You will again measure the rf output voltage. By comparing the results of the two steps, you will be able to see the circuit response for the two circuit conditions.

Experimental Procedure: For this experiment, you will need your tvom, your chassis and the following parts:

1 47k-ohm resistor
1 Test clip (CL8)

In this experiment, you will use the oscillator and amplifier circuits which you constructed earlier. The circuit is shown in Fig. 12.

To align the i-f transformer to approximately 456 kHz, proceed as follows:

First set the coils of the i-f transformer as far apart as you can to get minimum coupling. Only the coil at the open end of the fiber form is movable. Pull this coil gently and carefully toward the open end of the form until the distance between the two coils, measured between the inside faces of the coils, is 1-1/16 inches. This is distance D in Fig. 56-2. The open end of the fiber form is flared outward slightly to keep the coil from falling off. Don't pull the coil beyond this flare. If it does not reach 1-1/16 inches, use the maximum distance you can get as minimum coupling.

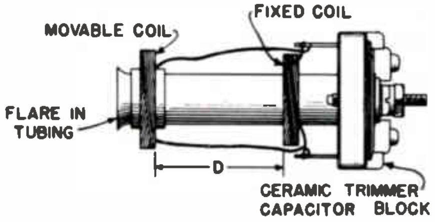

Fig. 56-2. Measure distance D when adjusting the i-f coils for different degrees of coupling.

Set the knob pointer on the variable capacitor that controls the rf oscillator frequency to exactly 50 on the calibrated scale. Use a small screwdriver through chassis holes L_1 from the bottom and L_2, and turn both trimmers of the i-f transformer as far as they will go easily in the clockwise direction. Then back each one off 1/4 turn. Turn the rf oscillator output control (the 1k-ohm potentiometer) for full output – all the way clockwise.

Slip the test clip on the probe of your tvom. Then you can clip the probe to the test point and have both hands free.

Connect the ground clip of the tvom to the chassis, and the probe to the green terminal of the i-f transformer which is the output terminal. Turn on the power.

Turn the trimmer adjustment screw through chassis hole L_2. Turn this adjustment in the direction that gives an increased voltage. Switch to higher voltage ranges of the tvom, when necessary, to keep the meter pointer from going off scale. If you find the meter pointer tends to go off scale when the 120-volt range is used, readjust the 1k-ohm potentiometer to reduce the output from the oscillator so that you will stay on this voltage range. Continue adjusting the trimmer through hole L_2 until you find the maximum reading.

Adjust the trimmer through chassis hole L_1 for maximum output; then readjust the trimmer through hole L_2 for maximum output. This is necessary to compensate for the interaction between the coils of the i-f transformer. If the output exceeds 120V, set the 1k-ohm potentiometer for a lower input. Now, make a final touchup adjustment of both trimmers to be sure that you have them set at the positions that give the maximum meter reading.

The adjustments you have made tune the i-f transformer to resonance with the frequency produced by the rf oscillator. For the rest of the experiment, the tuning of the i-f transformer will remain essentially the same as you have it now.

Step 1: To determine the frequency response of the rf amplifier stage.

Proceed as follows:

First, set the variable tuning capacitor at zero (0) on the calibrated scale (maximum capacity), so that the rf oscillator will produce its lowest frequency.

Set the rf oscillator output control (the 1k-ohm potentiometer) to apply exactly 1 volt (measured on the 3V range) to the control grid, pin 1, of the 12BA6 tube. If you make this adjustment accurately, you will not need to recheck it during any one set of frequency measurements at a particular coil spacing. The tuning range of the oscillator will be restricted to the low frequencies, at which the output of the oscillator is essentially constant.

Reconnect the probe of your tvom to the 1-megohm load resistor at the green transformer terminal, set the range switch to 12V, and measure the rf voltage. Enter your reading for the 0 dial setting in the first space in the first column of Fig. 56-3. If this voltage is less than 1 volt on the 12V scale, estimate the value as well as you can. *Don't switch to a lower range – take as many measurements as possible on the same scale.*

Set the oscillator tuning control to 30, 40, 50, 60, 70, and 100, and record the output voltage for each setting in the first column of Fig. 56-3. As the frequency of the oscillator approaches that to which the i-f transformer has been tuned, the output voltage should become high enough to make it possible to use the 120V range. The highest voltage you get should be when the oscillator frequency control is set at 50, the frequency to which the i-f transformer was adjusted.

30	.52	5.2
40	.94	7
50	.92	7
60	.56	5.4
70	0	5.7
100	0	2.7

Fig. 56-3. The chart for Steps 1 and 2 with a 1 megohm load on the transformer.

When you have finished this frequency run, return the oscillator tuning control to 0, and turn off the power supply.

The fixed coil of the i-f transformer is the primary winding, which is in the plate circuit of the amplifier stage, and is above ground potential by an amount equal to the dc plate voltage. For safety's sake, therefore, **ALWAYS TURN OFF THE POWER SUPPLY** before touching the coils to change the coupling.

Step 2: To show that closer spacing produces greater output.

Turn off the power and set the coils 5/8 inch apart. Rotate the tuning knob smoothly from zero to 100 on the dial scale and observe how the output varies. You should see the voltage rise to a peak at a dial setting of 50 and fall to a low value, as in Step 1. However, the peak rf voltage should be much higher than that obtained in Step 1. Record the voltages at zero, 30, 40, 50, 60, 70 and 100 on the dial scale in the second column of the chart in Fig. 56-3.

Step 3: To show the effects of overcoupling.

Set the coils 3/8 inch apart, and, after checking the rf input voltage to see that it is still 1 volt, repeat the frequency run: Rotate the tuning knob smoothly from zero to 100 while observing the rf output voltage. This time there should be two voltage peaks, with one below and one above the resonant frequency of the i-f transformer.

Repeat the test and record the frequency settings for the two peaks. These peaks may or may not be of equal value and may or may not be spaced an equal distance away from the resonant frequency setting of 50 at which the previous signal peaks were obtained. Furthermore, the peaks may not occur at one of the main scale divisions. Record the frequencies at which the peaks occur and the peak voltages in the chart in Fig. 56-4. Also, record the voltage with the dial set to 50.

only one pk.

Fig. 56-5. The chart for use with Step 4.

Step 4: To show the effect of loading an overcoupled circuit.

Remove the 1-megohm resistor across the transformer secondary and replace it with a 47k-ohm resistor. This increase in the load increases the current drawn from the transformer. Repeat the frequency run with the coil spacing still at 3/8 inch.

Again, you should find two voltage peaks, but now the maximum voltages should be much less than those you measured in Step 3. The difference between the maximum voltages and the voltage at resonance, 50 on the scale, should be much less than it was in Step 3, when the load was much less. The actual peak voltage on each side of resonance may not occur at a main scale division.

Find and record the actual positions and the peak voltages as in the previous step. Record your readings in Fig. 56-5. Also, record the voltage at the dial setting of 50.

Turn your equipment off.

Discussion: You have observed the output of an i-f amplifier with a double-tuned output transformer under various conditions. In Step 1, you had maximum spacing between the transformer coils, and hence minimum coupling. The response curve of the transformer is represented by curve 1 in Fig. 56-6.

The curve shows that the transformer passes little signal voltage at the dial setting of zero. The voltage rises to a maximum at 50, decreasing again as the oscillator is tuned higher. We can see that the transformer is resonant at 50 or that its center frequency is at a dial setting of 50.

Note that at dial settings of about 45 and 55 the voltage is about 70% of its maximum value. These points on the graph are called the half power points, in that the voltage and current are about 70% of the voltage and current at resonance. Thus, the transformer bandpass, the band of frequencies between the half power points, is about 20 kHz, as determined from the chart in Fig. 56-1.

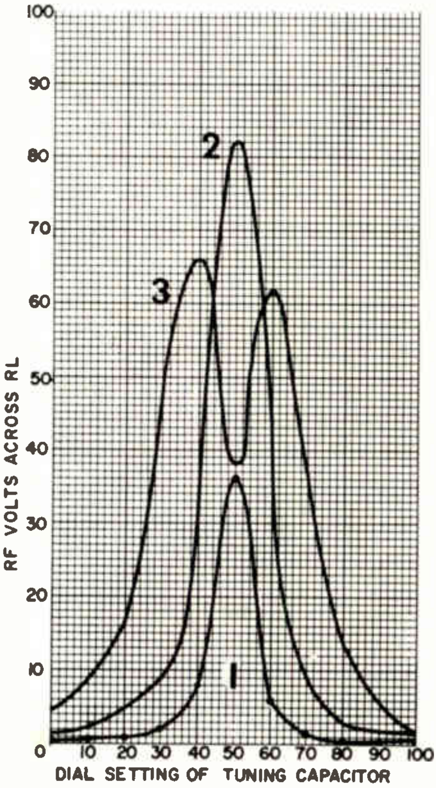

Fig. 56-6. Curves plotted from typical values for different degrees of coupling with a 1-megohm load resistor.

In Step 2, closer spacing of the i-f transformer coils was used. This change produced a higher peak voltage and a slightly broader bandpass, as shown by curve 2 in Fig. 56-6. Note that the peak still occurred at the same frequency, with a dial setting of 50. The coil spacing was very close to "critical" coupling, which is the spacing that produces maximum output at the center frequency.

With a coil spacing of 3/8 inch in Step 3 you should have obtained a double peak response as in curve 3 in Fig. 56-6. The coils were overcoupled and they interacted with each other. You will note that the output at the center frequency was lower than in Step 2. The resonant frequency of one coil became lower, and the resonant frequency of the other became higher than their natural frequencies. This resulted in the peaks on either side of the center frequency. Because of the two peaks, the bandwidth of the overcoupled transformer is greater than it is with critical coupling.

In Step 4, if you plotted the points, you would have found a response curve similar to the graph in Fig. 56-7. Comparing this with curve 3 of Fig. 56-6, you can see that loading the output of the transformer lowered the output voltage at the peaks and broadened the bandwidth.

Loading in this manner is a technique used frequently to increase the bandwidth of a resonant circuit. It reduces the output voltage and makes the bandpass curve more gradual.

Instructions for Statement 56: For this Statement, you will determine the effect of loading the transformer when there is wide spacing between the coils.

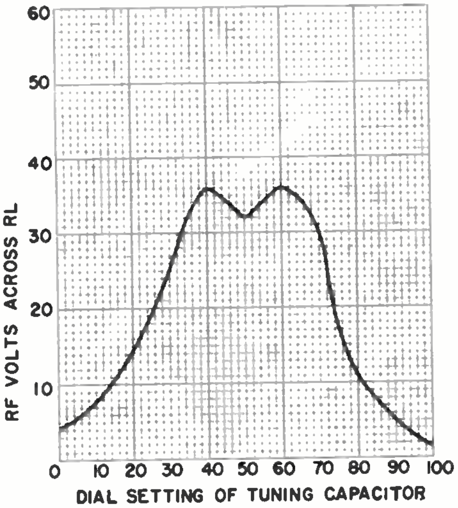

Fig. 56-7. Typical curves for a 47k-ohm load resistor and 3/8-inch spacing.

Set the coils 5/8 inch apart. At this spacing, you should have a single-peak response curve. With the 47k-ohm resistor in the circuit, run the frequency test and note the voltage across the load resistor. Note the voltage at dial settings of 10, 40, 50, 60 and 90.

Compare these voltage readings with those you recorded for Step 2 in Fig. 56-3 and answer the Report Statement.

EXPERIMENT 57

Purpose: To show that an amplifier stage can provide both gain and amplitude limiting of an rf signal and to show diode limiting.

Introductory Discussion: A limiter is a special type of i-f amplifier stage used in many FM receivers. Its function is to limit the amplitude of the FM i-f signal, thereby removing the variations in the strength or amplitude of the signal reaching the demodulator. The block diagram in Fig. 57-1 shows the location of the limiter in the signal path of a typical FM receiver.

An FM signal has the intelligence in the variations in the frequency of the carrier wave about the assigned center frequency. The transmitted signal has uniform amplitude. Along the transmission path between the transmitting and receiving antennas, the signal picks up noise from vehicle ignition, static, etc. The noise takes the form of variations in the amplitude of the FM signal.

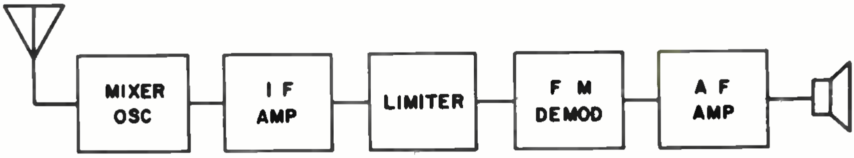

Fig. 57-1. Block diagram of a basic FM receiver.

For noise-free reception, it is necessary to either remove the noise before the signal is demodulated, or to use a demodulator which is not sensitive to amplitude variations. As you will see, both methods are used.

Limiting is usually accomplished in one of two ways:

One or two limiter stages are connected into the signal path between the i-f amplifier stages and the demodulator or diodes are placed across the secondary winding of one or more i-f transformers.

Experimental Procedure: For this experiment, you will need the experimental chassis, your tvom and the following parts:

1	**100k-ohm resistor**
1	**47k-ohm resistor**
2	**22k-ohm resistors**
1	**6.8k-ohm resistor**
2	**4.7k-ohm resistors**
1	**100-mfd electrolytic capacitor**
1	**.1-mfd tubular capacitor**
2	**Signal diodes (CR10)**

You should have circuit board EC25 on your chassis and the board should have 2 NPN transistors mounted on it. You should also have the 1k-ohm potentiometer mounted inside the right side of the chassis at hole AZ.

Unsolder and remove all parts and leads connected to lugs 6, 7, 8 and 9 of the circuit board. Also, unsolder all connections to the i-f transformer and remove the transformer from the chassis. Remove the 12BA6 tube from the socket.

Construct the transistor amplifier circuit shown in the schematic in Fig. 57-2. Note that the oscillator circuit is unchanged. The amplifier transistor (Q_2) is already on the circuit board. Its base, collector and emitter leads are connected to lugs 2, 3 and 10, respectively. Ground lug 10 with a short length of wire. Connect a 4.7k-ohm resistor between lug 2 and ground.

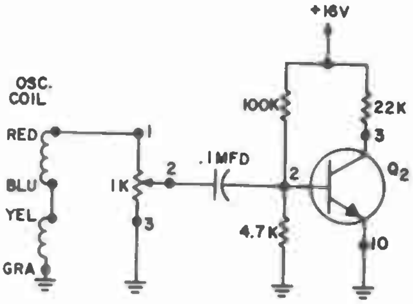

Fig. 57-2. The limiter-amplifier circuit diagram.

Connect a 100k-ohm resistor between lug 2 of EC25 and lug 5 of EC24. Connect a 22K-ohm resistor between lug 3 of EC25 and lug 5 of EC24.

Connect one end of a .1-mfd tubular capacitor to terminal 2 of the 1k-ohm potentiometer. Notice that there are two solder pads in the foil strip connecting the base of Q_2 to lug 2. Place the .1-mfd capacitor in such a position, ***under the board***, that the lead is near the hole next to the base of Q_2. Poke the lead of the capacitor through the hole in EC25 near the base of Q_2 and solder.

Be sure to check your work carefully against the schematic diagram.

Step 1: To show that the amplifier gain varies with the input signal level.

Energize the circuit and check it as follows: Rotate the knob on the 1k-ohm potentiometer fully clockwise and measure the ac voltage at the base and collector of the rf amplifier, Q_2. You should have at least .2V at the base (lug 2) and 2V at the collector (lug 3).

INPUT VOLTAGE	OUTPUT VOLTAGE	GAIN
.05V	1.14	22.8
.1	1.18	11.8
.2	1.21	6.05
.4	1.28	3.2
.6	1.35	2.25
.8	1.41	1.7625
1.0	1.45	1.45

Fig. 57-3. Chart for Step 1.

Now move the tvom probe to terminal 2 of the 1k-ohm potentiometer. Adjust the potentiometer for an input signal of .05V. Measure the collector voltage and record it on the chart in Fig. 57-3. Readjust the input to the base to .1V and measure and record the corresponding collector signal voltage. In a similar manner, set the input to each of the voltage levels given in the first column in Fig. 57-3 and measure and record the resulting ac output voltages at the collector.

When you complete the chart, compute the gain of the amplifier at the various input levels. Record the gain for each input voltage in the third column.

Step 2: To demonstrate how low supply voltage affects limiter action.

For this step, you will use the circuit shown in Fig. 57-4. Unsolder the lead of the 22k-ohm resistor from lug 3 of EC25 and connect it to lug 4 of EC24. Connect a 6.8k-ohm resistor and a 100-mfd electrolytic capacitor between lug 4 of EC24 and ground. Note that the positive capacitor lead goes to lug 4. Connect a 4.7k-ohm resistor between lug 4 of EC24 and lug 3 of EC25. Energize the circuit and measure the dc voltage at lug 4 of EC24. This is the supply voltage for the limiter stage. Jot down the value in the margin. Measure the ac voltage at lug 4 of EC24. You should read zero, as this point is at signal ground.

2.5V

Now apply each of the input voltage levels given in the chart in Fig. 57-5 and measure and record the corresponding output voltages. You should find that limiting takes place at a low input signal level.

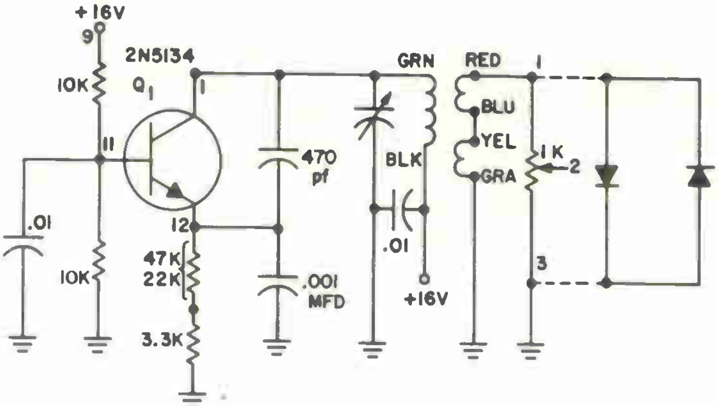

Fig. 57-6. The circuit used in Step 3.

Step 3: To show diode limiting.

For this step, you will connect diodes across the secondary winding of the oscillator transformer. You will then vary the oscillator output level and observe the effect of the diodes on the output signal level. You will use the circuit shown in Fig. 57-6.

Unsolder and disconnect the .1-mfd capacitor from terminal 2 of the 1k-ohm potentiometer and push the lead aside. Also disconnect the lead of the 3.3k-ohm emitter resistor from lug 12. Connect a 47k-ohm resistor between lug 12 and the free lead of the 3.3k-ohm resistor. Energize the circuit and measure the ac voltage across the 1k-ohm potentiometer, which is the output load resistance. You can connect the tvom between the red terminal of the oscillator coil and ground. Record your voltage reading on the first line of the second column of Fig. 57-7.

Connect two signal diodes across terminals 1 and 3 of the 1k-ohm potentiometer as shown in Fig. 57-6 by the broken lines. Measure the ac signal voltage across the potentiometer again. Record this value in the second column of Fig. 57-7.

Replace the 47k-ohm resistor in the emitter circuit of the oscillator with a 22k-ohm resistor. Repeat the measurements, first with the diodes disconnected, and then with the diodes connected across the transformer winding. Record both values on the second line of Fig. 57-7.

Unsolder and remove the 22k-ohm

resistor and reconnect the 3.3k-ohm resistor to lug 12. Again measure the output voltage with and without the diodes and record your voltage readings in the chart.

Turn your equipment off.

Discussion: In this experiment, you demonstrated the action of a limiter-amplifier stage and diode limiting. You should have found that with both methods the output variation was significantly reduced by the limiter action.

The limiter stage which you used in Step 1 can be classified as an overdriven amplifier. The stage has high voltage gain and requires only a very low level of input signal for maximum output. When this level is exceeded, limiting occurs. If the limiter is properly biased, the transistor should be driven into cutoff on one-half of each cycle of the i-f signal and into saturation on the other half-cycle. Fig. 57-8 shows typical input and output signal voltage waveforms for this type of limiter.

Your chart in Fig. 57-3 shows that the amplifier has high gain for low level signals and that the gain drops off as the input signal level is increased. When the input is greater than about .4V, limiting takes place. The output at this point is about 6V. Thus, as long as the signal is .4V or more, the output will be maximum.

In Step 2, you found that the limiter was more effective than it was in Step 1. The transistor became saturated on the positive peaks of the input signal. On the negative peaks, the transistor was cut off and collector voltage rose to the level of the supply voltage, about +3.5V.

In Step 3, you found that the diodes across the transformer secondary winding caused a very noticeable decrease in the amount by which the transformer output voltage varied. At NRI we found that without the diodes, the voltage across the secondary varied from .3 to about 1.5V. This is a change of about 1 to 5. On the other hand, with the diodes in place, the variation was from .3V to .4V. This change was about one-third. Note that the minimum output level was about the same whether or not the diode limiting was used.

The diodes you used are silicon signal diodes which conduct when the voltage at the anode becomes about .6V more positive than the cathode. The diodes are connected with opposite polarities so that one will conduct whenever the voltage across them becomes either positive or negative by about .6V. Each diode conducts on one-half cycle. Therefore, the peak-to-peak voltage across the load will be about 1.2V. Due to the waveform, the tvom will indicate about .4V ac.

In many portable FM receivers, you will see diodes labeled "overload" connected across windings of one or more of the i-f transformers. In reality they are limiters and their function is to limit the amplitude of the signal to minimize distortion in the following stages.

Instructions for Statement 57: For this Report Statement, you will increase the value of the collector load resistor in the limiter circuit used in Step 2 and note the effect on the limiting action.

Remove the two diodes connected across the 1k-ohm potentiometer and reconnect the .1-mfd capacitor to the center terminal of the potentiometer.

(1) had higher gain.

(2) limited more sharply.

(3) did not limit.

EXPERIMENT 58

Purpose: To demonstrate amplitude modulation and demodulation.

Introductory Discussion: An AM signal is one in which the amplitude of the fixed frequency carrier is varied by the intelligence or the audio modulating signal. This is illustrated in Fig. 58-1A. An rf carrier and an audio signal are applied to a modulator stage. In this stage the modulating signal causes the amplitude of the carrier to vary. The amount by which the rf amplitude varies is determined by the strength of the audio signal. The rate of amplitude variation is determined by the frequency of the audio signal.

Detection, which is the process of recovering the audio from the rf carrier, is illustrated in Fig. 58-1B. Notice that the modulated rf is fed into the demodulator circuit and the audio signal appears at the output. In the process, the rf carrier is filtered out.

In this experiment, you will use your rf

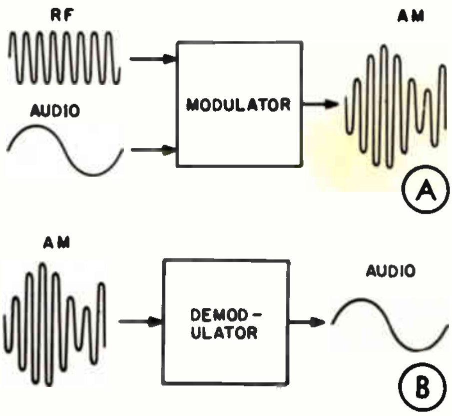

Fig. 58-1. (A) Amplitude modulation; (B) basic amplitude demodulation.

oscillator as an rf carrier signal source. This rf voltage will be modulated by a 60 Hz sine wave to produce an amplitude modulated signal similar to that shown in Fig. 58-1. The modulated rf will be transformer-coupled to a diode detector circuit. As you will demonstrate, the detector recovers the 60 Hz modulating signal.

Experimental Procedure: For this experiment, you will need the experimental chassis with the power supply and rf oscillator circuit, your tvom and the following:

1	**PNP transistor (TS22, 2N5138)**
1	**RF transformer (TR31)**
1	**150k-ohm resistor**
1	**100k-ohm resistor**
1	**15k-ohm resistor**
1	**4.7k-ohm resistor**
1	**1k-ohm resistor**
1	**.25 mfd tubular capacitor**
2	**.05 mfd disc capacitors**
1	**.001 mfd disc capacitor**
1	**470 pf disc capacitor**
1	**Trimmer capacitor (CN58)**
1	**50k-ohm potentiometer (PO100)**
1	**Signal diode (CR10)**
1	**4-lug terminal strip**
1	**3/8" X 6-32 screw**
1	**6-32 hex nut**

Before you begin the experiment, you must prepare the chassis and circuit board. Unsolder and remove transistor Q_2 and all parts and leads connected to lugs 2, 3 and 10 of the experimental circuit board and lug 4 of circuit board EC24. Be careful to avoid overheating the transistor.

The PNP transistor should have been removed from the other experimental circuit board (EC26). Solder the PNP transistor to circuit board EC25 as shown in Fig. 58-2.

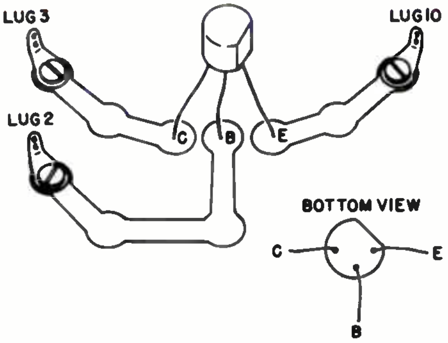

Fig. 58-2. Mounting the 2N5138 transistor.

Refer to Fig. 58-3 as you perform the next four steps.

Mount the rf transformer at holes AL and W. Position the transformer so the terminals color-coded red, yellow and blue are toward the front of the chassis. Remove the screw at hole W. Also remove one nut from each mounting screw on the rf transformer. Slip the mounting screws through the holes in the chassis, attach the nuts and tighten.

Remove the 1k-ohm potentiometer from hole AW, and install a 50k-ohm potentiometer in its place.

Mount the trimmer capacitor on top of the chassis at hole AK. Use the screw, lockwasher and nut just removed from the chassis.

Install a 4-lug terminal strip at hole U. Position the strip as shown. Attach with a 6-32 screw, lockwasher and nut. This is terminal strip C and its terminals are labeled on the photo.

Now wire the circuit shown in the schematic diagram in Fig. 58-4. The oscillator circuit is unchanged. However, note that only the blue/red winding of the oscillator transformer is used to couple the rf signal to the experimental circuit.

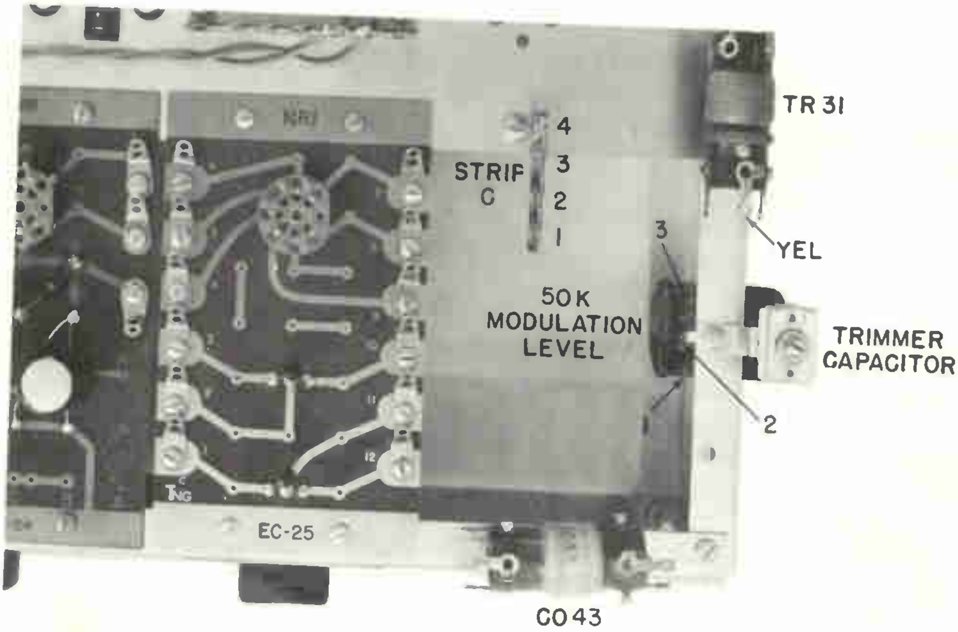

Fig. 58-3. Mounting the parts on the chassis.

The circuit is fairly complex. To avoid undesirable coupling, etc., perform the wiring carefully. Use short lengths of hookup wire when possible and route the leads where they will not cause interference.

Unsolder and disconnect all leads and parts from the gray, yellow, red and blue terminals of the oscillator coil.

Unsolder the lead of the 10k-ohm resistor from lug 5 of EC24 and solder it to the black terminal of the oscillator coil.

Connect a length of wire from lug 5 of EC24 to lug 9 of EC25.

Connect a 1k-ohm resistor between lug 9 and lug 10 of EC25.

Connect a .001-mfd capacitor between

lug 10 of EC25 and terminal C4. Solder lug 10.

Connect a 4.7k-ohm resistor between lug 5 of EC24 and lug 2 of EC25.

Solder a 100k-ohm resistor between lug 2 of EC25 and ground.

Connect a .25-mfd capacitor from the red terminal of the oscillator coil to the foil near lug 2 of EC25. Position the capacitor under the circuit board and push the lead up through the hole in the foil. Solder both connections.

Connect a length of wire from the blue terminal of the oscillator coil to the terminal of the 50k-ohm potentiometer nearest the front panel. Solder the potentiometer terminal.

Solder a .05-mfd capacitor between the blue terminal of the coil and ground.

Connect a length of hookup wire from terminal 3 (the terminal toward the rear) of the 50k-ohm potentiometer and terminal C4. Solder the lead to the potentiometer terminal.

Connect a 150k-ohm resistor between terminals A2 and B2. Solder A2.

Solder a length of hookup wire from terminal B2 to the center terminal of the 50k-ohm potentiometer.

Before you connect any leads to the rf transformer, be sure to remove all wax from the terminals. If any wax remains on the terminals it will be impossible to make a solder connection.

Connect a short length of hookup wire from the blue terminal of the rf transformer (TR31) to the nearer terminal of the trimmer capacitor. Connect a length of wire between the red transformer terminal and the free terminal of the capacitor. Solder both capacitor terminals carefully. Make sure all of the blades are soldered at each terminal.

Solder a 470-pf disc capacitor across the terminals of the trimmer capacitor.

Solder a length of hookup wire from lug 3 of EC25 to the blue terminal of the rf transformer.

Connect a length of wire between the red and black terminals of the rf transformer. Solder the red terminal.

Solder a length of hookup wire from the black terminal of the rf transformer to terminal C4.

Solder the anode lead of a signal diode to the green terminal of the rf transformer. Solder about a 2-inch length of wire to the cathode lead and connect the end of the wire to terminal C3.

Solder a .05-mfd capacitor and a 15k-ohm resistor in parallel between terminals C3 and B7.

Check your wiring with the schematic and be sure all connections are soldered.

Step 1: To adjust the modulator circuit.

Slip the test clip on the probe of the tvom and clip it to the green terminal of the rf transformer. Clip the ground lead to the chassis. Set the tvom to measure ac voltage on the 12V range. The polarity switch should be in the normal position.

Set the oscillator frequency selector to 70 on the dial scale, turn the 50k-ohm potentiometer fully counterclockwise, and energize the circuit. Adjust the trimmer capacitor fully clockwise. While observing the meter, turn the adjusting screw in the trimmer capacitor slowly counterclockwise. The reading should rise to a peak and then begin to fall. Set the trimmer for the voltage peak near the fully clockwise position. Readjust the frequency control to 50 on the dial. Use this frequency throughout the experiment.

Move the tvom probe to terminal C3 and measure the ac voltage at the output of the diode detector. Vary the 50k-ohm potentiometer, which is the modulation level control, and note the variation in the ac voltage. If necessary, switch the tvom to a lower range.

Step 2: To show amplitude modulation.

Turn the modulation control fully counterclockwise. Connect your tvom to measure the ac voltage between the green terminal of the rf transformer and ground. The tvom will indicate the unmodulated rf carrier voltage across the transformer winding. Record your reading in the first column in Fig. 58-5.

Turn the modulation control fully clockwise, then disable the rf oscillator by shorting lugs 11 and 12 of EC25 together. This will stop the oscillator. Again measure the ac voltage across the winding with modulation applied and with the oscillator stopped. Record your reading in the second column of Fig. 58-5. When you have recorded your results remove the short from the oscillator circuit.

With the modulation control still set fully clockwise and the oscillator operating, measure the amplitude modulated voltage across the transformer secondary winding. Record this value in the last column of Fig. 58-5.

Step 3: To show diode detection.

Move the tvom probe to terminal C3. Your meter now reads the voltage across the diode detector load consisting of the 15k-ohm resistor and the .05 mfd capacitor.

(A) Turn the modulation control to minimum (fully counterclockwise) and measure and record the ac voltage in the first column for Step 3A Fig. 58-5. Adjust the modulation control to maximum and short lugs 11 and 12 together. Read the ac voltage and record it in the second column of Fig. 58-5. Finally, measure and record the ac voltage with the rf carrier amplitude modulated. Turn the circuit off.

(B) With the tvom probe still connected to terminal C3, switch the tvom to read positive dc voltage on the 3V range.

Turn the circuit on, turn the modulation control fully counterclockwise, and measure the dc voltage with the rf carrier only. Record the reading in the first column of Fig. 58-5 for Step 3B. Similarly, measure and record the dc voltage with the rf oscillator shorted out and modulation applied, and with the rf

oscillator fully modulated. Turn the circuit off.

Step 4: To see the effects of removing the .05 mfd rf filter from the detector load.

Unsolder the lead of the .05 mfd capacitor from terminal C3. Energize the circuit and measure the dc voltage as you vary the modulation control. You should see some small variation.

Switch the tvom to read ac voltage. Observe the ac voltage across the 15k-ohm resistor as you vary the modulation. Note that when you turn the modulation control to minimum, the voltage does not go to zero. Turn the circuit off.

Discussion: An amplitude modulated signal consists of a carrier frequency signal which has intelligence in the amplitude variations. The carrier alone contains no useful information. It must be modulated or changed in some way.

In Step 2, you found that the rf carrier by itself produced an ac voltage across the secondary of the rf transformer. This voltage is proportional to the strength (level) of the carrier. The voltage is present only when the rf oscillator is operating. This is because the 60 Hz modulating frequency is too low in frequency to pass through the resonant circuit in the collector circuit of Q_2.

You should have found in Step 3 that there is an ac voltage at the detector output which varies with the modulation. This is the detected or demodulated 60 Hz ac voltage which was used to modulate the rf carrier. You also found that the detector produced a dc voltage which varied with the strength of the carrier signal.

A diode detector is a half wave rectifier and filter circuit very similar to the circuit you used in your power supply experiments. The diode passes only the positive portion of each cycle of rf, thus causing current flow up through the 15k-ohm load resistor. The .05 mfd capacitor filtered out the pulses of rf voltage, leaving only the low modulating frequency at the output. With the capacitor removed you should have observed that even with no modulation present there was still an ac voltage developed across the 15k-ohm load resistor.

Instructions for Statement 58: For this Report Statement you will simulate a defective detector diode and determine how it affects the detector output signal.

Solder a short length of wire across the leads of the diode between terminal C3 and the green terminal of the rf transformer. Reconnect the lead of the .05 mfd capacitor to terminal C3.

Energize the circuit and measure the ac and dc voltages across the 15k-ohm resistor and .05 mfd capacitor with the modulation control fully counterclockwise and fully clockwise. This should give you enough information to answer the statement.

Turn the equipment off and answer the Statement here and on your answer sheet.

Statement No. 58: When the diode was shorted, the detector circuit:

(1) worked normally.

[✓ *(2)*] *produced no output.*

(3) produced a high negative dc voltage.

The FM Detector

In your regular lessons you have learned that there are several types of FM detectors in wide use. Two of the more common types in FM receivers are the phase detector, commonly known as the discriminator, and the ratio detector.

When the discriminator is used, it is always preceded by a limiter stage. The purpose of the limiter stage is to eliminate variations in the carrier amplitude caused by static or other electrical noise. The FM signal fed to the discriminator therefore has a constant amplitude.

The ratio detector does not need a limiter stage because, under ordinary conditions, it is unaffected by variations in carrier strength. In this case, the detector can be preceded by an i-f amplifier. You may find in some receivers that a limiter stage is used with a ratio detector. The limiter is added to make certain that no noise pulses get through to the output.

In the next experiment you will study the phase detector or discriminator. Later you will study the ratio detector.

Although the principles of FM operation have been covered thoroughly in your regular lessons, we will review the detector action here. Let us see how a discriminator demodulates an FM signal by studying the basic Foster-Seeley Discriminator shown in Fig. 13.

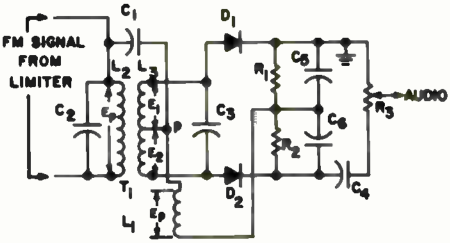

Fig. 13. Basic Foster-Seeley discriminator circuit.

The discriminator transformer, T_1, is of special design. Its primary winding, L_2, is tuned to the resting frequency by C_2, and its center-tapped secondary winding, L_3, is tuned to the same frequency by C_3. The current flowing through L_2 induces a corresponding FM voltage in L_3, and produces across the two sections of L_3 voltages E_1 and E_2, which are always equal in magnitude and 180° out-of-phase with each other.

At the same time, the primary voltage E_p is applied through C_1 to choke coil L_1. Since the reactance of C_1 is small, the voltage across L_1 is very nearly equal to E_p.

The limiter output voltage E_p (across L_1) in series with E_1 is applied to diode 1. Likewise, the limiter output voltage E_p in series with E_2 is applied to diode 2. These voltages are not in-phase: E_1 and E_2 are 180° out-of-phase with each other, and each is out-of-phase with E_p. The net voltage applied to each diode section is, therefore, the vector sum of the two individual voltages acting on that section.

Each diode rectifies its net applied rf voltage, and produces a proportional dc output voltage across its load resistor. The load resistor for diode 1 is R_1, and that for diode 2 is R_2. Electrons flow in opposite directions through R_1 and R_2, as you can easily see by tracing the diode circuits. This means that the combined voltage across R_1 and R_2, which is the output voltage of the discriminator, at any instant is equal to the difference between the individual voltages across these resistors. If the individual voltages are equal, the discriminator output voltage will be zero. If the voltages across R_1 and R_2 are different, the combined voltage will have the polarity of the larger of the two individual voltages, and will be equal in magnitude to their numerical difference.

Now let us consider the factors that make the output voltage of one diode higher than that of the other. First of all, we must choose some reference voltage or current. Since E_p is common to all circuits under study, we can use it as our reference voltage.

Phase relationships in this discriminator circuit must be considered for three different conditions: 1) when the signal frequency is equal to the frequency to which the discriminator resonant circuits are tuned; 2) when the signal frequency is lower than the resonant frequency; 3) when the signal frequency is higher than the resonant frequency. The vector diagrams for these three conditions are shown in sketches A, B, and C, respectively, of Fig. 14, with primary voltage E_p serving as the reference vector in each case. The rf voltage E_s that is induced in secondary winding L_3 is 180° out-of-phase with the primary rf voltage E_p, so it is shown 180° out-of-phase with reference vector E_p in each of the vector diagrams.

When the signal is exactly at the i-f resting value to which the discriminator circuits are tuned (in other words, when no sound is being transmitted), the secondary tuned circuit L_3-C_3 is at resonance, and the secondary current, I_s, flowing through L_3 is in phase with E_s, as indicated in sketch A of Fig. 14. When this current flows through the inductance L_3, the voltage produced across this inductance must lead the current by 90°. The coil ends must always be 180° out-of-phase (when one end is positive, the other is negative). Therefore, if we assume that voltage E_1 leads I_s by 90°, then E_2 must lag 90° behind I_s. This makes E_1 and E_2 each 90° out-of-phase with E_p, because E_p is 180° out-of-phase with I_s.

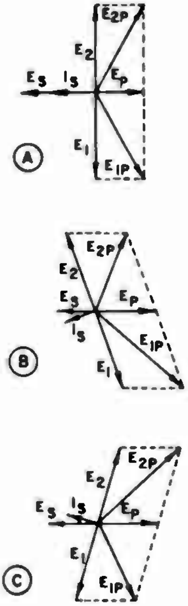

Fig. 14. Phase relationships in the discriminator circuit. (A), when signal is at resonant frequency; (B), when signal frequency is below resonant frequency; (C), when signal frequency is above resonant frequency.

Adding E_p and E_2 vectorially gives E_{2p} as the resultant voltage acting upon diode 2. Likewise, adding E_p and E_1 vectorially gives E_{1p} as the resultant voltage acting upon diode 1. The vector diagram in sketch A shows these two voltages E_{1p} and E_{2p} for the no-modulation condition; therefore, the dc voltages developed across R_1 and R_2 by the two diodes are equal in magnitude and their sum is zero. This is just as it should be, since no audio signal should be obtained when there is no modulation at the transmitter.

When the frequency of the signal is lower than the i-f resting frequency to which resonant circuit L_3-C_3 is tuned, the circuit becomes capacitive, and I_s leads E_s as shown in Fig. 14B. Since voltages E_1 and E_2 must be 90° out-of-phase with I_s, the resultant voltages (E_{2p} and E_{1p}) are unequal, with E_{1p} (the voltage applied to diode 1) the larger. Referring to Fig. 13, you can see that with diode 1 getting the higher rf voltage, there is a higher dc voltage across R_1 than across R_2. The combined voltage across R_1 and R_2 is, therefore, negative with respect to ground. The more the signal frequency swings below the i-f resting frequency, the greater the negative voltage applied to the audio amplifier input.

By a similar analysis we can get the vector diagram shown in Fig. 14C, in which the signal frequency is higher than the resonant frequency. When this occurs, the net voltage applied to the input of the af amplifier (the sum of the drops across R_1 and R_2) is positive with respect to ground.

Thus the frequency discriminator circuit shown in Fig. 13 produces a dc voltage that is proportional to the deviation between the incoming signal frequency and its resting value. Its polarity is determined by the direction of this frequency deviation. In this way the discriminator converts an FM signal directly into a replica of the original audio signal voltage that was used to modulate the FM transmitter.

RF bypass capacitors C_5 and C_6 in Fig. 13 must have a low reactance at the i-f resting frequency, and yet must have a high reactance at audio frequencies so that there will be no serious shunting effect upon the af voltage developed across R_1 and R_2.

The relationship between the incoming rf signal frequency of an FM receiver and the dc output voltage of a discriminator is shown in Fig. 15. At the resting frequency, the dc voltage across the discriminator load resistors is zero when the circuit is properly adjusted. When the frequency is above or below the resting frequency, a dc voltage that is equal to the difference between the voltages across the individual load resistors appears across the combined load. This voltage may be either + or − with respect to the zero level at the resting frequency. A discriminator set up like the one we just described has the response shown in Fig. 15, in which frequencies below resonance produce positive output voltages. This curve is commonly known as an "S" curve.

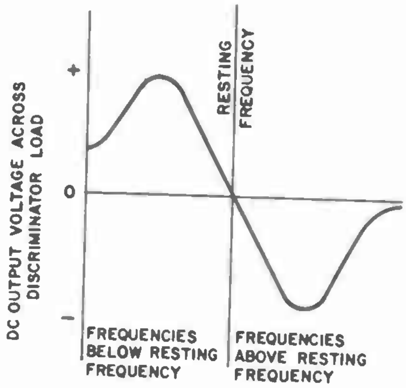

Fig. 15. Typical S response curve for a discriminator circuit.

EXPERIMENT 59

Purpose: To show that in an FM discriminator the amplitude and polarity of the dc output voltage depend upon the frequency deviations of the incoming signal; and

To show that unless this circuit is preceded by a limiter stage, variations in the amplitude of the rf carrier will affect the dc output.

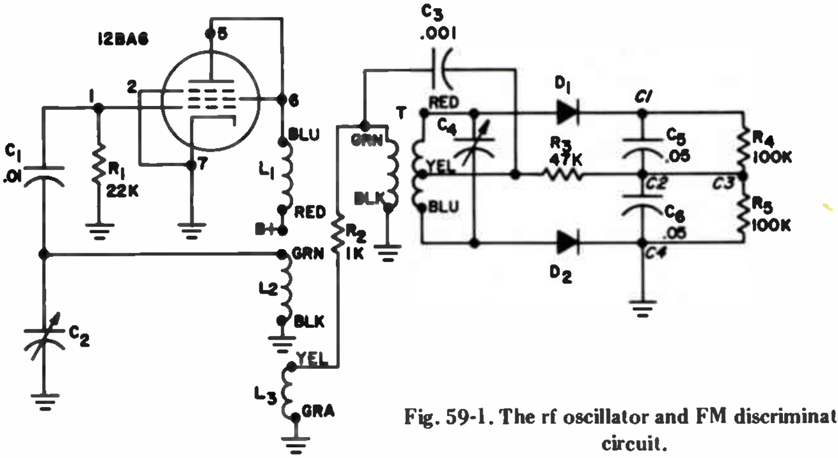

Fig. 59-1. The rf oscillator and FM discriminator circuit.

In proving that a phase discriminator will demodulate an FM signal, you will use the circuit shown in Fig. 59-1. As you can see, it is essentially the same as the basic circuit in Fig. 13. Although we have substituted a resistor for the series inductance L_1 in Fig. 13, the circuit action is the same as that described for the basic circuit.

In normal operation, the audio modulating voltage changes the frequency of the rf carrier so rapidly that the S-curve characteristic can be observed only with an oscilloscope.

However, if we manually adjust the frequency of the rf oscillator to different values above and below an assumed resting frequency, we can measure the dc output voltage for each frequency and plot the S curve.

As shown in Fig. 15, the polarity of the dc voltage across the discriminator load depends on whether the incoming rf signal is above or below the resting frequency. If an ordinary voltmeter is used to indicate the dc output, the polarity of the test leads must be changed when the voltage changes polarity. To avoid this troublesome procedure, servicemen use a voltmeter that has its zero at the center of the scale. Negative voltages swing the meter pointer to the left of zero and positive voltages swing it to the right of zero. There is no need to change the polarity of the test leads to make a reading.

The tvom which you are using in your practical training course can be adjusted so that the zero voltage pointer position is at the center of the scale. When this is done, of course, each range is effectively cut in half. For example, on the 12-volt range you can measure positive or negative 6 volts. When you are instructed to do so, set the tvom to center zero by rotating the zero control and take your readings on the lower two scales. As you perform the steps in the experiment, you may take readings on any range that seems convenient. The important thing is that you take all your readings on the same range.

Experimental Procedure: In order to perform this experiment you will need your tvom, the experimental chassis with the parts on it and the following:

1 1k-ohm resistor
1 22k-ohm resistor

1	47k-ohm resistor
2	100k-ohm resistors
1	.001 mfd disc capacitor
1	.01 mfd disc capacitor
2	.05 mfd disc capacitors
1	12BA6 tube
2	Signal diodes

Some of these parts will be removed from circuits which you used earlier.

First dismantle the circuit wired on the chassis. Unsolder and remove all parts and leads connected to the rf transformer except the leads connecting the blue and red terminals to the trimmer capacitor. Disconnect the leads and parts from the 50k-ohm potentiometer, the oscillator coil, and the 4-lug terminal strip, strip C. Also, remove the leads and the parts connected to all lugs except lugs 4 and 5 on circuit board EC25. Unsolder the tuning capacitor lead from lug 1 of EC25 and connect it to the green terminal of the oscillator coil.

Loosen the screw at hole U and turn the 4-lug terminal strip around so that terminal C1 is toward the rear of the chassis.

Construct the circuit shown in the schematic in Fig. 59-1. Coils L_1, L_2, and L_3 are windings of the oscillator coil mounted at the front of the chassis. The transformer connected to the diodes is the rf transformer. To wire the circuit, proceed as follows:

Connect a length of wire from lug 6 to lug 8 on EC25. Solder lug 8. Solder a length of hookup wire from lug 6 to terminal B1.

Connect a length of wire from the foil connected to pin 6 of the tube socket to lug 9. Solder a length of wire from lug 9 to the blue terminal of the oscillator coil at the front of the chassis.

Connect a 22k-ohm resistor from lug 7 to terminal B7. Solder a .01 mfd capacitor to lug 7. Solder a short length of wire between the free lead of the capacitor and the green terminal of the oscillator coil.

Solder a length of wire from the black terminal of the oscillator coil to ground. Connect a short length of wire from the gray terminal of the oscillator coil to ground. Solder a length of wire from the red terminal of the oscillator coil to terminal A6.

Solder a 1k-ohm resistor to the yellow terminal of the oscillator coil. Solder a piece of hookup wire to the free lead of the resistor and connect the other end of the wire to the green terminal of the rf transformer.

Connect a .001 mfd capacitor between the green and yellow terminals of the rf transformer. Connect the black terminal of the rf transformer to ground, using a short length of wire.

Connect a 47k-ohm resistor between the yellow rf transformer terminal and terminal C2.

Connect a 100k-ohm resistor between terminals C1 and C3. Connect another 100k-ohm resistor between terminals C3 and C4.

Connect a .05 mfd capacitor between terminals C1 and C2. Connect a .05 mfd capacitor between terminals C2 and C4. Solder a piece of wire between terminals C2 and C3.

Connect a signal diode between the red rf transformer terminal and terminal C1, with the cathode lead to terminal C1. Connect a second signal diode between the blue transformer terminal and terminal C4, with the cathode lead to C4. (Use lengths of wire to extend the diode leads.)

Insert the 12BA6 tube in the socket on EC25.

When you complete the wiring, check your work against the schematic diagram. Look for short circuits between the B+ circuit and ground and around the lugs on the circuit board. Also look for poor connections.

To test the oscillator circuit, turn the circuit on and measure the negative grid leak bias voltage across the 22k-ohm resistor in the grid circuit. You should read a negative voltage of 25 volts or more. The presence of grid leak bias is a good indication that the circuit is oscillating.

Step 1: To make the preliminary adjustment of the discriminator circuit.

Set your tvom to measure dc voltage on the 12V range. The polarity switch should be set to reverse, as you will be measuring a negative voltage.

Turn the adjusting screw on the trimmer capacitor fully clockwise for maximum capacity. Clip the tvom ground lead to the chassis. Slip the test clip on the tvom probe and clip the probe to terminal C2.

Set the tuning capacitor to 50 on the dial scale and energize the circuit. Adjust the trimmer capacitor for maximum negative voltage on the meter. If necessary, switch to a higher range to keep the meter from going off scale. Set the trimmer capacitor for the highest negative voltage.

Step 2: To complete the adjustment of the discriminator circuit.

Disconnect the probe from the circuit and return the polarity switch to "normal." Adjust the zero adjust control for center scale zero. The tvom should be set to the 12V range. Clip the probe to terminal C1 and turn the circuit on. Observe the meter carefully. If it does not indicate exactly zero (center scale), readjust the trimmer capacitor slightly until you read zero on the meter. This adjustment is critical so make it very carefully.

Step 3: To show that frequency variations in the incoming signal will cause a variation in the dc output voltage.

Leave your meter connected from terminal C1 to the chassis, and vary the frequency of the incoming signal by varying the setting of the tuning capacitor. Note that when you move the pointer to the right of 50, the meter pointer will go in one direction; when you move the pointer to the left, it will go in the other direction. This shows that the discriminator responds to frequency variations.

Step 4: To show that the polarity of the dc output voltage depends upon whether the frequency deviation of the

carrier is above or below the resting frequency of the carrier.

Reset the rf oscillator frequency control to 50 on the scale, and check to make sure that the meter pointer has not moved to the right or to the left of the center zero position. If it has, bring it back by carefully adjusting the trimmer capacitor.

Set the tuning capacitor to 0 (maximum capacity), and read the meter on the ±6V (12V) scale. Record your reading in Fig. 59-2.

Set the tuning capacitor to each of the dial settings listed in Fig. 59-2, read the meter on the 12V scale for each setting, and record your readings in Fig. 59-2. At 50 the meter pointer should be at center scale, indicating 0 volts. Meter deflections to the right indicate positive polarity; meter deflections to the left indicate negative polarity.

Step 5: To plot your results on the graph in Fig. 59-3.

Oscillator dial settings below 50 on the scale should have produced positive voltages and caused meter pointer deflections to the right of the center zero position. Oscillator dial settings above 50 should give negative voltage readings, causing deflection to the left of the center zero position. Plot the point for the voltage reading for each setting of the dial. Then connect them by drawing a smooth line through the points.

When you have your curve completed, compare it to the curve shown in Fig. 15. Your curve should have a similar shape. It probably won't be as symmetrical as this, but it should be approximately S-shaped.

Step 6: To show that variations in the amplitude of the rf carrier affect the output of the discriminator.

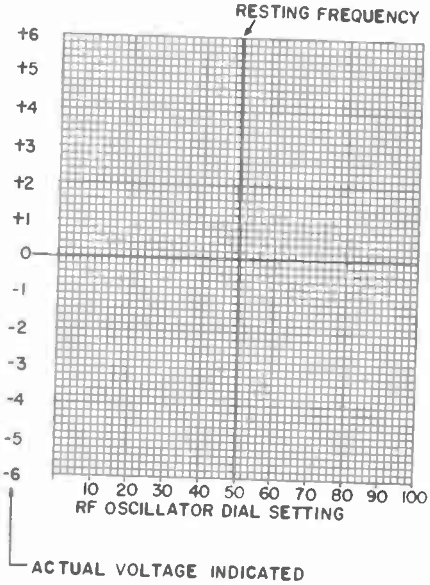

Fig. 59-3. Plot readings for Exp. 59 here.

Adjust the tuning capacitor to some point above or below the resting frequency at which an appreciable meter deflection is obtained, and change the rf input by momentarily shorting the green terminal at the rf transformer, TR31, to the chassis with a screwdriver blade. When this is done, the output of the discriminator should vary. Turn your equipment off.

Discussion: You have shown that changing the frequency of the rf carrier signal applied to a discriminator changes the amplitude of the dc output voltage. Thus, in an FM receiver the dc voltage at the output of the discriminator corresponds to the original signal used to frequency-modulate the carrier. This shows that the discriminator detects, or demodulates, the signal. As you vary the oscillator frequency through resonance with the tuning capacitor, output also varies. The output curve you plot should have nearly an S shape.

Under ideal conditions the S curve will be symmetrical above and below the zero voltage axis of the graph. However, in a practical circuit it is unlikely that the curve will be symmetrical. The circuit may not be balanced due to unequal capacities to ground, variations in the tubes, etc.

In the last step you showed that amplitude variations also affect the dc output. This effect is undesirable in an FM receiver. In an actual receiver a limiter stage is used to remove the amplitude variations, so that the signal applied to the discriminator is of a constant amplitude. In a ratio detector, amplitude variations in the carrier caused by noise or static have very little effect on the output. Thus, a limiter stage is ordinarily not necessary. You will work with a ratio detector in the next experiment.

Instructions for Statement 59: For your report on this experiment you are to find out what will happen when one of the diodes become defective.

Connect the tvom to measure the dc voltage between terminal C1 and the chassis, with the probe connected to C1. Adjust the tuning capacitor so that the voltage is at zero center between the two peaks.

Now disconnect the diode lead from the blue terminal of the rf transformer. Again measure the voltage between C1 and the chassis, and see if the voltage between these points is still zero. Answer the Statement here and on the Report Sheet. Reconnect the diode lead to the blue terminal of the rf transformer.

EXPERIMENT 60

Purpose: To show that a ratio detector will demodulate an FM signal, and that its characteristic has an S shape similar to that of a phase discriminator.

Introductory Discussion: As you learned in the last experiment, the phase discriminator can respond to variations in the amplitude of the input signal, and it will respond to noise signals as well as to the desired FM signal. This response can be overcome by adding a limiter stage between the last i-f amplifier and the FM detector. Many FM receivers, however, use a detector circuit that is in itself relatively insensitive to variations in the amplitude of the rf carrier.

One of these amplitude-insensitive detectors is the "ratio" detector shown in Fig. 60-1. As you can see, it is similar to the discriminator you built in the last experiment, except that one diode is reversed, capacitor C_4 is added, and a change is made in the output connections. As in the phase discriminator,

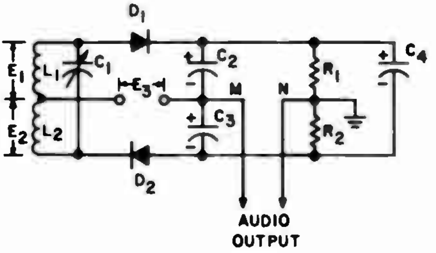

Fig. 60-1. Ratio detector circuit for Exp. 60.

voltages E_1 and E_2 are 180° out-of-phase, and voltage E_3 is 90° out-of-phase with the voltages across L_1 and L_2 when the rf voltage at the input is unmodulated.

As long as the input i-f signal remains at the frequency that corresponds to the center resting frequency of the FM signal, the voltage $E_1 + E_3$ is equal to the voltage $E_2 + E_3$, so the rectified dc voltage across capacitor C_2 is equal to that across capacitor C_3. Since one of the diodes (D_2) is reversed from the connection used in a phase discriminator, the dc voltage across capacitor C_2 and C_3 is the sum of the two voltages rather than the difference. This voltage is across the load resistors R_1 and R_2 and is also applied to capacitor C_4.

The audio output of the stage is developed between points M and N. When the voltages across capacitors C_2 and C_3 are equal, the dc voltage is the same at M as at N. Thus, the audio output, as seen in Fig. 60-2A, is zero when the received signal is at the resting frequency.

Let us suppose we have a voltage of 5 volts each across capacitors C_2 and C_3 in Fig. 60-2A. This makes the total voltage across capacitor C_4 10 volts. Since the value of this capacitor is rather large, it holds its charge for an appreciable time even when the input changes.

Suppose that the frequency of the input i-f signal changes so that the voltage across C_2 increases to 8 volts; the voltage across C_3 decreases to 2 volts. This is shown in Fig. 60-2B. The sum is still 10 volts; and the sum voltage divides equally across the equal value resistors R_1 and R_2. This means that the voltage at M will be 3 volts negative with respect to N. Similarly, if the input frequency should deviate the same amount in the other direction, the voltage across C_2 will decrease to 2 volts, and that across C_3 will increase to 8 volts. As shown in Fig. 60-2C, M will then be 3 volts positive with respect to N.

The action so far is the same as that of the usual phase discriminator circuit. However, the presence of capacitor C_4 makes a difference because it minimizes the effect of amplitude variations in the input. Let us see how.

Capacitor C_4 is charged so that the average voltage across it is proportional to the FM signal strength. Since the capacitor is large, generally 5-mfd to 20-mfd, the time-constant of the circuit consisting of C_4, R_1, and R_2 is about 0.1 to 0.4 second. This means that C_4 is slow in responding to variations in the amplitude of the input signal. If the input signal increases or decreases suddenly, the capacitor voltage is not able to follow the variations. The dc voltage across C_4 can, however, follow slow variations in the amplitude of the input signal.

Let us assume, for example, that a certain value of frequency deviation pro-

duces an 8-volt drop across C_2, and 2 volts across C_3, as shown in Fig. 60-2B. The output voltage will be −3 volts. Now assume that for some reason, say a burst of static or an interfering station, the amplitudes of voltages E_1, E_2, and E_3 all increase equally. The voltages across capacitors C_2 and C_3 will both try to increase. However, since they must always be equal to that across C_4, which cannot change quickly, the voltages across C_2 and C_3 will remain constant despite the sudden increase in input voltage. The extra voltage will be dropped across D_1 and D_2 because more current will flow through them as they attempt to increase the charge on C_4.

Experimental Procedure: For this experiment you need the setup from the last experiment, plus:

1 .01-mfd capacitor
1 6-mfd electrolytic capacitor

Wire the circuit as shown in Fig. 60-3. Only a few changes are necessary to convert your phase discriminator into a ratio detector. First, reverse the connections to diode D_1 so that the cathode is connected to the red terminal at the rf transformer and the anode is connected to terminal C1. Second, separate the junction of R_4 and R_5 from the junction of capacitors C_5 and C_6. To do this, remove the piece of bare wire you connected between terminals C2 and C3. You will measure a dc voltage between these points to get the necessary data for drawing an S curve. Finally, connect a 6-mfd electrolytic capacitor between terminals C1 and C4. Make sure you observe the polarity of the capacitor; connect the positive lead to terminal C4, as shown in the diagram. Check your work carefully.

Step 1: Adjust the ratio detector circuit.

The adjustment of this circuit is essentially the same as for the phase discriminator, except that the connections for dc output voltages are different. Adjust your tvom for center scale zero as in the last experiment. Connect the ground clip at the junction of resistors R_4 and R_5, terminal C3, and the probe at the junction of capacitors C_5 and C_6, at terminal C2. The tvom should be set to

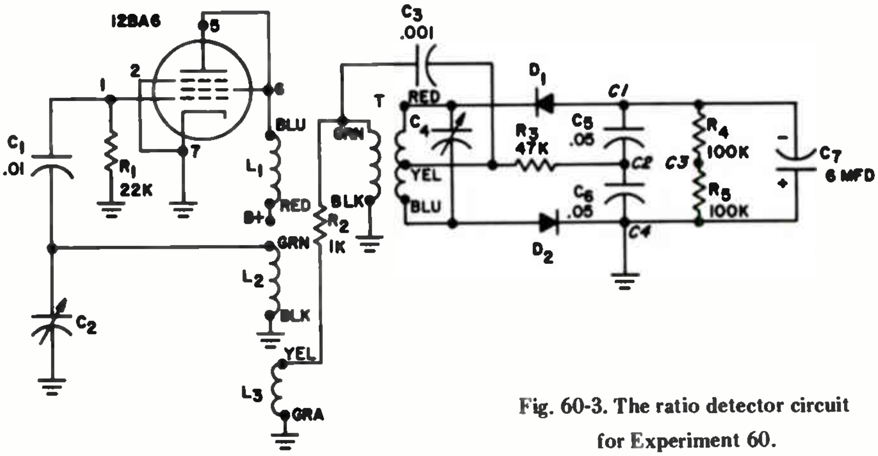

Fig. 60-3. The ratio detector circuit for Experiment 60.

"normal." Apply power to the circuit. Now, set the tuning capacitor to 50 and adjust the trimmer capacitor for the zero-center reading between the two peaks.

Step 2: To show that a ratio detector will demodulate an FM signal.

Apply power and tune the tuning capacitor to either side of the resting frequency as you did in the previous experiment, noting that the dc output voltage changes as the input signal varies in frequency.

Step 3: To show that a ratio detector has an S-shaped dc output characteristic.

With the tvom connected as described in Step 1, turn the range selector switch to 12V, and measure the dc output of the ratio detector. You will not make measurements over the entire frequency range, only enough to show the S-shaped characteristic.

Starting with the tuning capacitor, set at 30, take the readings of the dc output at each of the settings listed in Fig. 60-4. Record your readings in Fig. 60-4. Notice that the readings for dial settings below 50 should make the meter pointer move to the right. Frequencies higher than the resting frequency should make the meter pointer move to the left.

Plot your results in Fig. 60-5. The curve should be S-shaped.

Discussion: Again as in the previous experiment, the S curve is small because of the limited rf input voltage. We can increase the rf input by reducing the value of R_2, but doing so will decrease the degree of isolation between L_3 and the rf transformer. If the rf transformer is not sufficiently decoupled from L_3, any adjustment of capacitor C_4 will tend to change the frequency of the rf oscillator.

A ratio detector is properly tuned when the secondary of the rf transformer is set for zero dc output at the i-f resting frequency. In some ratio-detector circuits a single resistor is used in place of R_4 and R_5. In order to check a circuit of this type for proper tuning, you will have to add a series combination of two resistors of equal value in parallel with this single resistor. This will give you a point to which you can connect a dc voltmeter.

Instructions for Statement 60: For your report on this experiment you are to determine how the capacity of the stabilizing capacitor C_7 affects the dc voltage across resistors R_4 and R_5 when the amplitude of the input is varied rapidly.

Solder a short length of hookup wire to the yellow terminal of the rf oscillator coil. Arrange the free end of this lead so that you can tap it against the chassis two or three times a second, thereby varying the rf input rapidly between its normal value and zero. Readjust the Zero control so that the meter pointer is at 0 on the left side of the meter scale. Connect the ground lead of the tvom to the chassis and connect the probe to terminal C1. Set the polarity switch to reverse.

After making sure that the ratio detector is properly adjusted, measure the dc voltage across capacitor C_7. Now vary the amplitude of the rf carrier by tapping the lead you soldered to the yellow terminal at the oscillator coil against the chassis. Watch the meter when you do this. There should be very little if any change in the meter reading.

Now, disconnect the 6-mfd capacitor C_7, and connect a .01-mfd capacitor in its place. Check the dc voltage across this capacitor, repeat the grounding procedure to simulate a varying rf amplitude, and watch the meter. Turn your equipment off and indicate the results of this test in the Statement for this experiment.

Statement No. 60: When I decreased the capacity of capacitor C_7 to .01-mfd, and then rapidly changed the amplitude of the rf signal, the dc voltage across the .01-mfd capacitor:

(1) remained unchanged.
[✓ *(2) varied appreciably.*]

A REVIEW

This completes your demonstrations of basic circuit actions; you will go on to service techniques in your next kit. Let us review what you have learned.

First of all, you have learned how to solder, a technique all radio and television technicians must master. You should now be able to use just the right amount of solder to make good electrical connections. Also, you should have formed the habit of checking your soldering iron tip frequently, and filing and retinning it when necessary.

By assembling and dismantling circuit after circuit, you have learned how to handle many kinds of electronic parts. Perhaps you learned the hard way that resistor and capacitor leads may break after being bent back and forth several times, and that you must be careful when you work with them.

Your work of assembling and tracing circuits undoubtedly speeded up after you learned to identify resistor values by the color code and after you became adept at handling your pliers, cutters, hookup wire, and the NRI tvom. You no longer should find it necessary to puzzle over the connections for any kind of measurement the instrument will make. The correct procedures should now come to you naturally.

Another important accomplishment you have gained is the ability to assemble a circuit without the aid of a pictorial diagram. You now know that there are many different ways in which a circuit can be assembled and still correspond electrically to a schematic.

Your work with rf circuits taught you the important technique of tuning circuits to resonance at a given frequency so as to produce a maximum output voltage. You will use this every time you align a radio or TV set.

If there is any question in your mind concerning your ability in any one of the techniques we have listed here, concentrate on that particular technique. For example; if you still find it difficult to use a schematic diagram to locate parts, get an old receiver and the circuit diagram for it and practice tracing out the circuit. It is still not too late to master the technique of tuning resonant circuits, of tracing circuits, or of soldering.

These are only a few of the many practical things you have learned as you demonstrated fundamental circuit actions ranging from Ohm's Law to the theory and practice of frequency modulation.

LOOKING AHEAD

In your next kit you will build an ac-dc receiver, complete with a PM speaker and an efficient ferrite loop antenna. You will get a special chassis on which to assemble the set, and a 2-gang tuning capacitor. When you have the receiver assembled, you will carry out complete voltage measurements and make point-to-point resistance tests on it. Then you will align it for normal operation within the standard broadcast band.

The ten experiments in the next kit have been designed to give you practical experience in recognizing the symptoms of common defects in general radio service work. This experience, plus the training you have already had, will give you the background you need to qualify as a real expert.

You will probably want to do some experimenting on your own using the parts left over from the experiments. If so, you will want to put your audio oscillator back into operation and you will want to build an rf oscillator.

Audio Frequency Oscillator. The oscillator which you used in the early part of this kit is complete except for the 1k-ohm stability control. Reinstall the potentiometer on the board and wire it in as shown in the schematic diagram in Fig. 6. To use the oscillator, connect 12V to 20V dc between the ground foil and square 5F and take the output signal between square 1E and ground.

When you need a 1k-ohm potentiometer in the experiments in the future kits, you will have to remove the potentiometer from your oscillator.

RF Oscillator. The schematic diagram of an oscillator which you can build from your available parts is shown in Fig. 16. This is a Clapp oscillator and, as you can see, it is very similar to the Colpitts oscillator which you used in experiments 56 through 58. You should still have circuit board EC25, the oscillator coil and the tuning capacitor mounted on the

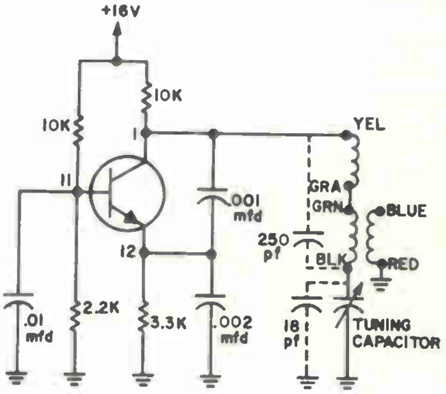

Fig. 16. Schematic of rf oscillator circuit.

chassis. Therefore you will find the circuit easy to wire. Wire the oscillator from the schematic. For the present, do not connect the 250 pf and 18 pf capacitors. The connections to the transistor are made to lugs 1, 11, and 12, and the operating voltage is supplied by the low voltage power supply on circuit board EC24.

Remove all other parts from the chassis and clean their leads and terminals. Put the parts in a safe place as you may need them for carrying out future experiments.

To test the oscillator, you can measure the ac voltage across the secondary (red/blue) winding of the oscillator coil. You should read up to 1V ac as you vary the oscillator frequency. A more reliable way to test the oscillator is to tune an AM receiver to a station at about the center of the dial and see if your oscillator can produce interference. Solder about a 3 ft length of hookup wire to the yellow terminal of the oscillator coil and bring the end near the receiver. Tune your oscillator throughout its range while listening to the radio. You should be able to hear the interference.

Refer to the schematic in Fig. 16 to see how the oscillator works. The transistor is operated in the common base configuration, with the input applied to the emitter and the output taken off at the collector. The feedback necessary to sustain oscillations is coupled through the capacitive voltage divider from the collector to the emitter. Collector voltage is provided through the 10k-ohm load resistor.

The frequency of oscillation is determined by the network made up of the series-connected coils, the tuning capacitor and the capacitive voltage divider. The tuning capacitor, being in series with the two coils, varies the effective or net inductance of the coils. This net inductance, in turn, resonates with the total capacitance of the capacitors in the voltage divider. The oscillator frequency is approximately equal to the resonant frequency of this circuit.

The frequency range of the basic oscillator circuit is from about 570 kHz to about 1650 kHz, which nearly covers the AM broadcast band. The frequency range can be lowered to include the AM receiver intermediate frequency by connecting the 250 pf and 18 pf capacitors as shown in Fig. 16. The lower range is approximately 410 to 540 kHz.

You can determine the oscillator frequency by "zero beating" its output with known radio frequencies such as the carrier frequencies of AM radio stations. Tune in a station on the radio and adjust the oscillator until you hear a squeal in the audio. What you hear is the difference frequency between the radio station carrier frequency and the output of your oscillator. As the oscillator frequency is brought closer to the carrier frequency, the pitch of the audio becomes lower. The oscillator frequency is then nearly equal to the carrier frequency.

To set the oscillator to the receiver intermediate frequency, (usually about 455 kHz) connect the 250 pf and 18 pf capacitors into the circuit as shown by the dotted lines in Fig. 16 and tune the oscillator until you hear a squeal in the receiver. This should occur at a dial setting of about 50. Try other stations. They all have the same i-f, therefore they should all have interference.

Disconnect the oscillator circuits from the low voltage power supply whenever they are not being used to minimize undesirable interference.

Will Power and Won't Power

People point out a successful man and say he has a lot of will power. It's true that will power is a necessary requisite of success. But seldom mentioned and just as important is "won't power" – the power to say "No" at the proper time.

"Won't power" alone does not guarantee success in any venture, but when used at the right time, is as important as will power.

When you are tempted to neglect your studies, use *won't* power. If you have not already done so, lay out a schedule for regular study every week and use *will* power to stick to it.

That combination of "I will" and "I won't" can lift you to heights even beyond your fondest dreams today.

INSTRUCTIONS FOR PERFORMING RADIO-TV EXPERIMENTS 61 THROUGH 70

This transistor radio kit is designed to give you practical experience working with transistor circuits. You are already familiar with the principles of operation of a radio receiver. In previous kits you have worked with typical circuits found in receivers. From your transistor experiments you know how transistor stages operate. In this kit you perform experiments on every stage of an all-transistor radio receiver.

You may or may not have already performed the 7YY experiments on the NRI ac-dc five-tube radio receiver. If you have experimented with the tube receiver, you are familiar with many troubleshooting techniques that are common to both tube and transistor receivers. That experience will help you with your transistor radio troubleshooting. For example, a block diagram of an AM receiver will apply to either type; the same signals are present in the various sections of either type of receiver.

However, from the standpoint of practical servicing, the receiver types are quite different. Big differences are found in the voltage level of signals in various sections of the receiver. The impedance levels tend to be very low in transistor circuits compared to similar points in tube circuits. Many test procedures that work on tube receivers are useless on transistor sets.

On the other hand, if you have not experimented with the tube set, it will not cause difficulties. This transistor radio set of experiments is complete in itself, just as the tube experiments are complete. After you complete these experiments on the transistor receiver, you may want to obtain the 7YY Kit on the tube receiver. Both kits give you practical experience in troubleshooting radio receivers. The 7YY Kit helps you learn to service tube receivers and the 7TT Kit pertains to transistor receivers.

Before you perform the experiments in this kit, you assemble the receiver. The set goes together quickly because most of the parts are mounted on a printed circuit board. Since this may be your first experience with printed circuit boards, you are given instructions pertaining to soldering, replacing components, and repairing printed circuit boards.

Even if you have worked with printed circuit equipment, you can learn from these instructions. We have included some extra printed circuit wiring on the board especially for these instructions. Since this part of the board is not used for the radio, you don't have to worry about damaging the foil. You experiment with this wiring before any parts are mounted on the board.

You complete the receiver and test it before you run the experiments. In some experiments, you remove and replace components from the circuit board. This duplicates parts replacement, which is often performed when repairing receivers. In one of your final experiments, you practice alignment procedures and finally peak up your receiver for best operation. After completing the experiments you install the receiver in its cabinet. You then have an attractive table model receiver for your own use.

CONTENTS OF THIS KIT

In this kit you receive all the parts necessary for building your complete transistor radio. Additional parts are supplied for experiments. Some of the parts for the experiments are parts that are left over from previous kits.

IMPORTANT: The oscillator and i-f transformers supplied in this kit have been preset. Do not move the adjustments on these transformers until you are told to do so. The use of preset transformers assures that your receiver alignment will be accurate enough to receive some stations when you complete construction. After you have the set in operation, you will be instructed how to improve the alignment.

The parts for building the radio are illustrated in Fig. 1 and listed below the photograph. The parts used in the experiments are listed separately. The list indicates those parts left over from previous experiments that will be used again here.

Check the parts you receive against the Parts List to be sure you have all of them. If any part in the kit is obviously defective or has been damaged in shipment, return it to NRI immediately, as directed on the packing slip included in this kit.

LEARNING TO WORK ON CIRCUIT BOARDS

Etched circuit boards are widely used in all types of electronic equipment. The circuit board, EC21, supplied with this kit is typical of those used in radio and TV receivers. Examine the circuit board carefully. The board is made of a phenolic insulating material with a pattern of copper foil bonded onto one side. The terms "etched circuit" or "printed circuit" board come from the manufacturing process. The stock board consists of the phenolic material with a thin sheet of copper foil bonded to one side.

The circuit pattern is transferred to the foil by a photographic process or a silk-screen process similar to that used in the printing industry. The board is then placed in a chemical bath that etches away the copper foil in those places not covered by the circuit pattern. The board is cleaned. Then the writing and symbols are screened on to the "phenolic" or "component" side of the board. The component leads are soldered to the circuit wiring on the "foil" or "circuit" side of the board.

Certain precautions must be followed when working on circuit boards to prevent damage. The phenolic material is somewhat brittle. It can break easily if it is dropped or if too much pressure is applied to it. An assembled board with heavy components on it is subject to cracking.

Rough handling will sometimes produce a board crack that breaks one or more of the foil circuit paths. These cracks often produce intermittent defects and may be difficult to locate. In cases where you cannot see the crack, it is sometimes easiest to simply flow molten solder along the circuit path where a crack is suspected. The solder will bridge the break and repair the circuit.

On some finished circuit boards, the entire foil surface is covered with solder. The solder is put on as part of the board assembly operation. The component leads are inserted through the holes in the board, the foil side of the board is dipped into a container of molten solder. Solder adheres to all exposed foil and solders all the component leads in place at one time.

Excessive heat can weaken the bond between the foil and the phenolic; heat and pressure will cause the foil to peel off the phenolic. Once the foil breaks clear of the phenolic, it is quite fragile and will break off easily. A 35-watt soldering iron is adequate for assembling or repairing the circuit board. If you use a higher wattage iron, you must not hold it against the foil for too long a time. Excessive heat can also char the phenolic material and produce leakage paths between different circuits on the board.

The foil associated with holes Q, R, S, and T on your circuit board is not part of the radio circuit. This foil is for you to practice on. You can apply enough heat to damage the foil. In steps that follow we even show you the wrong way to solder the circuit board. In this way you will get a feel for how much heat it is safe to apply when constructing or repairing etched circuits.

Practice Wiring to Circuit Board. You will need your hand tools, etched circuit board EC21, and two 1k-ohm resistors (brown-black-red) that are among the parts furnished for experiments.

Bend the leads 90° on each end of a 1k-ohm resistor. Insert the leads through holes Q and S from the phenolic side of the board. Push the resistor firmly onto the board. Spread the leads slightly so the resistor stays in place when you turn the

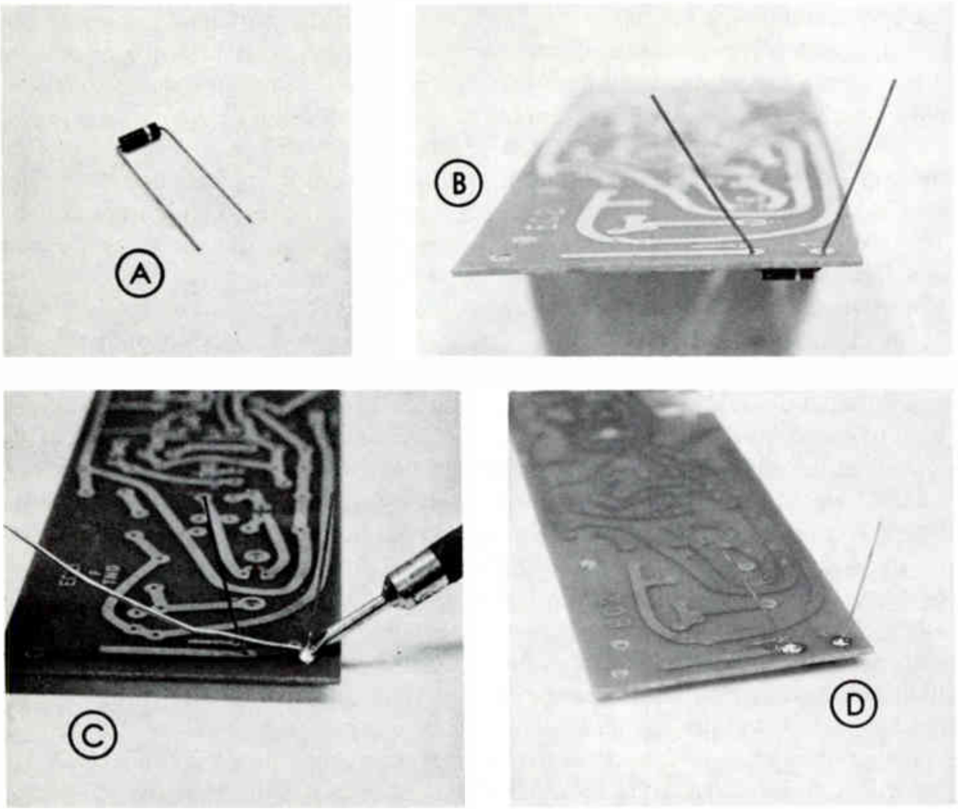

Fig. 2. (A) Bend the resistor leads 90° before inserting into mounting holes of circuit board; (B) bend leads slightly to hold resistor in place during soldering; (C) hold the soldering iron tip in contact with both foil and lead while solder is being applied; (D) use just enough solder to fill in the joint between foil and lead.

board over. Fig. 2A and Fig. 2B show how to install the resistor.

Next hold the hot soldering iron in contact with both the foil and the lead, as shown in Fig. 2C. Touch the solder to the junction of the iron tip and the circuit. Watch the solder spread over the foil and the lead, making sure that it adheres to both of them. Limit the amount of solder that you apply to the junction. Use just enough to produce smooth rounded fillets between the lead and the foil, as shown in Fig. 2D.

Excess solder can be removed by heating the joint and holding the board in a position that lets the solder run down onto the iron tip. Too much solder or too little heat produces round globs of solder that do not "wet" down into the junction. Too little solder leaves the junction weak or fails to fill in all around the lead. Too much heat causes the junction to smoke and the area to change color. When the solder hardens, clip off the lead that extends beyond the soldered connection.

When troubleshooting on a circuit board, it is sometimes desirable to disconnect one end of a component from the circuit. This can be done if you work carefully. Try it on the resistor you just installed at holes Q and S. Simply heat the connection on the foil side at hole Q. Use a scratch awl or thin-bladed screwdriver to pry the resistor away from the phenolic side of the board while you hold the iron tip against the connection. Lift the end of the resistor at hole Q high enough to remove the lead from the hole. The resistor is now positioned so that you can take resistance measurements or other tests for which the resistor must be isolated from the circuit.

Clean the solder out of the hole before you attempt to reconnect the resistor lead to the circuit. A round toothpick makes an excellent tool to clean the solder from the hole. Simply heat the solder, force the end of the toothpick into the hole from the foil side of the board, and remove the soldering iron. The solder will cool and will leave a hole when you remove the toothpick. In place of the toothpick, you can use a wire paper clip or other wire that solder will not stick to.

If you attempt to reconnect the resistor lead without cleaning the hole, you risk pulling the foil loose from the board. When you force the lead through the hole, the lead tends to catch on the edge of the foil in the hole. Heat and pressure will then cause the foil to separate from the board. The narrow sections of foil like that at hole Q are especially liable to damage. Try reconnecting the lead at hole Q. When you are satisfied with the connection, unsolder and remove the resistor from holes Q and S. If the foil is not damaged, reheat the foil at hole Q. Apply enough heat, and if necessary some pressure, so you see what is required to remove the foil.

Examine the unbonded edge of the foil. Notice that it is quite thin and brittle. From this you can see that once the foil separates from the board, that part of the foil can no longer be counted on to form a reliable portion of the circuit. You have to perform additional repairs to the foil circuit for a reliable repair job.

The foil at hole S may have separated from the board when you removed the resistor. When applying heat to the foil on a circuit board, always consider the area of the foil. Hole S has only a small area of foil so it is easy to overheat it. When the foil is wider or covers a larger area, the heat is conducted away from the point where the soldering iron touches and the foil is less likely to be damaged.

Clean the solder off the leads of the resistor that you removed from holes Q and S. Adjust the lead spacing to fit and install the resistor at holes R and T. Seat the resistor body against the phenolic side of the board and carefully solder the lead connection, using the right amount of heat and solder.

How to Repair Broken Wiring. As mentioned before, etched circuits may develop cracks from rough handling. Or during troubleshooting you may want to isolate a component by cutting the foil on a circuit board. In either case you need to repair the break to put the circuit back in operation. Simulate this condition by cutting the foil that extends from hole R. Use a pocket knife or razor blade to make a narrow cut at right angles to the strip of foil, as shown in Fig. 3A. Only a little pressure is necessary to cut through the foil. You can check with an ohmmeter to be sure that the foil is separated. Next, touch your soldering iron to the foil on one side of the cut. Flow some solder onto the heated foil. Notice that the solder does not readily flow across the cut. A hairline crack can often be exposed by this means. The solder melts right up to the crack, but the crack prevents the heat from conducting to the parts of the foil beyond the break.

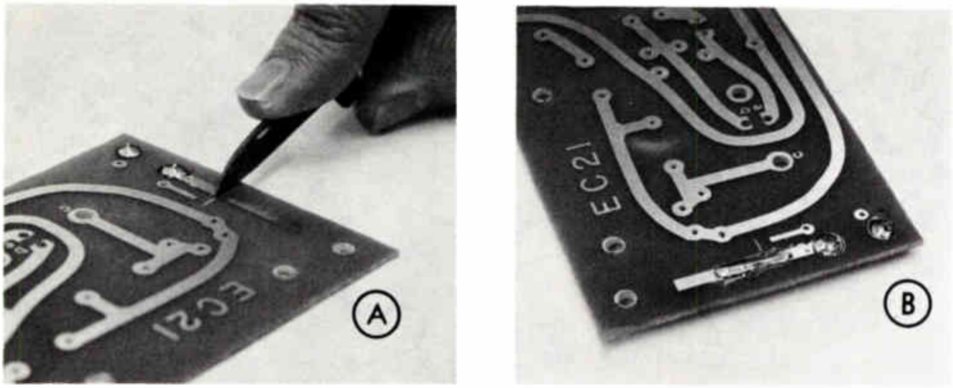

Fig. 3. (A) Cut through the foil to break the etched circuit board wiring, (B) the broken circuit can be bridged by soldering a piece of wire to foil.

Flow some solder onto the foil on the other side of the break and bridge the molten solder across the break. For a narrow break where the phenolic has not been damaged, this repair is adequate. However, if you made a wide cut you may have trouble getting the solder to bridge across it. In that case, reinforce the break with a short piece of bare hookup wire. Simply lay the wire along the foil so it extends across the break and solder it in place, as shown in Fig. 3B. The repair is stronger than the original circuit.

This repair technique can be varied to repair almost any damaged circuit foil. On occasion, you may wish to repair a board where the phenolic is cracked or where a piece has actually broken off the board. A stronger repair can be made by drilling a small hole on each side of the break. Use bare hookup wire to join the two sections together. Then solder the wire to the foil while holding the pieces of the board together in place.

How to Replace Components from the Top of the Circuit Board. The circuit board for your 7TT receiver is not very crowded with components. The parts have been spread out, so it is easy to assemble and perform experiments on the board. This will not always be true for sets that you may have occasion to repair. In some radios and on many TV receivers, the parts are densely packed on the circuit board. In other cases it is difficult to remove the board or reach the foil side of the board. Replacing a component from the top of the board may save you hours of work. You can practice this type of repair by replacing the resistor that you have installed at holes R and T of your circuit board.

Fig. 4 shows the steps involved in replacing a resistor from the top of the board. Use your diagonal pliers to crush the body of the resistor, as shown in Fig. 4A. Use your longnose pliers to straighten the short resistor leads that extend above the board, as shown in Fig. 4B. Next, bend the leads of the replacement resistor to attach them to the short leads extending through the board holes. The 1k-ohm replacement resistor may or may not be placed against the circuit board, depending upon how much room you have to work in. Twist the wires about half a turn so that connections are mechanically secure, as shown in Fig. 4C. Now solder

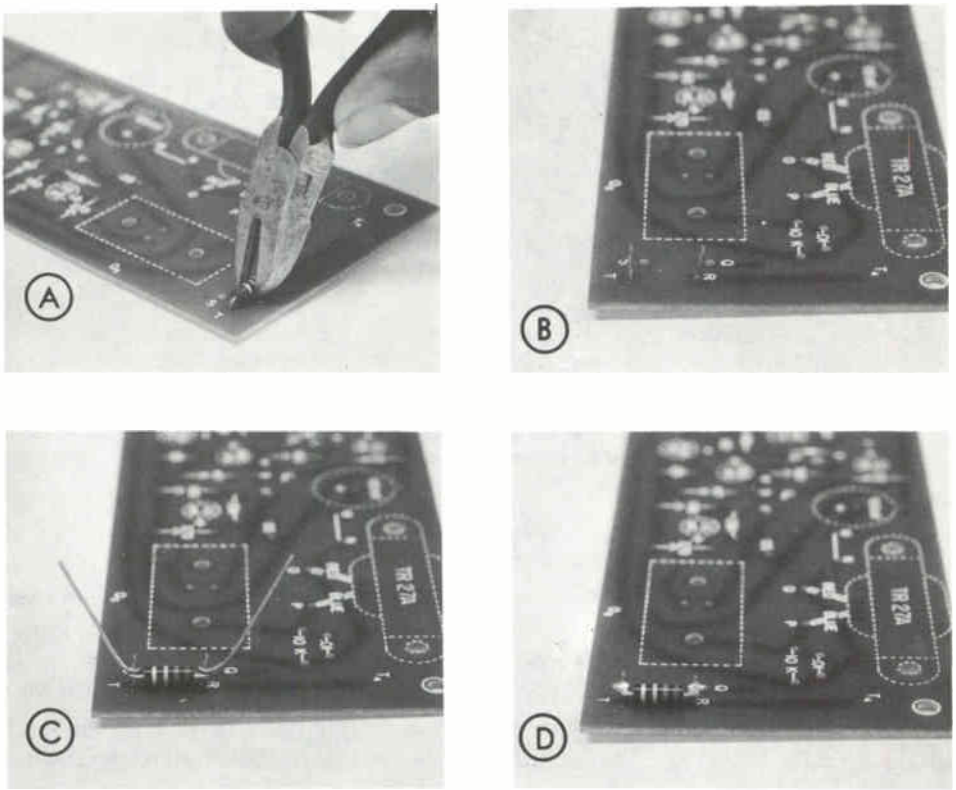

Fig. 4. Steps in replacing a resistor from the component side of the board. Crush the resistor with pliers as shown at (A); straighten the remaining leads as shown at (B). Connect the new resistor leads to the existing leads as shown at (C); solder the connections and clip off the excess lead length as shown at (D).

both joints. Make the solder connections quickly so you do not melt the solder that connects the original resistor leads to the foil on the board. Use your diagonal pliers to trim off the excess wire for a neat connection, as shown in Fig. 4D.

The techniques you practice here can be adapted to almost any repair problem that you will encounter when working on circuit boards.

Unsolder and remove the resistor that you connected at holes R and T.

Assembling Your Experimental Receiver

Your assembly work on your receiver is divided into three sections. First you assemble the etched circuit board. Then you assemble the parts that attach to the front panel. Finally you attach the assembled circuit board to the front panel and perform the interconnecting wiring.

When you perform the assembly work on this kit, remember that you are manufacturing a complete receiver. This is quite different from assembling an experimental kit where you expect to tear down the assembly after you complete the experiments. In this kit you are expected to make permanent wiring connections and be careful with parts placements and lead dress. Take the necessary time and effort to do a professional job. You will be repaid in pride of workmanship, and you will have the satisfaction of the set working the first time you turn it on.

Read and understand the entire sentence or paragraph of each step before you perform the work. Position each part and lead according to the description and illustrations. After you have completed each step, place a check mark in the space provided. This will ensure that you complete the steps in the correct sequence and do not omit any.

ASSEMBLING THE CIRCUIT BOARD

In this section you mount and solder the parts that attach to the circuit board. The instructions for mounting the parts are contained in Figs. 5, 6, 7, and 8. (Figs. 6, 7, and 8 are in the center of this book.) Fig. 5 is a detailed drawing. Fig. 6 shows the steps for mounting the resistors; Fig. 7 shows the steps for mounting the capacitors; Fig. 8 gives the steps for mounting the transformers, transistors, and diodes. Be sure to read all the instructions for work that you must perform before you carry out steps shown in the figures.

Mounting the Resistors. You will need your hand tools and soldering iron at your work surface. Gather the following parts:

1	Etched circuit board (EC21)
1	AC interlock (IC2)
2	1/4" X 6-32 screws
2	No. 6 lockwashers
2	6-32 hex nuts
1	82k-ohm resistor
1	470k-ohm resistor
1	270k-ohm resistor
2	22k-ohm resistors
1	18k-ohm resistor
1	10k-ohm, 2W resistor
1	10k-ohm, 1/2W resistor
2	6.8k-ohm resistors
1	4.7k-ohm resistor
1	2.2k-ohm resistor
1	1.5k-ohm resistor
1	1k-ohm resistor
1	820-ohm resistor
1	680-ohm resistor
1	560-ohm resistor
1	270-ohm resistor
1	250-ohm, 4W resistor
1	180-ohm resistor
1	100-ohm resistor
	Black hookup wire

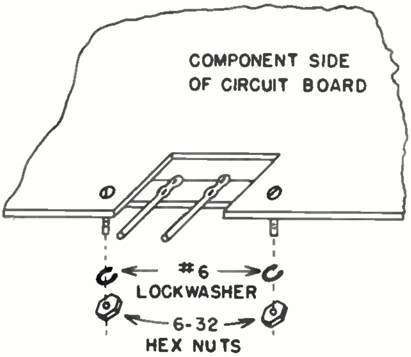

Fig. 5. Details for mounting the ac interlock at the cutout on the board.

Mount the ac interlock in the cutout at the rear edge of the circuit board. Place the interlock on the foil side of the board with the metal pins up toward the phenolic side of the circuit board, as shown in the detailed drawing, Fig. 5. Insert 1/4" X 6-32 screws through the mounting holes from the phenolic side of the board. The screws extend through the mounting holes of the interlock. Attach a No. 6 lockwasher and a 6-32 hex nut to each screw. Tighten the screws . . . . (✓)

Next, perform the steps for mounting the resistors and jumpers as outlined in Fig. 6. When you install a resistor, measure the part against the two mounting holes that the leads are to go in. Then bend the leads so they are at right angles to the body of the resistor, and so that the leads fit into the mounting holes. Put the leads through the holes from the phenolic side of the board. Bend the leads slightly on the foil side of the board so that the part will not fall out before it is soldered in place.

After you have mounted a few parts, stop and solder the leads to the copper on the foil side of the board, and then clip off the excess lead lengths.

NOTE: Use only RADIO ROSIN-CORE SOLDER. This is the type we supply with this kit. Do not use acid-core solder or paste flux. Either will ruin a circuit board so that it cannot be repaired. We cannot repair any kit on which acid-core solder has been used.

INSTALLING THE RESISTORS

In steps 5, 11, and 21 of Fig. 6, form each jumper from a piece of bare wire. Resistor lead scraps will do nicely. Install the jumpers from the component side of the board.

In step 20 of Fig. 6, the 250-ohm, 4-watt resistor connects between one mounting hole and one terminal of the ac interlock. Since this resistor gets warm in operation, mount it so the body of the resistor is from about 1/8" to about 1/4" above the board. The 2-watt resistor used in step 18 should be mounted about 1/8" above the board. All other resistors are mounted tight against the board.

In step 21 of Fig. 6, connect the jumper from hole G of the circuit board to the adjacent terminal of the ac interlock.

When you have completed the steps outlined in Fig. 6, place a check mark here . . . . (✓)

INSTALLING THE CAPACITORS

You will need the following parts:

1 220 pf disc capacitor
1 6.8 pf disc capacitor
1 220 mfd at 35 VDC electrolytic capacitor
1 100 mfd at 150 VDC electrolytic capacitor
1 100 mfd at 10 VDC electrolytic capacitor

3 10 mfd at 10 VDC electrolytic capacitors
1 .1 mfd disc capacitor
6 .05 mfd disc capacitors
1 .02 mfd disc capacitor
2 .01 mfd disc capacitors
1 .005 mfd disc capacitor
1 .001 mfd disc capacitor

The instruction steps for mounting the capacitors are contained in Fig. 7. When you mount the electrolytic capacitors, be sure to observe the polarity markings. A plus mark is screened on the circuit board near the hole for the positive lead of the capacitor. The 100 mfd capacitor installed in Step 8 may not have the positive lead identified. It is the lead in the center of the capacitor body, while the negative lead is bent down along the outside of the body. In Step 14, bend the positive lead down along the body of the capacitor before you install it. The circuit board may be screened "200 mf" at this location.

When you have completed all the steps outlined in Fig. 7, place a check mark here ....(✓)

INSTALLING THE TRANSFORMERS, TRANSISTORS, AND DIODES

You will need the following parts:

1 Oscillator transformer (TR75)
1 Input i-f transformer (TR76)
1 Output i-f transformer (TR77)
1 Audio output transformer (TR27A)
4 EN1132 transistors
1 Power transistor
1 Heat sink (BR73)
1 Detector diode
1 Power rectifier diode
4 3/8" X 6-32 screws
6 No. 6 lockwashers
4 6-32 hex nuts
2 No. 8 flat metal washers

The instruction steps for mounting the listed parts are contained in Fig. 8. Be sure to identify these parts carefully when installing them. It is very difficult to unsolder and remove the 5 or 6 terminals if you happen to mount a transformer in the wrong place.

In step 4 of Fig. 8, a green dot on the base of the transformer is used to identify terminal 1 of the transformer. Position the transformer so the dot on the transformer matches the dot indication on the screening of the circuit board.

In step 9 of Fig. 8, position the audio output transformer on the phenolic side of the board so the bare wires extend toward the edge of the board. Insert 3/8" X 6-32 screws through the mounting feet of the transformer and place a No. 8 flat washer over each screw. Pass the screws through the mounting holes in the circuit board so the two washers are between the mounting feet and the board.

Attach a No. 6 lockwasher and a 6-32 hex nut to each screw. Tighten the screws. Shorten the red and blue transformer wires to a length of about 2". Strip off about 1/4" of insulation from the end of each lead. Solder the red lead of the transformer into hole O and the blue lead into hole P, as shown in Fig. 8.

Consult the detailed drawing, Fig. 9, for identification of the transistor leads for steps 2, 3, 5, and 8. Mount these transistors about 1/4" above the board so the leads are not pulled tight against the mounting holes. You can use an alligator

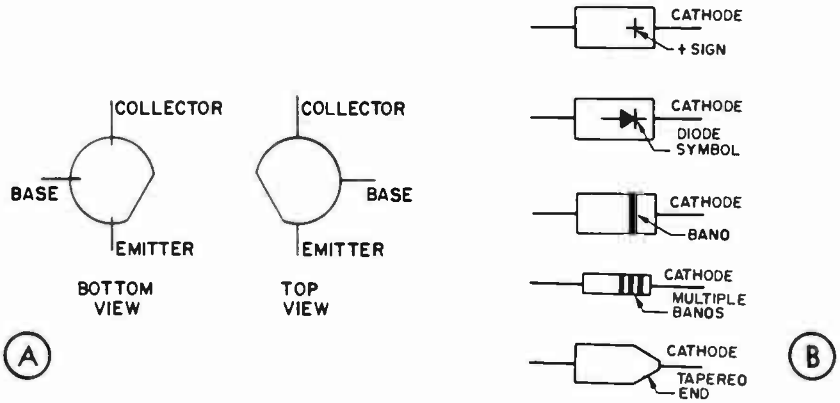

Fig. 9. How to identify transistor leads (A) and diode polarity (B).

clip as a heat sink while soldering the leads of the transistors. Simply attach the alligator clip to the lead on the component side of the board. Turn the board over and solder the connection.

In step 10 of Fig. 8, mount the power transistor (TS33) and its heat sink (BR73) with two 3/8" X 6-32 screws, four No. 6 lockwashers, and two 6-32 nuts (see detail A). First place the transistor inside the heat sink so that its pins pass through the small holes in the center of the heat sink, and so that the transistor mounting holes line up with the large holes at the ends of the heat sink. Pass a 3/8" X 6-32 screw through the transistor and heat sink holes at each end. Then put a No. 6 lockwasher on each screw. Now attach the assembly to the circuit board with two more No. 6 lockwashers and two 6-32 nuts. Be sure to position the transistor so that its pins plug easily into the circuit board. Finally, tighten the mounting hardware and solder the two transistor pins to the circuit board foil. Observe the polarity of the diodes for steps 7 and 11 of Fig. 8.

When you have completed the steps outlined in Fig. 8, place a check mark here .... ( )

This completes the assembly of your circuit board. Examine your work carefully. Look for poor solder connections where you used too little heat or too much solder. If necessary, reheat the connection and remove excess solder. Make sure you have not bridged solder from one part of the foil to the foil in another circuit. When you are satisfied with your work, set the board to one side while you assemble the other parts of the receiver.

ASSEMBLING THE FRONT PANEL

In this section you fasten parts to the front panel. Some hardware and parts are put together as an assembly before you attach the assembly to the panel. Treat the panel with care, because rough handling can mar the plastic finish or even crack the mounting posts.

You will need your hand tools and the following parts:

1 Front panel
1 Dial plate with red line
1 Plain dial plate
1 Gray edge mounting
2 Circuit board support brackets
2 Spade bolts

- 1 Tuning capacitor
- 1 Volume control bracket
- 1 Volume control with switch
- 1 Loopstick antenna
- 1 Speaker
- 2 3/8" cable clamps
- 8 1/4" No. 6 self-tapping screws
- 4 Speaker mounting clips
- 3 1/4" X 6-32 screws
- 4 6-32 hex nuts
- 5 No. 6 lockwashers

Attach Trim to the Front Panel. Refer to Fig. 10A and Fig. 10B as you mount the decorative trim on the front panel.

Position the dial plate with the red line so that the red line is pointing straight up. Put the dial plate in the upper recess of the panel after bending the three tabs so they pass through slots 1, 2, and 3 of the panel as shown in Fig. 10A. The red line should be between slots 1 and 2 . . . . (✓)

Put the plain round dial plate in the lower recess after bending the three tabs so they pass through slots 4, 5, and 6. (✓)

Mount the gray edge molding so the four mounting tabs pass through slots 7, 8, 9, and 10. Slot 9 is on the rear edge of the panel . . . . (✓)

With the three trim pieces pressed firmly against the front panel, bend the 10 mounting tabs as shown in Fig. 10B (✓)

Circuit Board Support Brackets. The next step will be to prepare the support brackets and fasten them to the front panel (as shown in Fig. 11 and Fig. 12).

Attach a 6-32 hex nut to each of the two spade bolts. Tighten the nuts against the "spade" part of the bolt . . . . ( )

Fasten one of the 6-32 spade bolts in hole B of one of the support brackets as shown in Fig. 11. Position the "spade" part parallel to the short dimension of the bracket and secure with a No. 6 lockwasher and a 6-32 hex nut . . . . ( )

In a similar manner, fasten the other

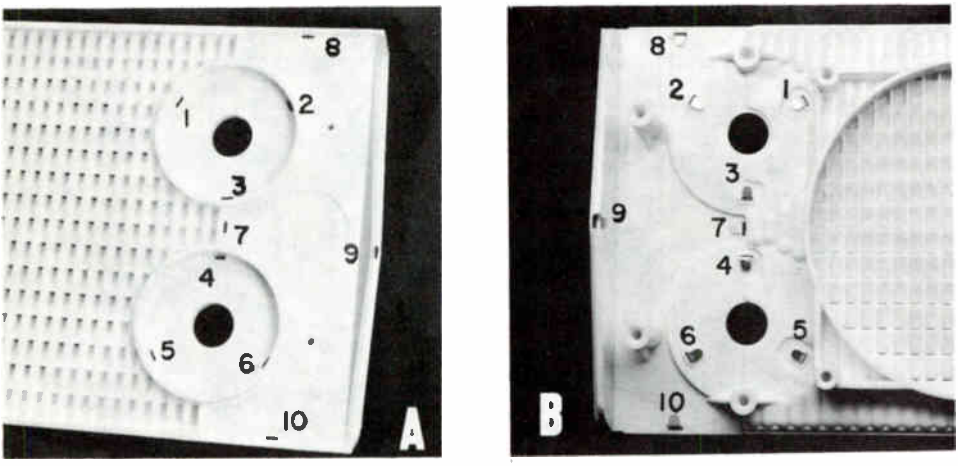

Fig. 10. Mounting the slots for panel trim (A); bending mounting tabs of panel trim (B).

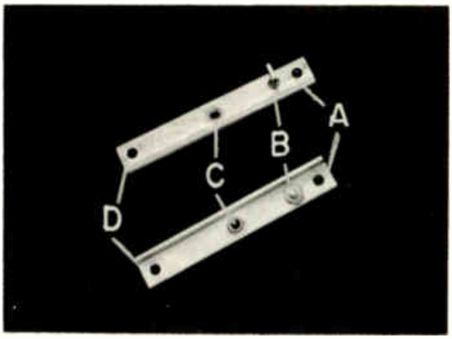

Fig. 11. Circuit board mounting brackets.

6-32 spade bolt in hole B of the other support bracket . . . . ( )

Place the front panel face down on a cloth in front of you. Position the two large holes in the panel to your left, as shown in Fig. 12.

Place one of the support brackets over the two posts on the left of the panel. Position the bracket so that holes A and D are over the holes in the ends of the posts. The "spade" part of the spade lug should be nearest you and pointing straight up. Fasten the bracket to the front panel with two 1/4" No. 6 self-tapping screws. It is important that you tighten these screws very slowly and that you do not overtighten them. As you turn the screw, it cuts threads in the plastic. If the screw starts to turn hard, back off about a quarter turn and again tighten the screw. This will tend to clear the threads and enable you to get the screw all the way in without cracking the plastic. The plastic posts, although strong, may crack if too much force is used in tightening these screws . . . . ( )

In a similar manner, fasten the other support bracket to the two posts on the right end of the front panel. Fig. 12 shows the support brackets mounted in place . . . . ( )

Mount the Speaker. Position the loudspeaker on the front panel with speaker lugs S1 and S2 to your right, as shown in Fig. 12 . . . . ( )

Push a loudspeaker mounting clip over each of the four loudspeaker mounting posts on the front panel. Make sure that the speaker presses evenly at all points against the front panel . . . . ( )

Mount Parts on the Volume Control Bracket. Set the front panel out of your

way temporarily while you assemble the parts on the volume control bracket. Fig. 13 shows a rear view of the bracket with the holes identified. Fig. 14 shows the bracket with the parts mounted.

Slip the shaft of the volume control potentiometer through hole D from the rear of the bracket. Position the control so the locating lug extends through hole D_1. Attach a control nut and tighten it firmly . . . . ( )

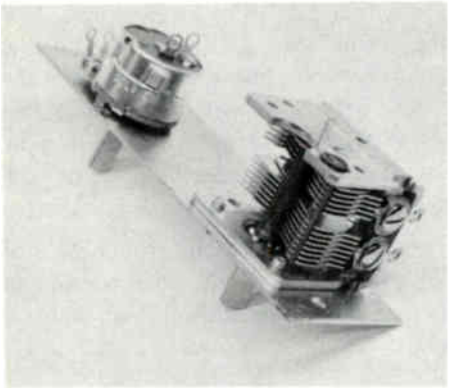

Fig. 14. Volume control bracket with parts mounted.

Slip the shaft of the tuning capacitor through hole C from the rear of the bracket. Position the capacitor so holes C_1, C_2, and C_3 line up with the three threaded holes in the tuning capacitor frame. Slip a No. 6 lockwasher over each of three 1/4" X 6-32 screws. Insert a 1/4" X 6-32 screw with lockwasher attached into holes C_1, C_2, and C_3 from the front of the bracket. Tighten the screws into the threaded holes in the frame of the capacitor . . . . ( )

Attach Volume Control Bracket, Antenna. Fig. 15 shows the front panel with all parts, except the circuit board, mounted in place. Position the volume control bracket, with parts attached, to the rear of the front panel so the shafts extend through the control shaft holes. In this position, holes A and E in the volume control bracket line up with mounting posts on the front panel.

Insert 1/4" No. 6 self-tapping screws through holes A and E and into the mounting post holes. Carefully tighten the screws into the plastic. Do not over-tighten . . . . ( )

Examine your loopstick antenna. The black ferrite core is quite brittle and will break rather easily if it is dropped. Also be careful not to apply any flexing pressure to the rod. The rod is partially covered with two wire windings. The long winding forms the coil for the rf tank circuit. The short winding is the secondary winding that carries the received signal to the input circuitry of the receiver. As shown in Fig. 15, the short winding end of the loopstick goes toward the tuning capacitor.

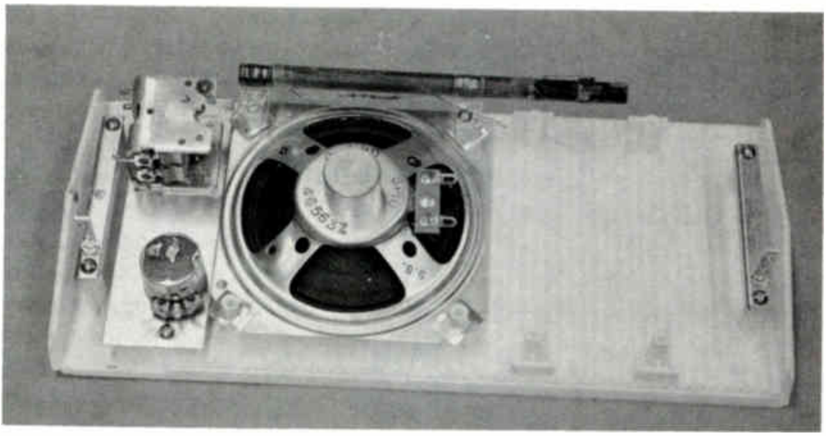

Fig. 15. Rear view of front panel with all parts, except the circuit board, mounted in place.

Slip a 3/8" plastic cable clamp over the long winding section of the loopstick. Slip another 3/8" plastic cable clamp over the bare end of the ferrite core at the short winding end. Hold the antenna next to the two top speaker mounting posts and slide the cable clamps to fit the posts. Insert 1/4" No. 6 self-tapping screws through the cable clamp mounting holes and into the holes of the speaker mounting posts. Tighten the screws carefully. Do not overtighten . . . . (✓)

FINAL ASSEMBLY AND WIRING

In this section you attach the assembled circuit board to the assembled front panel and complete the final wiring of the receiver. Fig. 16 shows a top view of the completed wiring. Fig. 17 shows a bottom view of the completed wiring.

You will need the assembled front panel, the preassembled circuit board, and:

1	Tuning knob
1	Volume control knob
2	1/4" X 6-32 screws
2	No. 6 lockwashers
2	6-32 hex nuts
	Assorted hookup wire

Position the circuit board to the rear of the panel so the board rests on the spade portion of the spade lugs. Position the board so the two board mounting holes line up with the holes in the spade lugs. Use the holes farthest from the panel so the board clears the switch terminals and speaker. Insert a 1/4" X 6-32 screw from the top of the board into each mounting hole. Attach a No. 6 lockwasher and 6-32 hex nut to each screw. Tighten the nuts firmly . . . . (✓)

Connect a 1-1/4" wire from hole A of the circuit board to one terminal of the on-off switch. Insert the wire into the hole from the top of the board. Route the wire over the edge of the board to the switch terminal. Solder both of the connections . . . . ( )

Connect a 1-1/4" wire from hole B of the circuit board to the other terminal of the on-off switch. Solder both connections . . . . ( )

Connect a 2-3/4" wire from hole C of the circuit board to the solder lug on the frame of the tuning capacitor. Solder hole C of the circuit board . . . . ( )

Connect a 2-1/4" wire from hole D of the circuit board to the terminal on the oscillator section of the tuning capacitor. Solder both connections . . . . ( )

Locate the two varnished wires from the secondary of the audio output transformer. Connect a transformer wire to each speaker terminal. Solder both terminals . . . . ( )

Prepare a 7" cable from three pieces of hookup wire. Cut a 7" piece each of red, white, and black hookup wire. Twist the three wires together so that they form a loose cable. Strip 1/4" of insulation off of the end of each piece of wire in the cable . . . .( )

Refer to Fig. 18 when you perform the following steps.

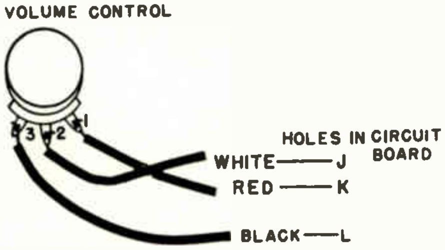

Fig. 18. Details for wiring the volume control to the circuit board.

Connect the wires at one end of the 7" cable to holes J, K, and L from the top of the circuit board. The white wire goes into hole J, the red wire into hole K and the black wire into hole L. Solder all three wires to the foil on the circuit board .... ( )

Identify the wires from the coils of the loopstick antenna. Two wires come from the short secondary coil and two wires come from the long rf coil. These wires are rather fragile and can be broken by rough handling. If you break a wire, or if a wire is too short to reach the indicated terminal, splice on a piece of hookup wire to reach the terminals.

Connect one wire from the short secondary coil of the loopstick antenna to hole E of the circuit board. Solder the wire to the foil .... ( )

Connect the other wire from the long rf coil of the loopstick antenna to the terminal on the rf section of the tuning capacitor. The rf section contains the largest number of plates and is the section nearest the front panel. Route the wire close to the front panel. Solder the connection .... ( )

Push the tuning knob onto the shaft of the tuning capacitor .... ( )

Push the volume control knob onto the shaft of the volume control potentiometer .... ( )

This completes the assembly and wiring of your receiver. You will not install the receiver in the cabinet until after you perform the experiments. Examine your work carefully. Look for bits of wire that may have fallen on top of the circuit board. Look for unsoldered connections, poorly soldered connections, or globs of solder that could cause short circuits. When you are satisfied with your work, proceed to the next section where you are given instructions for testing the receiver.

Testing and Analyzing the Receiver

In this section, you become familiar with your receiver circuitry in preparation for performing the experiments. You record a set of voltage and resistance measurements on your receiver. This assures you that your receiver is wired correctly. Also, you use the recorded voltage measurements as a reference when you are performing the experiments.

As you know, the voltage measurements will vary from set to set. These variations are caused by normal parts tolerances. When you record a set of readings using your own meter on your own receiver, you have a valid set of readings that you can refer to. This is important for analyzing results of experiments. The accurate readings are also helpful in case you have to troubleshoot your receiver.

For this section you will use two important illustrations that are located in the center of the book. Fig. 19 is the schematic diagram of the receiver. You will want to keep this diagram handy to follow circuit discussions. Fig. 20 is a "see-through" diagram of the circuit board. This diagram shows the circuit board as it appears from the foil side of the board. The components are shown in schematic form as they would appear if you could see through the circuit board. Use this drawing to locate test points in the circuit and parts on the circuit board.

CAUTION

Dangerous voltages are present in your receiver. As you know, any ac-operated device carries sufficient voltage to kill you. Even if you use an isolation transformer, the lethal voltages are present within the receiver circuitry. The isolation transformer only protects you from a difference in potential between the receiver and an external earth ground.

Since you have not installed the set in the cabinet, you have in effect defeated the purpose of the ac interlock. Observe all safety precautions. If you are not using an isolation transformer, be sure you are standing on an insulated surface. A damp concrete surface is especially dangerous. Do not work close to an earth ground such as a water pipe.

Unplug the line cord when you make changes in the circuitry. It is almost as easy to unplug the cord from the interlock as it is to turn off the switch. Unplugging the cord gives you complete protection to work on the circuitry. If you work on the energized receiver, steady the set by holding on to the plastic front. Use only one hand to touch live points in the circuit.

Remember that dangerous voltages are present at some points on the component side of the board. For example, the body and vaned heat sink of transistor Q_5 is at the B++ potential of approximately 120 volts dc.

PRELIMINARY TESTS

Before you plug your receiver into the ac power line, you should perform one simple ohmmeter test. Connect the ground clip of your meter to the foil marked B– on the circuit board. Touch the probe to the foil marked B++. You should measure about 4k-ohms of resistance. If you read 0 ohms or a sizable amount less than 4k-ohms, look for a short circuit on the circuit board. Look for solder that is bridged between the B++ and the B– foil on the board. Look for pieces of bare wire that may be shorting between component leads on the component side of the circuit board. If you energize the receiver before clearing the short, you will probably damage components in the power supply circuit.

When you are satisfied that the B++ line is not shorted, energize the receiver. Connect the power line cord to the ac interlock of the receiver. Plug the other end of the cord into a 115-volt ac outlet or into the outlet of an isolation transformer.

Turn the receiver on by rotating the volume control clockwise to actuate the on-off switch. Advance the volume control about halfway. Rotate the tuning knob to tune in a station. Adjust the volume control for normal listening level.

Determine what AM radio stations are available in your area and the transmission frequency of these stations. Your local newspaper probably lists all the local stations, their call letters, and their frequencies.

Tune your receiver across the band and determine if you can receive all available stations. Note the position of the tuning dial for each station to see if your dial indicates the frequencies of the received stations.

The transformers in your receiver are preset so the receiver should be fairly well aligned, but you can improve the alignment. Locate the plastic alignment tool, AT3, that is furnished with the receiver. You will need this tool and a small screwdriver.

Tune the receiver to a weak station. Make sure you are tuned exactly on the station, which is the tuning point where the signal comes in loudest. Using the "see-through" diagram in Fig. 20, locate the input i-f transformer, T_2, on the circuit board. Use your alignment tool to adjust the slugs in the transformer. The hexagon-shaped part of the tool at one end fits the hexagon hole in the transformer slug.

Rotate the top slug either clockwise or counterclockwise, as necessary, to increase the volume of the received station. A fraction of a turn should be all that is necessary to peak the signal. Reach the alignment tool through the hole in the circuit board to adjust the bottom slug in transformer T_2.

Locate the i-f output transformer, T_3. Use a screwdriver to fit the slot in the core at the top of the transformer. Adjust the core as necessary to again peak the received signal. The i-f amplifier is now properly adjusted.

Tune your receiver to the lowest frequency station that you can receive in your area. See if the tuning dial indicates the correct frequency. If not, set the dial to the correct frequency for the station and use a screwdriver to rotate the slug in transformer T_1 in either direction, as necessary, to receive the station.

Next, tune to the highest frequency station that you can receive. Identify the frequency of the station. Observe the position of the tuning dial to see if it indicates the frequency of the received station. If it does not, set the tuning dial to the frequency of the received station and adjust the oscillator trimmer capacitor to receive the station. The oscillator trimmer capacitor is attached to the oscillator section of the tuning capacitor. The oscillator section of the tuning capacitor is the section farthest from the front panel and having the fewest plates. Use a screwdriver to adjust the screw in the trimmer capacitor.

If you moved the core of T_1 very far or adjusted the oscillator trimmer very far, repeat these two adjustments until you get no further improvement.

Finally, adjust the trimmer capacitor on the rf section of the tuning capacitor. This is the trimmer closest to the front panel. Tune the receiver to a weak station near the high end of the broadcast band. Adjust the rf trimmer for maximum received signal.

The touch-up alignment adjustments that you just performed should be adequate for now. In your last experiment, you will perform alignment experiments and finally perform a complete alignment procedure on your receiver.

CIRCUIT DESCRIPTION

The line-operated, superheterodyne AM broadcast-band radio receiver shown in schematic form in Fig. 19 uses five transistors and two diodes. Diode D_2 rectifies the 115-volt ac from the power line. The 250-ohm, 4-watt resistor, R_{21}, is a surge-limiting resistor used to limit the current through the diode. The .01 mfd capacitor, C_{24}, protects the diode from line transients. The output of the half-wave rectifier is filtered by C_{23} and supplies about 120 volts dc B++ to the power output stage, Q_5. The B++ voltage is dropped by the 10k-ohm resistor, R_{20}, to about 19 volts B+ to supply all other stages of the receiver. The B+ line is filtered by the 200 mfd capacitor, C_{22}. Capacitor C_{21} is a ceramic disc capacitor used to provide an rf bypass on the B+ line.

The rf signals from broadcast-band radio stations are picked up by the loopstick antenna, L_1. The rf section of the tuning capacitor, C_1, and the trimmer capacitor, C_2, form the capacitor portion of the tuned rf tank circuit of the antenna. The received rf signals are transformer-coupled to the low-impedance secondary winding of the loopstick antenna, L_1.

The rf signal from the secondary is coupled through R_7 to the base of the mixer stage, Q_2. A local oscillator signal is coupled through C_7, developed across R_6 and C_9, and applied through the secondary of L_1 and through R_7 to the base of Q_2.

The local oscillator signal is generated by the transistor Hartley oscillator stage, Q_1. A positive supply voltage is applied through the voltage-dropping resistor, R_{19}, and through the 3-5 winding of the primary of T_1 to the emitter of the PNP transistor, Q_1. The entire primary winding of T_1 forms the inductive portion of the oscillator tank circuit. The oscillator section of the tuning capacitor, C_3, provides the capacitive portion of the oscillator tank circuit. Capacitor C_4 is the oscillator trimmer capacitor in parallel with C_3. The .05 mfd capacitor, C_5, completes the signal path circuit of the tank.

The secondary winding of T_1 provides a feedback path for the oscillator circuit and provides the oscillator output signal that is coupled through C_7 to the mixer stage. The phase of the signal at terminal 4 of the secondary of T_1 is of the correct polarity to sustain oscillation. The signal is coupled through C_6 to the base of Q_1. Transistor Q_1 is biased to its operating point by the potential at the junction of R_2 and R_1.

The 470k-ohm resistor, R_5, and the .1 mfd capacitor, C_8, isolate the capacitor frame and the volume control bracket from B−. As you know, B− connects to one side of the ac power line. If B− is connected directly to the capacitor frame and the volume control bracket, a dangerous situation could develop. It would then be possible to touch one side of the ac line by removing a knob and touching the metal shaft of either the tuning capacitor or the volume control. The R-C network, consisting of R_5 and C_8, provides a signal path to the tuning capacitor frame and keeps ac leakage to a safe value.

The PNP mixer stage, Q_2, is supplied a positive voltage from the B+ line through the 820-ohm dropping resistor, R_3, to the emitter. The collector circuit of Q_2 is completed to B− through the 5-3 tap-down section of the primary of T_2. The tapped winding on the primary of T_2 provides a low impedance match for the collector of Q_2, and the full primary winding and the capacitor across the winding form a high Q tank circuit tuned to the 455 kHz intermediate frequency of the receiver.

The fixed bias network for Q_2 is combined with the avc circuit. The voltage at the junction of R_6 and R_8 is applied through the secondary winding of L_1, and through R_7 to the base of Q_2. B+ voltage is supplied through the detector circuit (and through volume control P_1), through the 18k-ohm resistor, R_{11}, through R_8 and R_6 and returned to B−.

The detected audio signal at the output of the second detector, D_1, is a positive voltage that adds to the positive fixed bias. The larger the signal at the second detector, the larger the positive voltage that is added to the fixed bias. Since a positive voltage on the base of Q_2 acts as reverse bias, a larger detector signal reduces the gain of the mixer stage, Q_2. In this way, avc is applied to the mixer stage. The avc voltage is filtered by the 10 mfd filter capacitor, C_{11}.

An avc voltage is also applied to the i-f amplifier stage, Q_3. To see how this is done, examine the base circuit of Q_3 and the emitter circuit of Q_2. A static or fixed bias is applied to the base of Q_3 by the action of the voltage divider network consisting of R_3, R_4, and R_9. The dc potential at the emitter of Q_2 follows the dc potential at the base of Q_2.

Therefore, when an avc voltage raises the potential at the base of Q_2, the transistor conducts less and the emitter voltage also increases. The voltage at the emitter of Q_2 is filtered by C_{10}. The dc voltage at the emitter of Q_2 is supplied through R_4 and through the 2-6 winding of T_2 to the base of Q_3. In this way, avc voltage changes are applied to the base of Q_3 and affect the gain of the stage.

Since a positive avc voltage is applied to both Q_2 and Q_3, the avc voltage is reverse-acting. That is, a strong signal produces a positive avc voltage that reduces the conduction of Q_2 and Q_3, and reduces the gain of both stages.

The selected rf station signal and the local oscillator signal are heterodyned in the base-emitter junction of transistor Q_2. Amplified sum and difference signals, plus the two original signals, appear in the collector circuit of Q_2. The tuned i-f amplifier transformer, T_2, selects only the difference, 455 kHz, and rejects all other frequencies. The 455 kHz i-f signal is transformer-coupled to the secondary of T_2 and applied to the base of Q_3.

Transistor stage Q_3 is a transformer-coupled, neutralized, i-f amplifier. The amplified i-f signal is developed in the primary winding of the tuned i-f transformer, T_3, and coupled to the low impedance, untuned secondary winding of T_3. A sizable interelement capacitance exists between the base and collector of the transistor. The interelement capacitance can cause degeneration and loss of gain. Or when the collector load is inductive, it is possible for the capacitance to cause oscillation. To prevent this capacitance from causing degeneration, the capacitance is neutralized by the neutralizing capacitor, C_{14}. The signal at terminal 4 of T_3 is of the correct polarity to neutralize the effect of interelement capacitance in the transistor when the i-f is tuned to 455 kHz.

Now the signal from the secondary of transformer T_3 is applied to the second detector circuit. Diode D_1 rectifies the i-f signal and capacitor C_{15} filters the rectified signal. The detected audio signal is developed across the volume control potentiometer, P_1.

The desired amount of audio signal is picked off by the slider of P_1 and coupled through the 10 mfd electrolytic coupling capacitor, C_{16}, to the base of the audio driver stage, Q_4. The operating point for Q_4 is set by the voltage divider network consisting of R_{13} and R_{12}. The PNP transistor, Q_4, is supplied from the B+ line through the 560-ohm bypassed emitter resistor, R_{14}. The collector circuit is completed to B− through resistors R_{15} and R_{16}.

The amplified audio signal at the collector, Q_4, is direct-coupled to the base of Q_5. Since the circuit is direct-coupled, the collector potential for Q_4 is also the base voltage for Q_5. Therefore the operating point for Q_5 is fixed by the average conduction of Q_4.

Transistor Q_5 is an NPN transistor and is supplied from B++ through the primary of the audio output transformer, T_4, to the collector of Q_5. Resistor R_{18} and capacitor C_{20} damp out voltage transients that could exceed the breakdown voltage rating of the transistor. Capacitor C_{17} in the base circuit of Q_5 helps filter signal transients that could develop damaging voltages in the collector circuit of Q_5. The unbypassed emitter resistor, R_{17}, provides negative feedback that reduces distortion originating in the output stage, Q_5.

Capacitor C_{19}, in the emitter-base circuit of Q_5, improves the impedance match and shapes the audio response curve. The audio signal at the emitter of Q_5 is the same phase as the driving signal at the base of Q_5, because the emitter signal follows the base signal. Capacitor C_{19} couples the emitter signal back to the junction of R_{15} and R_{16} in the base circuit of the transistor.

The values of the resistors in the R_{15}-R_{16} network determine the amount of feedback. Since the signals are in phase, the feedback is essentially positive feedback that increases the gain of the stage. Also the positive feedback reduces the driving power required by the signal driving Q_5. This increases the effective input impedance of the Q_5 base circuit, so it more nearly matches the impedance of the collector circuit of Q_4.

The audio response is limited to a band of frequencies from about 100 Hz to about 6000 Hz. Capacitor C_{17} attenuates the high frequencies, including noise. Low frequency roll-off is caused by coupling capacitor C_{16} and by the small inductance of the audio output transformer. The audio section has more than adequate gain for normal strength stations. On strong local stations, the repro-

duced sound will distort badly before the volume control is turned wide open. Distortion remains well below 2% for audio output levels below 500 milliwatts. This is more than adequate sound for normal listening levels.

VOLTAGE AND RESISTANCE CHARTS

The voltage chart in Fig. 21 and the resistance chart in Fig. 22 give typical readings obtained on the CONAR Model 7TT receiver. Spaces are provided in the charts to record your own readings on your receiver. Use the schematic diagram of the receiver, Fig. 19, and the "see-through" drawing of the circuit board, Fig. 20, to locate the test points on your receiver. Be sure to observe the notes on the charts that give you the setup conditions for taking the readings. You will find these charts very useful in understanding the effects of defects that you insert in the receiver circuitry when performing experiments.

Performing Experiments 61 Through 70

Your receiver should now be in good operating condition for performing the experiments. In performing these experiments, you often remove parts and make circuit changes. We usually remind you to test the receiver after you complete each change. If you fail to correct a wiring change and go on with the experiment, you can end up with confusing symptoms.

As you complete each experiment, perform the step for answering the statement question. Be sure to read carefully all choices for each statement. In some cases a choice may be partially correct. In other cases you have to choose the most nearly correct of several choices. If you have made careful observations while doing the experiment and the step for the statement, you will have no trouble answering the statement. Take special care to correctly transfer your answers to the Report Statement sheet that you mail in for grading.

EXPERIMENT 61

Purpose: To show that a meter can be used to indicate the presence or absence of signals in certain stages of a transistor radio receiver.

Introductory Discussion: Your meter (vtvm or tvom) can often be used to quickly isolate a defect in a radio receiver. In this experiment you examine the capabilities and limitations of the meter for determining if signals are present in certain stages of the receiver.

It is convenient to be able to test for signals with the meter. When you first open the defective receiver, one of your first tests may be to check for the presence of the required power supply voltage. For this test, you would normally use your meter.

Since you have the meter hooked up to the receiver, it is convenient to use it to test for signals. In most cases, a reading or two with your meter will isolate the trouble to one section of the receiver or even to a particular stage. At least you will be able to eliminate several of the possible causes of the defect. Also, the results of your test will indicate to you what other methods of investigation should be used to locate the defect in the particular receiver you are working on.

In this experiment, you will examine what signals can be observed using only the meter. You may know of better ways to test a particular function of a receiver. For example, a circuit disturbance or signal injection method is probably the quickest and easiest way to test the audio section. But you can also trace the audio signal with your meter.

An experienced serviceman will always have several different methods of testing to choose from. He may use an alternate method of testing to prove a suspected defect, or special conditions may make the preferred test method impractical.

Knowing many test methods improves your understanding of circuit operation. It also reduces the chance of your being stumped by an unusual defect that does not respond to your usual preferred test methods.

Experimental Procedure: To perform the steps of this experiment, you need only your operating receiver and your meter.

Set the receiver on your work surface with the foil side of the printed circuit board facing you. A convenient position is with the chassis resting on its left end. The left edge of the front panel and the left edge of the circuit board support the receiver in a stable, upright position. In this position, the weight of the receiver is not resting on any parts that could otherwise be damaged. Also you can reach both sides of the circuit board. Tack-solder a short piece of hookup wire to the B– foil. This provides a convenient place to clip the common lead of your meter.

Use the schematic diagram of the receiver (Fig. 19) to follow the discussions relating to circuit operation. Use the "see-through" diagram (Fig. 20) of the circuit board to locate test points and components on the circuit board.

Test your receiver operation both before and after each step of an experiment; otherwise, you may introduce another defect before the previous one is corrected. This can cause waste of time, confusing results from an experiment, or damage to some components of your receiver.

Step 1: To show how the meter can be used to localize a defect causing a dead set to one section of the receiver.

The audio detector is the dividing line between the rf section and the af section of a receiver. A test at this point will isolate the defect to either one of these two signal-handling sections of the receiver. This test is a logical first step in isolating the defect in a dead receiver.

Tack-solder a short piece of hookup wire across the voice coil terminals of the speaker. This will simulate a dead receiver and allow you to turn the volume control maximum without the annoyance of the loud audio. Connect the ground clip of your meter to B– on the receiver. Set your meter to measure +dc on the 30-volt range. Touch the meter probe to terminal 3 of the volume control, P_1. You should read 15 volts or more.

From the schematic diagram, notice that the volume control is connected to the B+ line, so you will read approximately B+ anywhere in the detector circuit. Notice also that terminal 3 of P_1 connects to the output of the detector diode. Therefore, the detected audio signal will simply add to the B+ voltage value.

Tune the receiver slowly across the band while observing the meter pointer. The reading increases when you tune to a station, indicating that the detector is rectifying the received signal.

Move the ground clip of your meter to terminal 1 of the volume control, P_1. Turn the Range switch to the 3-volt range. Again touch the probe to terminal 3 of the volume control and tune across the band. With the meter hooked up this way, the meter indicates only the voltage produced by the action of the diode detector. On strong stations, you may get a reading of .5 volt or more. A very weak station may produce a reading of only .1 volt. Between stations, the pointer returns to zero.

This test tells you definitely that the rf section is working, and that the defect lies in the af signal path between the detector and the speaker.

Step 2: To trace a signal through the audio section of the receiver with a meter.

Leave the receiver and test equipment set up as you had it for Step 1. Switch the meter Function switch to ac and again touch the probe to terminal 3 of P_1. On a strong station, you should observe that the meter needle fluctuates a small amount, but does not give a very definite reading. Connect the ground clip of the meter to B– and touch the probe to the base of Q_4. When the volume control is turned fully clockwise, the ac reading will be about the same as that obtained at the output of the detector.

If you are used to working with tube radios, you may find these results unusual. As you know, the transistor is a current-operated device. The output of the detector must work into the relatively low impedance of the base circuit of the driver transistor. Therefore, the volume control potentiometer is 2.5k-ohms instead of about one-half a megohm, as usually found in tube receivers. Also, the coupling capacitor is 10 mfd instead of the .01 to .05 mfd commonly found in tube sets. This circuit is designed to vary the base current of the driver transistor. Therefore, the ac voltage variations are too small to give a usable indication on the meter.

Next, switch the Range switch of your meter to the 12-volt scale and touch the probe to the collector of the driver transistor, Q_4. You should read between 1 and 6 volts, depending on the strength of the station you are tuned to. The meter reading will fluctuate with the contents of the program. Vary the volume control setting, and notice that the amplitude of the reading also varies. Touch the meter probe to the emitter of Q_4. You do not get a reading because the emitter resistor, R_{14}, is well bypassed by the capacitor, C_{18}.

From the schematic diagram, notice that the signal at the collector of Q_4 is also the signal at the base of Q_5 because the transistors are direct-coupled. Next, touch the probe to the emitter of Q_5, and again observe a reading similar to that obtained at the base. This is what you would expect, because the emitter resistor, R_{17}, is not bypassed, and the emitter signal tends to follow the base signal.

Turn the Range switch to the 120-volt position and touch the probe to the collector of Q_5. With the volume control fully clockwise and tuned to a strong station, you should read 50 or 60 volts ac. The reading will fluctuate with changes in the audio signal.

From these tests you can see that the meter is not very good for tracing the audio signals in the circuit immediately following the detector of a transistor receiver. However, you do get a usable indication in the stages after the signal has been amplified. Therefore, the test can isolate the defect to a very small section of circuitry. For example, suppose your test indicates that the detector is working but you do not get a signal at the collector of the driver transistor, Q_4. The suspected circuitry would include the coupling capacitor, C_{16}, the transistor Q_4, and its associated circuitry.

Step 3: To show that the meter can be used to indicate the presence of signals in some stages of the rf section of the receiver.

Unsolder and remove the short piece of hookup wire that you connected across the terminals of the speaker. In this step you can turn the volume down to the desired level and it will not affect the readings in the rf section of the receiver. Tune the receiver to a strong local station. Set the meter to read ac on the lowest range. Connect the ground clip to B- and touch the probe to terminal 4 of T_3, which is the junction of the i-f output transformer and the detector diode.

You should get a readable indication of about .25 to .5 volt if you are tuned to a strong station. Tune across the station, and notice that the reading is greatest when properly tuned, and drops to zero between stations. Also notice that touching the probe to this point in the circuit does not noticeably affect the volume of the recovered sound. The secondary of the i-f output transformer is a low-impedance circuit, so the capacitance of the probe does not detune or load the circuit appreciably.

Next, touch the probe to terminal 2 of T_3, and again read an indication of the presence of the 455 kHz i-f signal. Notice that touching terminal 2 detunes the primary circuit and lowers the volume of the recovered sound. Touch the probe to terminal 6 of T_3, which is also the collector of Q_3, and read an indication of the i-f signal. This point is a lower impedance than terminal 2, so touching it produces little or no detuning. Touch the probe to the base of Q_3 and look for an indication on the meter. The signal is too small to give you a usable indication.

Touch the meter probe to the collector of Q_2 and tune to a strong local station. You should read some small value of ac voltage as an indication of the presence of a signal. The meter gives a fair-sized indication, because four signals are present at this point.

As you know, the collector of the mixer, Q_2, carries the oscillator signal, the incoming rf signal, the sum of these, and their difference, or i-f signal. The combined effect of these four signals is sufficient to produce a reading on the meter. Attempt to measure the signal at the base of Q_2. The local oscillator signal is coupled to the base circuit through C_7 and the rf signal is direct-coupled from the loop antenna. However, these signals are too small at this point to give an indication on your meter.

Next, use your meter to determine if the local oscillator is operating. Touch the probe to terminal 4 of the oscillator transformer and measure a small value of ac voltage. Tune the receiver across the band, and notice that the amplitude varies somewhat at different points. This is normal, since the efficiency of the oscillator varies for different frequencies. The amplitude variations are unimportant as long as the oscillator signal is above the minimum amplitude required to properly operate the mixer stage.

Touch the probe to the base and then the emitter of Q_1. The oscillator signal is too small at these points to produce a usable meter indication. Touch the probe to terminal 2 of T_1 and measure an ac voltage of 2 to 5 volts. Since this measurement is taken across the high-impedance tank circuit, you get a sizable reading. Tune the receiver across the band, and notice the large change in oscillator voltage amplitude at various settings of the tuning capacitor.

The results of this step show that the meter has limited value for tracing signals in the rf section of the receiver. However, the ability to use the meter to determine that the local oscillator is operating is very useful in troubleshooting. Also, being able to determine that an i-f signal is present in the i-f output transformer is useful. For example, suppose you get no indication of an audio signal at the output of the detector. If you then read an i-f signal at the i-f output transformer, you can be pretty sure that the detector diode is open. If the diode is shorted, it will, of course, short the i-f signal to the detector filter circuit and no appreciable signal can be measured on the i-f output transformer.

Instructions for Statement 61: For this statement you will use your meter to determine if the local oscillator is operating, and investigate the effect of meter loading, if any, on the operation of the receiver.

When servicing the receiver, it is convenient to measure the local oscillator signal at the tuning capacitor because this point is easy to locate in the circuit. You know that the local oscillator tunes to a frequency higher than the incoming rf signal. Therefore, the small section (fewer plates) of the tuning capacitor is the variable capacitance for the local oscillator. To take the reading you simply clip the ground lead of the meter to B-, touch the probe to the capacitor terminal, and measure the ac oscillator voltage.

Perform the preceding test on your receiver. Attempt to tune in a station while the probe is in contact with the capacitor terminal. Remove the probe, tune in a station, and again touch the probe to the capacitor terminal. Observe the effect, if any, on the received signal, then answer the statement.

Statement No. 61: When I touched the meter probe to the terminal of the oscillator tuning capacitor to measure the local oscillator voltage,

(1) the meter probe loaded the circuit only slightly and I was able to receive most stations at their usual places on the tuning dial.

(2) the meter probe capacitance changed the frequency of the local oscillator and the few stations I could tune to appeared at the wrong place on the tuning dial.

[✓ *(3)*] *the meter probe loading shunted out the radio station i-f signals, so I was not able to receive any stations.*

EXPERIMENT 62

Purpose: To show how to use a circuit disturbance test to isolate a defective stage.

Introductory Discussion: A circuit disturbance test is the equivalent of a signal-injection test. As you know, signal injection consists of injecting the type of signal normally carried by the circuit to some point in the signal path and determining if the circuit processes the signal. For example, if an audio signal is injected into any point in the audio signal path circuits, the amplified audio signal should be heard from the loudspeaker.

If a modulated i-f signal is injected anywhere in the i-f amplifier circuit signal path, the circuit should amplify the signal, the detector should detect the audio modulation, the audio amplifier should amplify the detected signal, and you should again hear the processed signal from the loudspeaker. Likewise, a modulated rf signal can be applied to the antenna to test the operation of all circuits in the receiver.

In practical servicing, a circuit disturbance test is usually substituted for signal injection because it is quicker and produces satisfactory results. For a circuit disturbance test, you need only change the level of the dc voltages somewhere in the signal path to produce an audible click at the speaker.

In the audio section of the receiver, you can inject a 60 Hertz signal by merely touching your finger to the signal path. Your body picks up enough 60 Hertz signal from the house wiring to provide a usable signal for the high-gain audio amplifier stages. You will then hear a 60 Hertz hum from the speaker.

In a transistor receiver, touching the signal path in the rf or i-f section of the receiver may or may not produce enough disturbance to get a click at the loudspeaker. As you know, the slight change in dc operating voltage levels must shock-excite the tuned circuit in the stage. This will produce a few cycles at the resonant frequency of the tuned circuit. The oscillations quickly die out. The change in amplitude of the rf signal constitutes the modulation, so the detector produces a small signal that is reproduced in the speaker as a click. At some points in a low impedance transistor circuit, touching the low impedance point may not produce enough change to be heard in the speaker.

Experimental Procedure: For this experiment you will need your operating receiver, your meter, your hand tools, and the following part:

1 .27 mfd capacitor

Step 1: To show that a sudden change in current through the output transformer primary will produce a click in the loudspeaker.

Unplug the receiver from the power line. Set the Function switch of your meter to ohms and the Range switch to the lowest range. Clip the meter ground lead to the collector of the output transistor, Q_5. Touch the ohmmeter probe to the B++ line. Observe the schematic to see that with this connection you are placing the ohmmeter across the primary of the audio-output transformer. You should hear a click in the speaker each time you make or break the connections. The battery in your ohmmeter is forcing a small amount of current through the primary of the transformer. The change in current through the primary induces a current in the secondary that drives the voice coil of the speaker to produce the click. Remove the meter ground clip from the collector of the output transistor.

This procedure tests the audio output transformer and the speaker. This is an easy test to make on these parts when testing a dead receiver. If this test does not produce a click, then you would use the ohmmeter to measure continuity through the transformer primary and secondary and through the voice coil of the speaker.

It is necessary to disconnect one wire from the speaker to measure its continuity. Both the secondary of the transformer and the voice coil are in parallel and both have a very low resistance.

Many receivers do not have an audio-output transformer. Instead, the voice coil of the speaker is driven directly from the output transistors. In these receivers it is sometimes necessary to disconnect one lead of the speaker to make a valid resistance check of the speaker voice coil.

Step 2: To show how a circuit disturbance test can be used to prove whether or not the audio section of the receiver is operating.

Connect the receiver to the power line and tune to a point between stations. Turn the volume control fully clockwise. If you are in a noisy location, you will hear a lot of noise from the loudspeaker. To get rid of the noise, tack-solder a short piece of hookup wire from terminal 3 to terminal 4 of the i-f transformer, T_3. This simulates a defect in the i-f section of the receiver.

Touch the blade of a screwdriver to terminal 2 of the volume control (center terminal) and touch your finger to the screwdriver blade. You should hear a 60 Hertz hum from the loudspeaker. Rotate the volume control from maximum to minimum, and notice that the volume drops to zero. From the schematic diagram, you can see that when the volume control is at minimum, terminal 2 is in effect connected to terminal 1, which is also the B+ line. Therefore, the filtering on the B+ line filters the 60 Hz pickup signal from your body and no hum is produced in the speaker.

Touch the screwdriver to the base of Q_4 and again hear the 60 Hertz hum. Notice that varying the volume control still changes the volume. The signal is lost through the large coupling capacitor, C_{16}, to the B+ line when the volume control is turned down. You should still hear a click when you touch the circuit. Next, touch the screwdriver to the base of Q_5, which is also the collector of Q_4. Again you will hear a click, but the 60 Hertz hum is not audible. The single stage does not have enough gain to give a usable indication of the hum signal. The collector of Q_5 is at a high positive voltage of about 110 volts dc. Touch the collector of Q_5 and notice that it does not produce an audible click.

Remove the short circuit that you tack-soldered across terminals 3 and 4 of the i-f output transformer, T_3. Tune to a place on the dial between stations and turn up the volume control. Again perform the circuit disturbance tests in the audio section. Notice that you get a distinct click in the speaker when you touch any point in the audio signal path. Even when you touch B++ or B- you hear a click. This occurs because the disturbance produces an rf signal that is picked up by the antenna. Even though the signal is quite weak, the high gain of the receiver is such that it processes the signal and produces a click in the speaker. From this experiment, you can see why a receiver picks up electrical noise from appliances, machinery, etc.

Step 3: To show how a circuit disturbance test can be used to indicate the operation of an i-f or mixer stage.

Use a clip lead or a short piece of hookup wire to short out the oscillator tank circuit. Connect the short between the capacitor terminal on the oscillator section of the tuning capacitor and the ground lug on the frame of the capacitor. This connection will stop the local oscillator. The signal path through the radio is unaffected, but no stations will be received. Turn the volume control fully clockwise.

Energize the receiver and touch the screwdriver blade to the collector of Q_3. You should get a loud click from the receiver. Touch the base of Q_3, the collector of Q_2, and the base of Q_2. In each case, the circuit disturbance will produce a loud click in the speaker, indicating that the stages are able to pass a signal. Touch the antenna terminal where it connects to the rf section of the tuning capacitor. A disturbance in the rf tank circuit of the antenna induces a signal in the secondary of the loopstick, which in turn acts as a signal to the base of Q_2. Try holding your hand against the wires of the loopstick. You should hear noise and hum from the speaker, depending on the amount of pickup signal available in your area. These tests indicate that the rf and i-f sections of your receiver are capable of amplifying a signal.

Touch your screwdriver blade to the base and then to the emitter of the oscillator transistor, Q_1. Even though the circuit is not oscillating, it amplifies the circuit disturbance and injects a signal to the base circuit of Q_2, producing a click in the speaker.

Disconnect the receiver from the power line and carefully unsolder the collector lead from Q_2. Energize the receiver and again perform the circuit disturbance test in the rf and i-f sections of your receiver. Touching the collector and base of Q_3 produces the usual loud click. Also when you touch terminal 5 of T_2, which is the point where the collector of Q_3 usually is connected, you get a loud click. The circuit disturbance in the primary of T_2 is readily coupled to the secondary to furnish a signal to the base of Q_3.

Touch the base of Q_2 and other points in the signal path ahead of Q_2. You may hear a faint click in the speaker, but not nearly as loud as when Q_2 was operating.

The preceding tests show how you can use the circuit disturbance to isolate the defect to one stage of the receiver.

Step 4: To show limitations of the circuit disturbance tests.

Carefully resolder the connection of the collector of Q_2 to the circuit board. Temporarily disconnect the short on the oscillator section of the tuning capacitor, and test the radio for proper operation. Then disable the oscillator by reconnecting the tuning capacitor short circuit. Next, tack-solder a short piece of hookup wire from terminal 4 of T_2 to B− (the foil at terminal 3 of T_2 is a convenient B− point for the connection). This connection places a short circuit across the primary of the transformer, T_2.

Energize the receiver and perform the circuit disturbance test in the rf and i-f sections of your receiver. When you touch the base and collector of Q_2, you should get an audible click from the speaker. You may note that the sound is not quite as loud as before you shorted the transformer, but the stage is still passing the signal.

Now remove the short from the oscillator section of the tuning capacitor to activate the local oscillator. Attempt to tune in a station. If you have a very strong local station in your area, you will be able to hear it faintly. Unplug the receiver from the power line. Unsolder and remove the short circuit that you had connected from terminal 4 of T_2 to B−. Test the receiver for proper operation.

The results of this step indicate that the circuit disturbance tests have serious limitations. Thus a short in the relatively low-impedance transistor circuit did not prevent the circuit from passing a circuit disturbance signal. In an earlier step, you found that touching the oscillator transistor produced a click even though the oscillator was not oscillating. Therefore, you can see that the circuit disturbance tests give you only rough indications of whether the circuits are working or not. The fact that these tests can be made quickly makes them useful even though they have serious limitations.

Instructions for Statement 62: For this statement you will investigate the effectiveness of stage blocking in the signal path of a transistor receiver. As you know, stage blocking consists of intentionally killing the signal in one stage at a time. This troubleshooting technique is often used for tracking down the point at which noise is getting into the signal path. For example, suppose you block the i-f output stage. If the noise is still present, you know that the noise is getting into the signal path somewhere between the stage and the speaker. On the other hand, if the noise disappears, it must be getting into the signal path in an earlier stage.

For this statement, you will use a .27 mfd capacitor to attenuate the i-f signal in the i-f section of your receiver. Tune your receiver to a local station and adjust the volume for a normal listening level. Next, use a clip to attach one end of your .27 mfd capacitor to B- on the receiver. Then touch the free end of the capacitor to the foil at the collector of Q_2, and note the effect on the received program. Next, touch the free end of the capacitor to the foil at the base of Q_3, and again note the effect on the program. Finally, touch the free end of the capacitor to the foil at the collector of Q_3. Remove the capacitor, test the receiver for proper operation, and answer the statement.

Statement No. 62: When I attempted to kill the i-f signal by shunting a .27 mfd capacitor from the i-f signal path to B-,

(1) the capacitor completely eliminated the signal at each point that I touched.

(2) the capacitor affected the volume only slightly at each point that I touched.

(3) the capacitor killed the signal when I touched the collectors, but I could still hear the program when I touched the base of Q_3 because this is a low-impedance point in the circuit.

EXPERIMENT 63

Purpose: To show how to use the meter to locate a defective transistor.

Introductory Discussion: Your meter can be an effective tool to determine quickly if a transistor is defective. In most cases, you can determine positively whether or not the transistor is defective without removing it from the circuit. You are able to make these tests by knowing what voltage readings are reasonable at each element of the transistor. The voltage readings you take on the transistors should tell you if the transistor is conducting, and if proper voltages are applied to the transistor. From these voltage tests, you should be able to determine if an inoperative stage is the result of a defective transistor or the result of defective circuitry associated with the transistor.

Let's examine each of the few facts that you must remember while you are making voltage tests on the transistor. These facts about transistor voltages apply to any circuit, and do not require you to know the correct voltages for the particular receiver you are working on.

Fig. 63-1 shows a PNP and an NPN transistor symbol, with the polarity of voltages at each element of the transistor. The polarity markings of the collector and emitter are relative to each other. In each case, the base polarity is the same as the collector to provide forward bias for the transistor.

These diagrams should be removed from the book so you can refer to them quickly and easily. Carefully open the staples, remove the diagrams, and then close the staples again so the book will not fall apart.

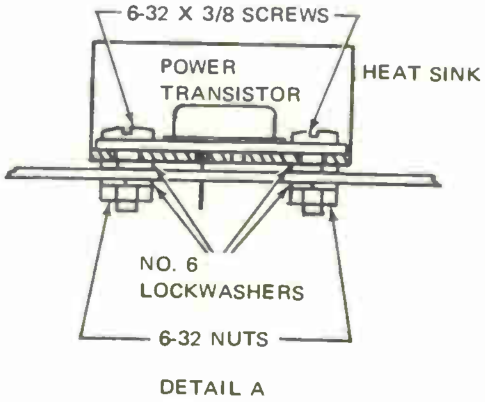

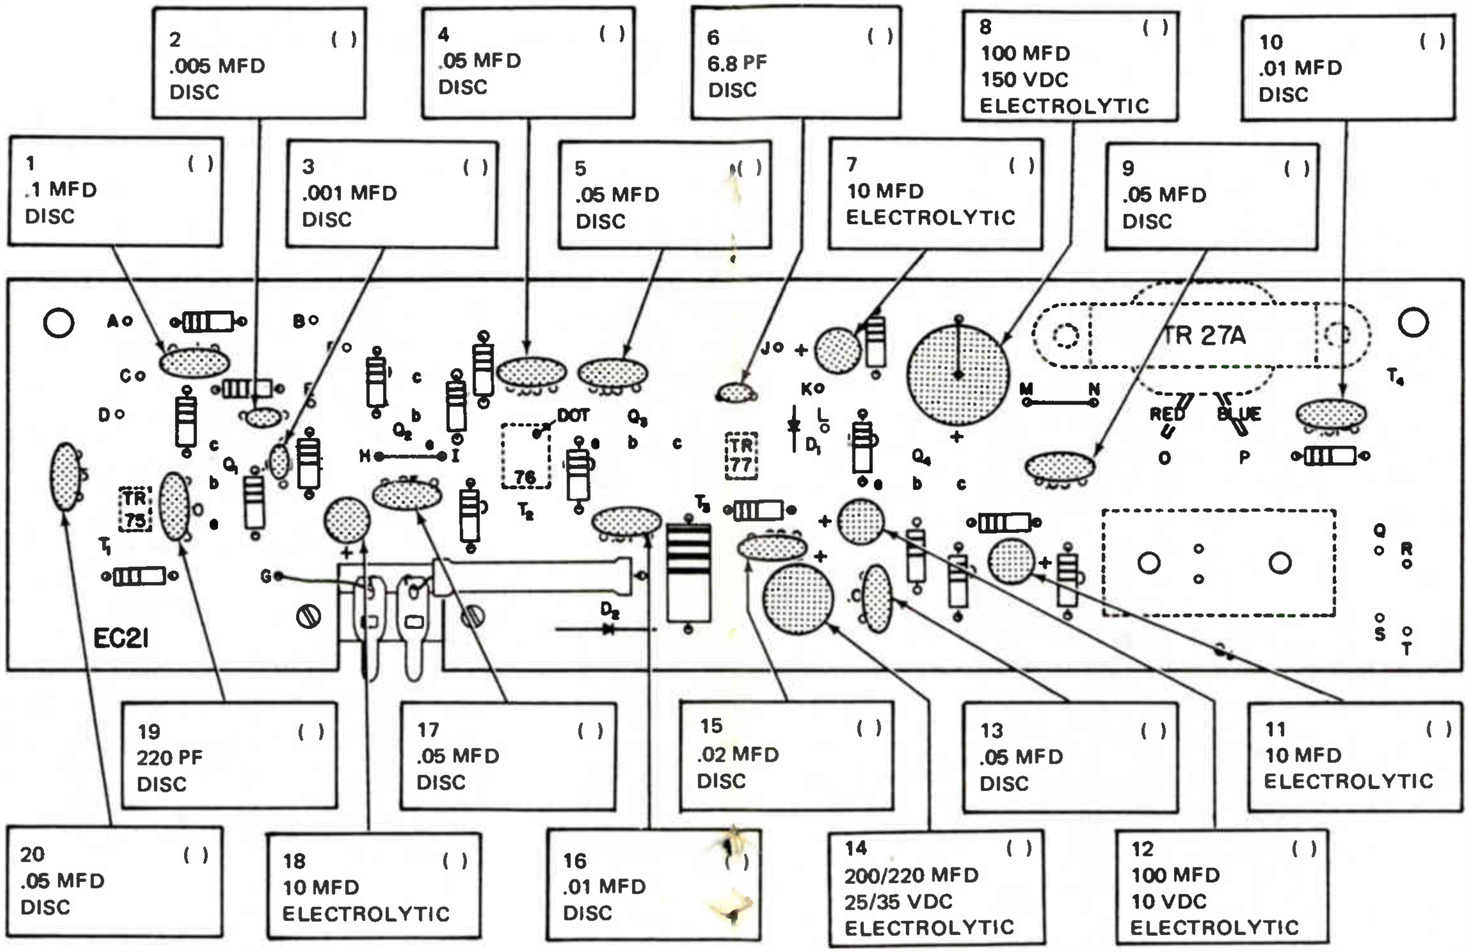

Fig. 7. Installing the capacitors on the circuit board.

These diagrams should be removed from the book so you can refer to them quickly and easily. Carefully open the staples, remove the diagrams, and then close the staples again so the book will not fall apart.

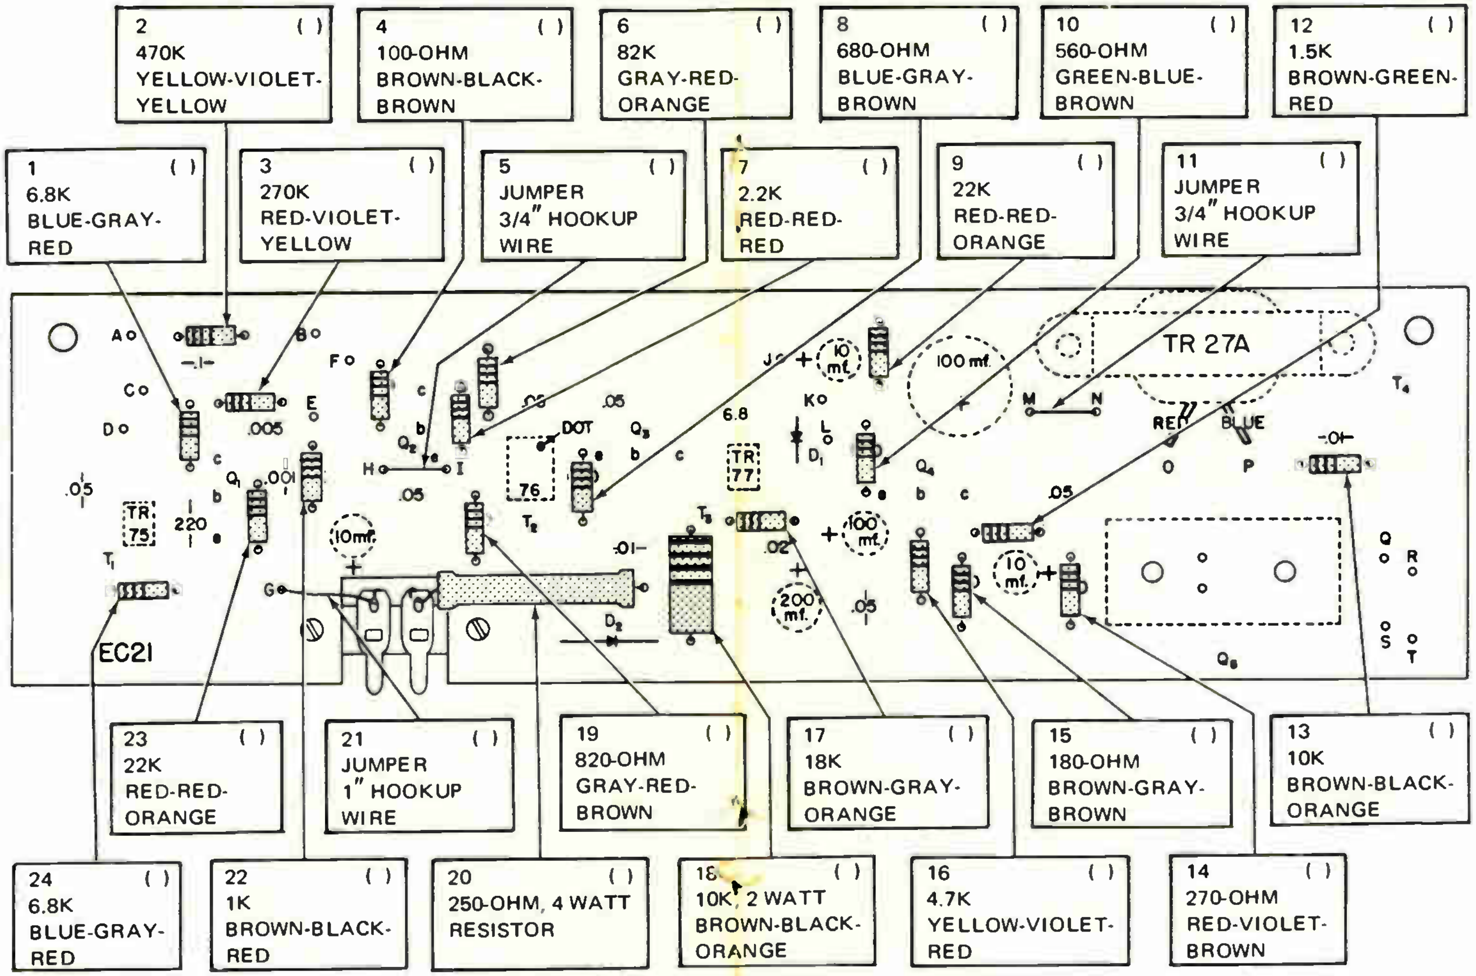

Fig. 6. Installing the resistors on the printed circuit board.

Again examine the schematic diagram of the receiver (Fig. 19) to see how element polarity is applied to a transistor in a circuit. For example, from the schematic you can see that Q_3 is a PNP transistor. Or you can determine the polarity from the transistor symbol. You know that the electrons must flow against the arrow on the emitter symbol. This means that the collector must be negative to force electrons through the transistor against the arrow. Since the collector is negative, the base must also be negative to provide forward bias.

Now look at the schematic of the receiver in terms of taking actual voltage measurements on the elements of transistor Q_3. You clip the ground lead of the meter to a B– point in the circuit. What dc voltage can you expect at the collector of Q_3? From the schematic you see that the collector connects to B– through only a few turns of the transformer, T_3. The dc voltage at the collector will probably read zero volts. But the collector must be negative in relation to the emitter for the transistor to operate.

Therefore we can expect to read a positive voltage at the emitter. If the emitter measures positive, then the collector is negative with respect to the emitter even though the actual collector voltage measured is zero. Next we measure the base voltage. To be forward biased, the base voltage must have the same polarity as the collector.

However, the collector measures zero and the emitter is positive. Therefore, we can expect to measure a positive voltage on the base. As long as the measured voltage is less positive than the emitter, the transistor will be forward biased. The voltage difference between the base and the emitter is usually quite small. In some cases you have to observe the meter needle very carefully to detect the very small difference.

Which voltage measurement will tell us if the transistor is conducting? From the schematic diagram of the receiver, you can see that any current through transistor Q_3 must also flow through the 680-ohm emitter, resistor R_{10}. If this resistor has a drop across it, the transistor must be conducting. Therefore the difference between the B+ voltage and the emitter voltage reading is an indication of how heavily the transistor is conducting.

Some circuits will have a resistor in both the collector circuit and the emitter circuit. Both of these resistors will carry the conducting current of the transistor. The drop across the larger resistor will usually give the best indication of the conduction of the transistor. In some cases, the emitter resistor or the collector resistor may be part of a voltage-divider network. In that case, the drop across the resistor may not be a reliable indication of transistor conduction.

This discussion may seem incomplete to you. Read it again after performing this experiment. In the experiment you will take measurements on transistors with simulated defects. In each case, you should find that the readings on the defective transistor do not meet the requirements presented in the discussion.

Experimental Procedure: For this experiment you will need your operating receiver, meter, and hand tools.

Step 1: To measure the voltages in the circuit of a properly operating transistor stage.

Take the voltage measurements indicated in the table of Fig. 63-2, and record your readings in the spaces provided. Be

	TUNED TO POINT BETWEEN STATIONS		TUNED TO STRONG LOCAL STATION

Fig. 63-2. Chart showing typical readings obtained on transistor stage Q_3, with spaces for recording your readings.

sure to check your meter for exact zero before taking each measurement. Estimate the meter reading carefully when the needle indicates between graduations on the scale. On the 30-volt range it is difficult to read the meter accurately to tenths of volts. However, you must read the meter accurately or your readings will be misleading.

The first set of readings in Fig. 63-2 is taken with the receiver tuned between stations. Examine the typical readings. The difference between the B− to base reading and the B− to emitter reading is 17.8 − 17.1 or .7 volt.

In the emitter-to-base column we show a typical reading of −.7 volt. This reading was taken by clipping the common lead of the meter to the emitter and touching the probe to the base (meter set to read −dc on its lowest range). Since the base is more negative than the emitter, the transistor is forward biased. The two values should be the same, but due to the difficulty of reading the scales and meter inaccuracy, the values may not be identical. You can expect similar discrepancies in your readings.

Now compare the first set of readings with those obtained when the receiver is tuned to a strong local station. Observe that B+ is increased by 1 volt with a station tuned in. The reason for this is simple. The received signal produces avc bias that reduced the gain of Q_2 and Q_3. The reduced conduction of these two transistors reduces the B+ current drain. This, in turn, reduces the drop across the 10k-ohm dropping resistor, R_{20}, so the B+ voltage rises.

Notice that the drop across the emitter resistor, R_{10}, decreased by nearly one-half when the station was tuned in. This also indicates that the transistor is passing less current. From the typical readings, there was no readable difference in the emitter-to-base voltage under the two operating conditions. This indicates that it takes only a small change in base-to-emitter voltage to produce a sizable change in transistor current.

Compare your set of readings with the typical readings given. Several factors may cause your readings to be quite different from the typical readings. Line voltage and normal parts tolerances could cause your readings to be considerably higher or lower. Be sure to use your readings for comparison when performing other steps in this experiment.

Step 2: To show typical voltage readings in a transistor circuit when certain elements of the transistor are shorted.

For this step you simulate shorts between the various elements of transistor Q_3 and measure the resultant voltages. In a servicing situation, these defects could be within the transistor or in the external circuitry.

Tack-solder a short piece of hookup wire from the foil at the base of Q_3 to the foil at the emitter of Q_3 to simulate a base-to-emitter short in the transistor. Energize the receiver and measure the voltages on the transistor. Compare your measurements with the readings you recorded for normal operation. The emitter-to-base voltage will, of course, be zero. This means the transistor has no forward bias. The B- to base and emitter will read very nearly the B+ value because the transistor is not drawing current. Likewise, the B+ readings will be very nearly normal.

Measure the drop across R_{10}. A typical reading will be .2 volt. To see why you have current through R_{10}, again examine the schematic diagram. The base-emitter short completes the circuit from B+ through R_{10}, through the short to the base, through part of the secondary winding of T_2 and through R_9 to B-. Current through this circuit produces the voltage drop across R_{10}.

Unsolder and remove the short from the base to the emitter of Q_3. Connect the short from the emitter to the collector. Energize the receiver, and again take voltage measurements. The voltage will, of course, be the same at the emitter and the collector. These two readings (both zero) by themselves would indicate that the transistor does not have the proper operating voltages applied to it.

Next, measure the base voltage. A typical value is about 7 volts, indicating that the transistor is reverse biased. Then measure B+. A typical reading is about 7 volts. Measure a drop of about 7 volts across the emitter resistor, R_{10}.

Now examine the schematic diagram to see why the emitter-collector short produces the voltage readings you observed. The short circuit allows excess current through R_{10}. Since R_{10} is a low-value resistor, it allows enough current to drop B+ to less than half its normal value. If you were servicing this set, you would have to isolate the components to pin down the exact location of the short. For example, the defect could be a shorted capacitor, C_{13}, or an internal emitter-to-collector short in the transistor.

Unsolder and remove the emitter-collector short. Connect the short between the foil at the collector and the base. CAUTION! Do not short the collector-to-base of a transistor circuit unless you are sure that it will not exceed the ratings of the transistor. In your receiver, the emitter resistor of Q_3 limits the current to a safe value. Energize the receiver and again take voltage measurements. The collector and base are at the same potential, so the transistor is forward biased. Measure the emitter-to-base voltage.

A reading of .7 volt is typical, indicating a forward-biased transistor. You may read some small positive voltage from B- to the emitter. B+ again measures very low, about 7 volts, and the drop across R_{10} is about 7 volts.

The preceding readings, if obtained on a defective receiver, would not definitely pinpoint the defect. The excessive drop across R_{10} accounts for the low B+ reading. You would have to isolate components to locate the short. In this case, the base-collector short places a large forward bias on the transistor so that the emitter-collector circuit is almost a short circuit. The transistor conducts heavily, producing a large drop across R_{10} and the resultant low B+ voltage. Unsolder and remove the short that you connected between the collector and the base. Test the receiver for proper operation.

In this step you have investigated the voltage indications of the three possible shorted conditions that might exist within a transistor stage. Voltage measurements at the elements indicate the bias condition and the operating voltages of the transistor. The voltage drop across the emitter resistor indicates the relative amount of current in the transistor circuit. From these tests you can see that, although the voltage tests indicate the presence of a short, you have to remove components and make additional tests to find the exact location of the short.

Step 3: To show typical voltage readings in a transistor stage when certain elements of the transistor are open.

Turn off the receiver and unsolder the collector lead of Q_3 from the foil on the circuit board. Handle the collector lead carefully, as too much flexing of the lead can break it off where it enters the transistor body. Grasp the collector lead with your longnose pliers, heat the foil at the collector connection, and gently pull the collector lead out of the hole. This will simulate an open collector within the transistor.

Energize the receiver and take voltage readings around the Q_3 transistor stage. Compare your readings with those obtained for normal operation. B+ should read normal or slightly above normal. The B- to emitter and B- to base readings should measure approximately the B+ voltage value. A typical emitter-to-base reading is .7 volt, indicating that the transistor is forward biased. However, you will read only a fraction of a volt drop (about .2 volt) across R_{10}, indicating that the transistor is drawing little or no current.

Since your readings indicate a large forward bias and adequate emitter voltage, it is reasonable to assume that either the collector is open internally or there is an open in the collector circuit through the primary winding of T_3. With the receiver turned off, you could use your ohmmeter to confirm the location of the open.

Next, unsolder and remove the base lead connection from Q_3 at the circuit board. Then reconnect and solder the collector lead connection. This simulates an open base in the transistor. Again take voltage readings in the stage. B+ should be slightly higher than normal. The emitter should measure nearly the B+ value, and the base connection (point on the foil where the base is usually connected) should measure something less than the B+ value. The emitter-to-base measures excessively higher than normal, a typical reading being - 1.3 volts. The drop across the emitter resistor, R_{10}, should be zero, since Q_3 is cut off.

The preceding readings definitely indicate a defective transistor. The proper polarity operating voltages are present. The higher-than-normal forward bias should produce transistor conduction. However, the emitter resistor indicates very little transistor current, so the transistor must be defective.

Unplug the receiver, unsolder and remove the emitter lead of Q_3. Then reconnect and solder the base lead to the circuit board. This simulates an open emitter in the transistor. Energize the receiver and again take voltage readings on the stage. B+ should read normal or slightly high.

The point on the foil where the emitter usually connects reads the B+ value and the base reads less than B+. The emitter-to-base reads about -1.5 volts, indicating very large forward bias. However, the drop across the emitter resistor, R_{10}, reads zero, indicating no current through the transistor. It follows then that the transistor or the emitter-collector circuit of the transistor must be open.

Turn off the receiver. Reconnect and resolder the emitter leads of Q_3. Test the receiver for proper operation.

Instructions for Statement 63: For this statement you short-circuit two elements of the audio driver transistor, Q_4, and observe the results. Simply tack-solder a short piece of hookup wire from the foil at the base of Q_4 to the foil at the emitter of Q_4. Energize the receiver, observe its operation, take voltage readings or other tests, as necessary, to answer the statement.

Turn the receiver off. Unsolder and remove the short that you connected from the base to emitter of Q_4. Test the receiver to be sure that it is operating properly.

Statement No. 63: When I shorted between the emitter and the base of the audio driver transistor, Q_4,

(1) the receiver operated almost normally but with reduced volume and some evidence of distortion.

(2) the receiver operated only on strong stations and the sound was garbled.

[✓ *(3)*] *the receiver produced no sound because the short circuit back-biased the audio driver stage.*

EXPERIMENT 64

Purpose: To show the effects of leaky bypass capacitors; and

To show how to locate them with an ohmmeter and with a voltmeter.

Introductory Discussion: The dc power supply line is maintained at signal ground potential by the use of bypass capacitors. Signals are bypassed around the power supply by providing a low impedance path (low impedance to the ac signals) from the dc power line to ground. These bypass capacitors are often electrolytic capacitors that tend to develop leakage. When the dielectric of the capacitor allows direct current to flow through the capacitor, we have leakage.

This condition can vary from a few microamps of leakage to a direct short through the dielectric of the capacitor. We can simulate a leaky capacitor by paralleling it with a resistor. The size of the resistor can be varied to simulate any degree of leakage through the capacitor.

A leaky bypass capacitor usually upsets the dc operating voltages in the receiver. A small amount of leakage will go unnoticed and have negligible effect on the operation of the receiver. In fact, most electrolytic capacitors will normally have some small leakage current. However, when the leakage becomes high, the condition is usually progressive. That is, the receiver may operate quite normally when first turned on, but when the set comes up to operating temperature the leakage increases. The excessive leakage current causes further deterioration of the dielectric and eventually the capacitor will short-circuit.

In this experiment, we limit the simulated leakage to values that will not damage other parts in the receiver. For example, excessive leakage through C_{23} could damage the power supply rectifier diode, D_2. This is a common servicing situation. A shorted filter capacitor overloads the rectifier, causing it to fail. Therefore, whenever you have to replace a rectifier diode, check to see if the filter capacitor is shorted. Otherwise, you may ruin the replacement diode.

Experimental Procedure: For this experiment you will need the operating receiver, the voltmeter, and the following:

1 10k-ohm resistor
1 6.8k-ohm resistor
1 2.2k-ohm resistor

Step 1: To show the effects of leakage in the B++ filter capacitor.

For this step you parallel the 100 mfd filter capacitor, C_{23}, with a 6.8k-ohm resistor. This arrangement exceeds the wattage rating of the resistor, so it will overheat if the receiver is left energized for even a few minutes. Therefore, leave the receiver energized only long enough to take the indicated measurements or observations; otherwise the 6.8k-ohm resistor will burn up.

	NORMAL READINGS	READINGS WITH 6.8K IN PARALLEL WITH C23	
B- to B++ VOLTAGE			
B- to B++ RESISTANCE			

Fig. 64-1. Chart for recording readings for Step 1.

Turn the receiver on and test it for proper operation. Tune in a station and adjust the volume for normal listening. Measure the B++ voltage, and record your reading in the Normal column in Fig. 64-1. Unplug the receiver from the line and measure the resistance between B++ and B–. Record your reading in the Normal column in Fig. 64-1.

Tack-solder the 6.8k-ohm resistor from the B++ foil to the B- foil. Again, measure the resistance from B++ to B- and record your reading in Fig. 64-1.

Set up your meter to measure +dc voltage on the 120-volt scale. Connect the line cord to the receiver, listen to the station, and quickly measure the B++ voltage. Turn off the receiver. Feel the body of the 6.8k-ohm resistor with your fingers. You will probably find it warm, even though the receiver was on for only a short time. Record your voltage reading in the space provided in Fig. 64-1.

Compare the readings you recorded in Fig. 64-1. Paralleling C_{23} with the 6.8k-ohm resistor increased current drain from the power supply. The parallel path caused the resistance to drop to approximately one-fourth of what it was originally. Likewise, the power supply voltage decreased, but only a small amount. You probably noticed little or no change in the operation of the receiver.

Consider what would have happened if the simulated leakage had occurred inside the capacitor. The same heat would be generated by the current through the resistance. The capacitor would probably overheat and fail completely. With less leakage, the receiver would continue to operate.

When servicing a receiver in which you measure lower than normal B+ voltage, always consider the possibility of leakage current. Check to see if the capacitor or other components in the circuit overheat. Then use resistance measurements to locate the leakage path in the circuit.

In a battery-operated transistor receiver, leakage seldom causes overheating. The complaint is more likely to be short battery life. Some reduction in volume or sensitivity may go unnoticed, but the increased drain on the battery can greatly reduce the life of the battery.

Step 2: To show the effects of leakage in the B+ filter capacitor, C_{22}.

For this step you parallel capacitor C_{22} with a 2.2k-ohm resistor to simulate leakage in the capacitor. Examine the schematic diagram of the receiver to see if you can predict the results.

Turn the receiver to a local station, adjust the volume for normal listening, and unplug the line cord. Tack-solder a 2.2k-ohm resistor from the foil at B– to the foil at B+, which is also the positive terminal of capacitor C_{22}. This connection simulates internal leakage in the capacitor. Connect the line cord of the receiver to the ac line and note any change in the reception of the station. Measure the B+ voltage and compare your readings with normal B+ voltage. Also measure B++ voltage to see if it has changed from normal.

Unplug the receiver and measure the resistance between B– and the B+ line. A typical reading is about 1.5k-ohms, with the 2.2k-ohm resistor in parallel with C_{22}. Unsolder the 2.2k-ohm resistor and again measure the resistance. A typical reading is about 10k-ohms.

From these tests, you can see that a sizable leakage is necessary to produce a noticeable change in the operation of the receiver. Even though the B+ voltage decreased by almost one-third, the receiver still operates. In a servicing situation the complaint might be reduced volume or reduced sensitivity.

Your voltage measurements would indicate that excessive current was being drawn from the B+ line; also your resistance measurements would indicate lower than normal resistance on the B+ line. Further voltage measurements on the circuit branches from the B+ line would help isolate the defect. However, you would have to isolate components and take more resistance measurements before you could definitely determine where the leakage exists in the circuit.

Step 3: To show the effects of leakage in the rf bypass capacitor, C_5.

Ceramic disc capacitors seldom develop leakage. This is particularly true in transistor radios where the supply voltages are low. However, leakage or complete short circuits can and do occur. In this step we investigate the effects of a leaky or shorted capacitor, C_5. From the schematic diagram, C_5 appears to be simply an rf bypass capacitor that completes the path for the ac signal in the tank circuit of the local oscillator.

Tune the receiver to a local station and adjust volume for normal listening.

Unplug the receiver and tack-solder a 6.8k-ohm resistor on the foil side of the board in parallel with C_5. Energize the receiver and note the effect, if any, on the receiver operation.

Turn off the receiver and remove the 6.8k-ohm resistor that you paralleled with C_5. In its place, tack-solder a piece of short hookup wire to simulate a shorted capacitor, C_5. Again, test the operation of the receiver. Next, measure the dc voltage from B- to the frame of the tuning capacitor. Six volts or so is a typical reading.

From this step of the experiment, you can see that a leaky or shorted C_5 does not affect the operation of the receiver. To see why C_5 is in the circuit, again examine the schematic diagram of the receiver.

As we stated before, C_5 completes the circuit for the local oscillator tank circuit consisting of the primary of T_1 and the oscillator section of the tuning capacitor. The other function of C_5 is to isolate the capacitor frame from the circuit for safety reasons. As you know, B- connects to one side of the ac power line.

If the capacitor frame were connected to B-, the capacitor mounting plate, the tuning capacitor shaft and the volume control shaft would be "hot". If a knob were removed from the operating receiver, a person could receive a dangerous electrical shock. To prevent this, the network consisting of R_5 and C_8 is used to isolate the metal part from B-.

Consider what could happen if a direct connection were used instead of C_5. A shorted transistor, Q_1, would connect B- through terminals 5 and 3 of the primary of T_1 directly to the metal frame of the tuning capacitor. The metal shafts would again be "hot," presenting a dangerous situation.

Unsolder and remove the short that you connected across C_5. Test the operation of the receiver.

Step 4: To show the effects of leakage in the emitter bypass capacitor, C_{13}.

Tack-solder a 6.8k-ohm resistor from the foil at the emitter of Q_3 to B-. This connection places a resistor in parallel with C_{13} and simulates a leaky capacitor. Energize the receiver and test its operation. Take voltage readings on the base and emitter of Q_3. You should find that both elements are almost exactly the same potential.

Examine the schematic of the receiver to see the effect of leakage in C_{13}. Resistor R_{10} and the leakage through C_{13} form a voltage divider that lowers the positive voltage at the emitter of Q_3. The base voltage must be negative (less positive) in respect to the emitter to provide forward bias for the transistor. The base voltage for Q_3 is set by the conduction of Q_2. With the Q_3 emitter voltage lowered, the transistor remains cut off and the receiver does not operate.

Unsolder and remove the 6.8k-ohm resistor that you had in parallel with C_{13}. Tune in a station and adjust the volume for normal listening. Temporarily shunt a 10k-ohm resistor across capacitor C_{13}. This simulates a smaller amount of leakage through C_{13}. Listen for a change in volume. It should decrease a noticeable amount. Remove the 10k-ohm resistor and test the receiver for normal operation.

From the preceding tests you can see that leakage in C_{13} upsets the dc operating voltages for the transistor. A small amount of leakage will produce reduced sensitivity, and a large amount of leakage will make the set completely inoperative. Careful voltage readings will help point to the cause of the trouble, but you would have to isolate components and take resistance measurements to pinpoint the defective components.

Instructions for Statement 64: For this statement you investigate the effect of simulated leakage in the emitter bypass capacitor of the audio driver stage, Q_4.

On the foil side of the board, tack-solder a 2.2k-ohm resistor to the foil at the terminals of the 100 mfd electrolytic capacitor, C_{18}. This connection simulates leakage through the capacitor. Energize the receiver and test its operation. Examine the schematic diagram of the receiver, take voltage measurements and other tests, as necessary, to answer the statement.

Unsolder and remove the 2.2k-ohm resistor that you tack-soldered in parallel with C_{18}. Test the receiver for normal operation.

Statement No. 64: When I simulated leakage in the emitter bypass capacitor, C_{18}, of the audio driver stage,

(1) the receiver operated normally, because C_{18} is already paralleled by a low value resistor.

(2) the receiver operated, but the volume was reduced and the sound was garbled.

(3) the receiver produced no sound, because the changed operating voltages back-biased the audio driver transistor, Q_4.

EXPERIMENT 65

Purpose: To demonstrate common causes of low sensitivity in a transistor radio receiver; and

To demonstrate forward-acting avc.

Introductory Discussion: A familiar complaint on transistor receivers is loss of sensitivity. The complaint may be that the receiver will no longer pick up a certain station or a station is not as loud as it used to be. In battery-operated receivers, the first thing to try is a new battery. Low battery voltage will usually show up first as loss of volume or reduced sensitivity. In other cases, the set may perform fairly well until the battery voltage becomes so low that the local oscillator drops out. In this case, the complaint will be a dead receiver.

Loss of sensitivity can be caused by faulty operation of any of the signal-handling circuits in the receiver. Good receiver sensitivity is the ability of the receiver to pick up weak stations. Therefore, the condition of the audio section of the receiver does not affect the sensitivity. In practice, however, a weak audio stage makes the receiver appear to have low sensitivity.

The avc circuits in transistor receivers have many variations. In general, a voltage from the second detector is fed back to control the gain of the i-f stages. The avc voltage may affect one or more stages in the receiver. The usual avc circuit uses what is called reverse-acting or reverse-biasing avc.

That is, the avc voltage fed back from the detector is of the correct polarity to reverse-bias the i-f stages. The stronger the received signal, the larger the reverse bias, which results in reduced current and reduced gain of the controlled stages.

Another type of avc circuit uses what is called forward-acting avc. The polarity of the avc voltage increases the conduction of the controlled stages. When you first trace out a forward-acting avc circuit, you may suspect that the detector diode is reversed. The forward-acting polarity is intentional, however.

The increased forward bias causes the transistor to draw increased current and lowers the emitter-to-collector voltage, causing reduced gain. You can think of the transistor as being operated near the saturation point on the transfer curve, which causes reduced gain. In this experiment you vary the bias on an operating i-f stage to simulate circuit conditions for forward-acting avc.

Experimental Procedure: For this experiment you will need your operating receiver, voltmeter, hand tools, and the following parts:

1 2200 pf disc capacitor
1 1.5 volt D cell battery
1 1k-ohm potentiometer (PO7)
1 470-ohm resistor

Step 1: To show the effects of an open circuit in the loop antenna of your receiver.

Unsolder and remove the loop antenna connection to the rf section of the tuning capacitor. Energize the receiver and test its operation. If you have strong local stations, you should be able to receive some of them fairly well. Touch your hand to the bare end of the antenna wire that you disconnected from the tuning capacitor. This should improve reception. Solder the antenna connection back in place to the rf tuning capacitor terminal, and test the receiver for normal operation.

A broken antenna wire is a common defect, especially in portable transistor receivers. The customer may break a connection by careless handling while changing the battery. Careful visual inspection will usually reveal the location of the break. Suspect a break in the antenna wires whenever touching the leads greatly improves reception.

Normally, the antenna circuit is tuned to resonance at the frequency of the incoming rf signal. Therefore, when you touch the terminals, your hand capacitance will tend to detune the circuit and decrease the sensitivity. If touching the circuit improves the reception, as it does when the circuit is broken, your body is providing additional signal pick-up.

This test is not always valid. The antenna tank circuit may not track perfectly at all frequencies across the band. Therefore, you may get some improvement in reception when you touch the circuit, even though the circuit is operating correctly.

Step 2: To show the effects of an open circuit in the secondary winding of the loopstick antenna.

Unsolder and remove the antenna connection from hole E on the circuit board. Energize the receiver and attempt to tune in a station. You should not be able to pick up any stations.

Examine the schematic diagram of the receiver to see why the set is completely dead. Notice that the local oscillator signal is coupled through C_7 and through the secondary winding of the loop antenna to the base circuit of the mixer stage, Q_2. When you open the secondary winding of the loop antenna, you effectively disconnect the local oscillator signal from the mixer stage so that the set is inoperative. Also, the base bias voltage is supplied to the base of the transistor through the secondary winding. When the secondary winding is open, so is the base circuit.

Tack-solder a short piece of hookup wire from the foil at hole E to the foil at the base connection of Q_2. This connection provides a path for the local oscillator signal to reach the base of Q_2.

Energize the receiver and again test its operation. You should be able to receive at least one strong local station. If necessary, touch your hand to the free end of the wire that you disconnected from hole E to improve reception.

Turn off the receiver. Unsolder and remove the short that you connected from the foil at hole E to the base of Q_2. Reconnect and solder the antenna wire at hole E. Test the receiver to make sure that it is operating properly.

In many receivers, the oscillator and the mixer functions are combined in the same stage so that opening the loop secondary will not remove the oscillator signal from the mixer. In these receivers, an open secondary in the loop antenna will simply cause reduced sensitivity.

Step 3: To show the effects of a shorted detector diode on the operation of the receiver.

Tack solder a short piece of hookup wire to the foil at each end connection of the diode detector, D_1. This connection simulates a direct short in the detector diode. Turn the receiver on and test its operation. You may be surprised to find that you are able to receive one or more strong local stations.

Since the detector diode is effectively out of the circuit, detection must be taking place elsewhere. With the diode shorted, the i-f signal is coupled through C_{16} to the base circuit of the audio driver Q_4. Detection takes place in the base-emitter junction of the transistor and the detected audio signal is reproduced in the collector circuit. Some of the i-f signal is attenuated in the detector filter circuit.

Unsolder and disconnect one lead of the .02 mfd filter capacitor, C_{15}. Again test the receiver operation. It should exhibit volume and sensitivity almost equal to that obtained by the diode detector circuit.

Reconnect and resolder the disconnected lead of capacitor C_{15}. Unsolder and remove the short you tack-soldered in parallel with diode detector D_1. Test the receiver for normal operation.

Ordinarily you expect a diode to fail completely when it goes bad. This step shows that you may get detection even if the diode shorts. Thus if you have low sensitivity or low volume, do not overlook the possibility that the diode has failed and some detection is taking place in the base-emitter junction of the first audio stage.

Step 4: To show the effects of a detuned i-f stage on the operation of the receiver.

For this step you detune the i-f transformer by bridging a capacitor across the windings. The added capacitance changes the resonant frequency of the circuit and reduces the gain of the stage. You can either tack-solder the capacitor in place, or simply hold the body of the capacitor between your fingers and touch the leads to the indicated terminals of the transformer.

Energize the receiver, tune to a local station and adjust the volume for normal listening level. Bridge a 2200 picofarad capacitor between terminals 3 and 4 of i-f transformer T_2. Note the change in level of the reproduced signal. Repeat the above procedure for terminals 1 and 2 of transformer T_2, terminals 1 and 2 of transformer T_3, and finally for terminals 3 and 4 of transformer T_3. Remove the capacitor and test the receiver for normal operation.

Paralleling the 2200 pf capacitor with a winding of an i-f transformer detunes the circuit and greatly reduces the gain of that stage. However, the receiver is still able to process strong local signals. You probably notice that shunting the 3-4 winding of T_3 produced only a small loss of signal.

The secondary winding of transformer T_3 is at a low impedance, and it is not tuned. The loss of signal is simply caused by the added capacitance shunting some of the signal that would otherwise go to the detector diode.

Most service situations related to detuning of the i-f occur when someone moves the tuning adjustments on the i-f transformers. This calls for either touch-up alignment or complete realignment of the receiver. In a later experiment you will work with alignment problems.

Step 5: To demonstrate how forward bias, simulating forward-acting avc, causes reduced gain of an i-f stage.

For this step you prepare a variable bias supply to control the gain of the i-f transistor, Q_3. Construct the circuit shown in Fig. 65-1B. (Fig. 65-1A shows terminal identification.) Connect a 470-ohm resistor from the positive terminal of the 1.5-volt cell at terminal 3 of your 1k-ohm potentiometer, PO7.

Connect a piece of hookup wire from the negative terminal of the cell to terminal 1 of the pot. Connect a 12" piece of hookup wire from terminal 3 of the pot to the foil at the emitter of Q_3. Connect a 12" piece of hookup wire from terminal 2 of the pot to the foil at the junction of R_4 and R_9 on the circuit board. This point is also the junction of terminal 2 of T_2 and one lead of C_{12}.

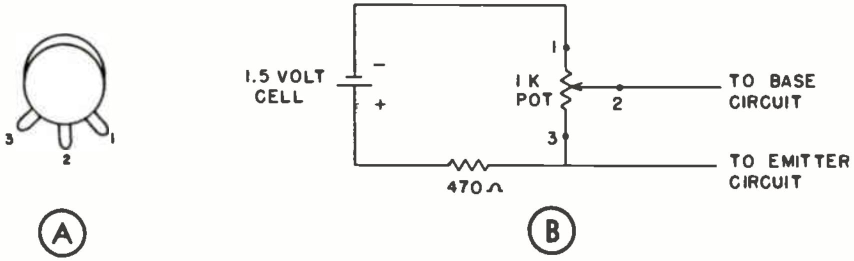

Fig. 65-1. (A) terminal identification; (B) variable bias supply circuit.

These connections will enable you to apply a variable dc bias between the base and emitter of Q_3. With the pot turned all the way clockwise, the difference in potential between the emitter and the base will be approximately zero volts. Rotating the pot counterclockwise applies a negative voltage to the base (in respect to the emitter). The negative voltage forward-biases the transistor.

Energize the receiver and tune to a station. Connect your meter between the emitter and the base of Q_3 so you can read the actual bias on the transistor. Set the meter to read -dc on the lowest scale. Adjust the bias for about -.6 volt and carefully tune in a station. Rotate the bias pot over its full range and note the range of bias voltages that gives reception. The transistor, Q_3, will be completely cut off at a bias voltage somewhere between -.4 and -.5 volt. Maximum gain will be obtained with a bias near -.6 volt.

As you make the bias more negative, the gain decreases. Further rotation of the pot will not produce a corresponding change in bias, because the increased base current produces a voltage drop in the pot circuit, limiting the bias voltage.

The i-f stage may go into oscillation as you increase the forward bias. The neutralizing values are selected for normal operating conditions. With increased forward bias, capacitor C_{14} provides a feedback path that may produce oscillations. Unsolder and disconnect one lead of C_{14} to minimize the tendency to oscillate. Also you can turn the slug adjustment on T_3 one-quarter turn to help prevent oscillation.

Measure the emitter-to-collector voltage change as you vary bias over the full range. With normal operating bias, the emitter-to-collector voltage will measure nearly B+ voltage. This indicates that the transistor is drawing only a small current and only a small amount of voltage is dropped across the emitter resistor, R_{10}. As you increase the forward bias, the transistor current increases and the emitter-to-collector voltage decreases. This decrease in emitter-to-collector voltage helps to explain why the gain decreases as the forward bias is increased.

A forward-acting avc circuit controls the stage gain in the same way as we have shown. The controlled stages have a fixed bias that produces maximum gain. When a station is tuned in, the detector produces avc voltage that is applied to the controlled stages. Polarity of the avc voltage is such that it increases the forward bias on the controlled stages. As you saw in this step, the increased forward bias caused decreased emitter-to-collector voltage and reduced gain for the stage.

Unsolder and remove the leads that you connected from the bias pot to the base circuit and emitter circuit of the board. Unsolder and remove the flashlight cell and other parts that you had connected to the bias pot. Reconnect and solder the disconnected lead of capacitor C_{14}. Energize the receiver and test for proper operation. If necessary, readjust the core of transformer T_3 for maximum output.

Instructions for Statement 65: For this statement you place a capacitor across a part of the secondary winding of i-f transformer T_2 and observe the effect on the operation of the receiver.

Tune the receiver to a station and adjust the volume for normal listening.

Tack-solder a 2200 pf capacitor between terminals 2 and 6 of transformer T_2. Energize the receiver and test its operation. Then answer the statement.

Unsolder and remove the 2200 pf capacitor you connected from terminal 2 to terminal 6 of T_2. Test the receiver for normal operation.

Statement No. 65: When I connected a 2200 pf capacitor from terminal 2 to terminal 6 of i-f transformer T_2,

[✓ *(1) the receiver operated normally, with no noticeable change in sensitivity.*]

(2) the receiver operated, but with greatly reduced sensitivity.

(3) the receiver did not operate at all, because the capacitor shunted the small signal normally applied to the base of Q_3.

EXPERIMENT 66

Purpose: To demonstrate typical causes of hum in a line-operated transistor radio receiver.

Introductory Discussion: The hum produced by the 60 Hz line voltage is normally associated only with line-operated receivers. One of the advantages of battery-operated receivers is the freedom from the hum and noise that originate from the power line.

Hum can get into the signal path in two different ways. Insufficient filtering in the B+ line allows an audible sound signal to be produced in the audio circuits of the receiver. If the hum signal gets into the signal path at one of the low signal level stages, the hum signal will be amplified along with the desired signal. Or the 60 Hz signal can modulate any rf stage of the receiver and be detected by the second detector.

This condition can occur even in a battery-operated receiver. If the receiver is in close proximity to a power line, the sensitive rf section of the receiver may pick up enough 60 Hz signal to modulate an rf stage and produce an audible hum.

Noise on the power line may be picked up by either a battery-operated or line-operated receiver. The noise may be described as hum, because it usually varies at the 60 Hz line rate. To hear this noise, simply tune a receiver between stations, turn up the volume control and hold a line cord near the loopstick antenna. The noise will come through loud and clear.

Neon or fluorescent lights are another source of similar noise. Line-operated receivers sometimes have noise filters in the line circuit to minimize this source of noise. The amount of noise on the power line varies with locations. Very little noise is usually present in residential areas, whereas in industrial areas the power lines are usually very noisy.

Experimental Procedure: You will need your operating receiver, voltmeter, hand tools and the following parts:

1 10k-ohm resistor
1 2.2k-ohm resistor
1 .001 mfd capacitor
1 .005 mfd capacitor

Step 1: To show the effects of high resistance in the B++ filter capacitor.

For this step you will simulate the conditions of a filter capacitor that has developed series resistance. A capacitor with this defect is also described as one having a poor power factor. Unsolder and remove the jumper that is connected between holes M and N on the circuit board.

In its place, tack-solder a 10k-ohm resistor. Energize the receiver and test its operation. The hum is clearly audible even with the volume control turned to minimum. The program material will sound garbled and the set will exhibit reduced sensitivity. Measure B++ and B+ voltages. Typical values are 65 volts and 10 volts. This large reduction in power supply voltage accounts for the reduced sensitivity and garbled sound.

The above symptoms always point toward a defective filter capacitor. The symptoms are the same if the capacitor develops reduced capacitance. The fact that the hum is present even with the volume control at a minimum is the clue to power supply trouble, and the capacitor is the most likely component to be defective.

Step 2: To show the effect of a small resistance in the filter capacitor.

In this step you change the size of the resistor in series with the capacitor to simulate a small reduction in capacitance or a small series resistance in the capacitor.

Unsolder and remove the 10k-ohm resistor you tack-soldered from hole M to N of the circuit board. In its place tack-solder a 2.2k-ohm resistor. Energize the receiver and test its operation. Turn the volume control to minimum and listen for hum. You may have to tune between stations and place your ear close to the speaker to hear the hum. On a local station at normal listening levels, the operation may seem quite normal. Turn up the volume and listen for distortion. Measure the B++ and B+ voltage. They should measure low.

This step illustrates the effect of only a small loss of capacitance in the filter capacitor. The operation of the set is marginal. The customer's complaint may be "garbled sound," "reduced sensitivity," "noise," or "hum." A careful listening test should make you suspect the power supply.

When you measure B++ and turn up the volume, you should notice that the meter needle varies with sound. This also is an indication that the power supply is unable to furnish the required current to the output transistor. Again the filter capacitor is the most likely component to be defective.

Unsolder and remove the 2.2k-ohm resistor you tack-soldered from hole M to hole N on the circuit board. In its place, install the original jumper. Test the receiver for proper operation.

Step 3: To show the effect of an open filter capacitor, C_{22}, in the B+ power supply line.

To simulate an open B+ filter capacitor, C_{22}, unsolder and remove the capacitor from the circuit board. To do this, grasp the body of the capacitor and pull gently while you heat the connection on the foil side of the board. This takes a little patience. Each time you melt the solder on a connection, the lead will "give" about 1/16". Then heat the other connection until that lead moves. Alternately heat the connections and pull on the capacitor until you work out the leads and the capacitor comes free. Use a toothpick or a paper clip wire to clear the solder from the holes so that they will be ready to receive the capacitor wires when you reinstall the capacitor.

Energize the receiver and test its operation. A distinct hum is audible even at minimum volume. You may be surprised that the hum level is so low with the filter capacitor removed. When you tune in a station and keep the volume low, the set may appear to function almost normally. Measure the B+ voltage. It should be about normal. The condition of C_{22} does not affect the value of B+ as did the input filter capacitor, C_{23}.

Switch the meter to measure ac on a low range and turn up the volume. As you can see, the lack of filtering allows signals to develop on the B+ line across the 10k-ohm dropping resistor, R_{20}. Tune across the band with the volume control wide open. The set will squeal and sputter. Feedback paths through the unfiltered common power supply line is causing oscillation. In some places the oscillations are so strong that the audio is completely drowned out.

When troubleshooting a receiver with this condition, try paralleling the suspected capacitors with a good capacitor. You usually have more than one capacitor in the power supply that could be causing the trouble. The capacitors may be hard to remove or be of odd sizes. If you parallel a suspected capacitor with a good one, a change in operation of the receiver will indicate that the capacitor is defective.

The test capacitor need not be exactly the same size. For example, a 50 or 100 mfd capacitor in parallel with an open 200 mfd capacitor, C_{22}, would improve the operation enough to prove that C_{22} was open. To effect the repair you would, of course, obtain the correct value capacitor for replacement.

Install the 200 mfd capacitor, C_{22}, in its place on the circuit board. Be careful to remove any globs of solder from the leads of the capacitor. If solder makes the leads oversized, it will be difficult to get them through the mounting holes. Be sure to observe the capacitor polarity. Solder the leads in place to the foil. Test the receiver for proper operation.

Step 4: To demonstrate how a 60 Hz line voltage can modulate an rf stage and produce hum.

Unplug the receiver and tack-solder one lead of a .001 mfd capacitor to the interlock terminal where it connects to the 250-ohm, 4-watt resistor, R_{21}. Tack-solder the other lead of the .001 mfd capacitor to the foil at the junction of R_6 and R_8. From the schematic diagram of the receiver, you can see that this is also the point where the oscillator signal is injected into the base circuit of Q_2.

Energize the receiver and test its operation. Tune to the weakest available station and listen to the quality of the program material. It will probably sound garbled and you should hear a noticeable hum signal. If you are in a noisy (electrical noise on the power line) location, the hum may be masked by power line noise. Or the line noise may appear to vary at the line frequency. With the volume turned up, the hum should be quite noticeable.

In this step you coupled the line voltage through a .001 mfd capacitor to the base circuit of the mixer transistor, Q_2. This connection caused a 60 Hz signal to be mixed with the rf and the local oscillator signal. Also the noise on the power line is coupled into the signal path. This step does not illustrate a practical defect that would occur during servicing, but it does enable you to recognize the symptoms when a condition develops where the line voltage modulates an rf stage in a receiver.

Unplug the receiver, unsolder and remove the .001 mfd capacitor that you tack-soldered from the foil at the junction of R_6 and R_8 to the power line terminal. Test the receiver for proper operation.

Instructions for Statement 66: For this statement you will observe the effect of coupling 60 Hz line voltage into the base circuit of the i-f transistor, Q_3. Unplug the receiver and tack-solder one lead of the .005 mfd capacitor to the interlock terminal where it connects to the 250-ohm, 4-watt resistor, R_{21}. Tack-solder the other lead of the .005 mfd capacitor to the foil at the junction of R_9 and C_{12}. Energize the receiver and test its operation, as necessary, to answer the statement.

Unplug the receiver. Unsolder and remove the .005 mfd capacitor that you had connected from the foil at the junction of R_9 and C_{12} to the power line. Energize the receiver and test it for proper operation.

Statement No. 66: When I coupled the 60 Hz power line voltage through a .005 mfd capacitor to the base circuit of the i-f transistor, Q_3,

(1) the receiver operated normally except for a little more noise.

(2) a loud hum was present as long as the receiver was on, and the hum volume did not change with the setting of the volume control.

[✓ *(3) the receiver produced garbled sound with hum and noise.*]

EXPERIMENT 67

Purpose: To show common causes of oscillation and how to locate them.

Introductory Discussion: The high gain stages and compact construction of transistor receivers makes oscillation a common complaint. As you know, a high gain circuit will tend to oscillate whenever energy from the output is fed back into the input. The requirements for oscillation are simple. The energy fed back must be of the proper phase to aid the signal producing the output and the circuit must have sufficient gain to overcome the losses in the circuit.

Since a receiver has many high gain stages, many opportunities for oscillation exist. The common power supply offers one possible feedback path between the output and the input of stages. For example, in a previous experiment, you saw how lack of filtering in the power supply produced oscillation.

The tuned stages in the receiver are particularly susceptible to oscillation. Since the i-f amplifier is tuned to a single frequency, it produces very high gain at that frequency. Even a rather poor feedback path is capable of coupling enough energy from output to input to produce oscillation.

In compact receivers where the parts are closely spaced, the close proximity of a part in an output circuit to a part in an input circuit can couple enough energy to produce oscillation. For this reason, when making repairs you are cautioned to position replacement parts in the same place as the original part. This condition does not exist on your receiver, because the parts are spread out and their position is relatively fixed by the circuit board mounting holes.

Oscillation can occur in high-gain audio stages of a receiver. The frequency of oscillation may vary from only a few Hertz to well above the audio range. The exact frequency at which the circuit oscillates is often determined by the R-C time constant of the feedback path.

The avc circuit of a receiver can provide a feedback path that produces oscillation. The avc circuit varies from receiver to receiver; but in general, a voltage from the output of the second detector is fed back to one or more i-f stages. The avc voltage is filtered, so it is dc that varies in amplitude with signal strength. The circuit has a long time constant compared to changes in signal strength.

A defect in the avc circuit can cause very low frequency oscillation (motorboating) or very high frequency oscillation. Insufficient filtering on the avc line can allow an i-f signal from the output to be fed back to an earlier stage and cause high frequency oscillation. Motorboating can result from a defect in the avc line that produces an extremely long time constant.

In this experiment you simulate defects that can produce oscillation. In some steps you provide feedback paths to produce oscillation so you can recognize the symptoms.

Experimental Procedure: For this experiment you will need your receiver, voltmeter, hand tools, and the following:

1 27 pf disc capacitor
1 1.2k-ohm resistor
1 .001 mfd disc capacitor
1 .005 mfd disc capacitor

Step 1: To demonstrate oscillation in the audio stages of the receiver.

Turn off the receiver and tack-solder a .001 mfd capacitor from the collector of Q_5 to the foil at the base of Q_4. Energize the receiver and test the operation. Vary the setting of the volume control to see the effect on the tone of the audio oscillation.

Unsolder and remove the .001 mfd disc capacitor that you tack-soldered from the base of Q_4 to the collector of Q_5. In its place, tack-solder a .005 mfd capacitor. Energize the receiver and note the lower frequency of the audio oscillation. From this you can see that the R-C time constant of the feedback circuit affects the frequency of oscillation.

If you phase a signal through the two-stage audio amplifier you will find that the output of the collector of Q_5 is in phase with the signal at the base of Q_4. Therefore, when you connect these two points with a capacitor, the circuit oscillates.

Unsolder and remove the .005 mfd capacitor that you connected from the collector of Q_5 to the base of Q_4. Test the receiver for proper operation.

Step 2: To demonstrate the symptoms of oscillation in an i-f stage of a receiver.

On the foil side of the board, tack-solder a 27 pf capacitor in parallel with the 6.8 pf capacitor, C_{14}. This capacitor connects between terminal 4 of the secondary winding of T_3 and the base of Q_3. As you know, the function of C_{14} is to neutralize the effect of base-to-collector capacitance in the transistor. When a large capacitance is placed in parallel, it provides an output-to-input feedback path that allows the stage to oscillate.

Energize the receiver and test its operation. You should be able to tune in some stations satisfactorily. Tuning will be accompanied by squeals and howls. The pitch of the squeals should reduce as you approach the station. The audible oscillations are the difference between the intermediate frequency of the signal and the oscillation frequency. The frequency of the oscillating i-f stage remains constant.

The i-f signal frequency is the difference between the local oscillator signal and the incoming rf signals. This frequency varies as you tune toward and away from the station. Therefore, the pitch of the audible difference frequency changes as you tune the receiver. Knowing these facts gives you a clue to the location of the circuit that is oscillating.

Tune the receiver close to a station so you can definitely hear the oscillation. Next, use a screwdriver to rotate the slot adjustment of the core of the output i-f transformer, T_3.

Listen to the oscillation as you rotate the adjustment. You should be able to detune the transformer enough so that the circuit ceases to oscillate. Detuning the stage reduces the stage gain enough so that the available gain does not exceed the circuit losses. Tune the receiver to other stations to prove to yourself that the circuit is not oscillating. Detuning the transformer reduces the receiver sensitivity, but it operates satisfactorily.

This step illustrates a condition that you will run into in practical servicing. When you attempt to peak up the alignment of the receiver, a stage will break into oscillation. You may not be able to locate the exact cause of the feedback and oscillation, or you may have replaced a transistor or tube with one having higher gain.

In some inexpensive receivers it may be easier to leave a stage slightly mistuned than to try to redesign the stage to eliminate the oscillation. This is particularly true if the receiver has adequate sensitivity with one stage slightly mistuned.

Unsolder and remove the 27 pf capacitor that you connected in parallel with C_{14}. Tune the receiver to the weakest available station. Be sure you are tuned exactly to the station. Readjust the transformer core in T_3 for maximum output. Test the receiver to make sure it is operating properly.

Step 3: To demonstrate the effects of an excessive local oscillator signal.

Tack-solder a 1.2k-ohm resistor on the foil side of the board in parallel with R_{19}, the oscillator supply voltage-dropping resistor. This connection will greatly increase the amplitude of the oscillator signal. Next, tack-solder a short jumper wire in parallel with resistor R_7 in the base circuit of Q_2. Energize the receiver and test the operation, especially on high frequency stations.

The symptoms of this condition are almost the same as when you had the i-f stage oscillating. The large oscillator signal drives the i-f stage so hard that the stage tends to oscillate at its natural frequency. The 100-ohm resistor, R_7, normally increases circuit losses and attenuates the signal that is driving the base.

Unsolder and remove the 1.2k-ohm resistor that you connected in parallel with R_{19}. Unsolder and remove the short bare wire that you connected in parallel with R_7. Test the receiver for proper operation.

Instructions for Statement 67: For this statement you simulate an open filter capacitor in the avc line by removing electrolytic capacitor C_{11} from the circuit board. Turn off the receiver. Carefully unsolder and remove the 10 mfd avc line filter capacitor, C_{11}, from the circuit board. Clean the solder from the mounting holes so the board will be ready when you reinstall the capacitor. Turn the receiver on and test its operation as necessary to answer the statement. Be sure to tune across the entire broadcast band.

Install the 10 mfd capacitor, C_{11}, that you removed from the circuit board. If necessary, remove any excess solder from the capacitor leads so they will fit easily into the mounting holes. Be sure to observe the polarity markings on the capacitor and circuit board. Solder the capacitor leads to the foil on the circuit board. Energize the receiver and test it for proper operation.

Statement No. 67: When I removed the avc line filter capacitor, C_{11}, the receiver,

[✓ *(1)*] *produced motorboating on some stations because of the increased time constant in the avc circuit.*

(2) produced squeals and whistles because the i-f circuit was oscillating.

(3) worked normally except for reduced sensitivity, because there was no avc voltage.

EXPERIMENT 68

Purpose: To show common causes of audio distortion and how to locate them.

Introductory Discussion: Any defect that affects the quality of the reproduced sound from the speaker might be considered audio distortion. The defect may cause a loss of only the low frequencies or only the high frequencies in the received program material.

Loss of lows produces the complaint that the radio sounds "tinny." A loss of highs may be described as causing the set to sound "boomy." The normal audio response curve of an inexpensive radio receiver is quite narrow. The low frequency cut-off point is usually around 100 Hz and the high frequencies fall off rapidly above 6000 or 7000 Hz.

Although this is a very narrow band of audio frequencies by high-fidelity standards, it is most satisfactory for AM radio reception. The attenuation of the high frequencies also attenuates the annoying noise associated with AM reception. The low frequency cut-off helps to prevent hum in a line-operated receiver.

Most receivers have only two audio stages so it is easy to isolate the defective stage. In an earlier experiment, you saw how hum could cause garbled sound when the hum signal entered the signal path in one of the i-f stages. Also, audio distortion can result from a power supply defect. Low supply voltage to the audio stage can upset the stage bias and produce distortion. Such defects are quickly isolated by taking voltage measurements in the audio stages.

When a defective speaker produces audio distortion, the trouble can be isolated by substituting a known good speaker. Mechanical defects are the usual cause of audio distortion from a speaker. The voice coil may become misaligned with the magnet.

Rough handling or a warped speaker frame may cause the voice coil to rub on the magnet. You can usually feel the mechanical contact between the coil and the frame by carefully depressing the speaker cone with your finger. Sometimes the condition can be corrected by evening up the pressure on the speaker mounting screws. Usually the speaker has to be replaced.

Most receivers will distort at full volume on a strong station. A strong local station produces a larger signal than the amplifier can handle. In your receiver, the audio driver stage will clip the peaks of a large audio signal and produce noticeable distortion. Therefore you cannot turn the volume up full on strong stations. The reserve gain of the audio amplifier is useful because it enables you to listen to weak stations. At normal listening levels the receiver has low distortion.

Experimental Procedure: For this experiment you need your operating receiver, hand tools, and the following parts:

1 22k-ohm resistor
1 680-ohm resistor
1 220-ohm resistor
1 .01 mfd capacitor

Step 1: To show how insufficient capacitive coupling causes a loss of low frequencies in the audio signal.

Tune the receiver to a local station and adjust the volume control for normal listening level. Unplug the receiver and do not change the volume control setting. Unsolder and remove the 10 mfd coupling capacitor, C_{16}, from the circuit board. In its place, tack-solder a .01 mfd disc capacitor. Plug in the receiver and listen to the received program.

The most obvious change in operation is reduced volume. When you turn up the volume, speech may sound quite normal. However, if you listen to music, the program material will obviously lack the rich deep tones.

Voltage measurements in the audio stages will not isolate this defect. The condition of reduced capacitance can vary all the way from a completely open capacitor to one having only a small loss of capacitance. When you suspect this condition, the easiest check is to bridge the suspected capacitor with a known good capacitor. Any noticeable improvement in operation indicates a defective capacitor.

Unsolder and remove the .01 mfd capacitor you installed in place of the 10 mfd capacitor for C_{16}. Replace the original capacitor, being sure to observe the correct polarity markings. Solder the capacitor in place and test the receiver for normal operation.

Step 2: To show the effects of a leaky or shorted audio coupling capacitor.

Tack-solder a 680-ohm resistor on the foil side of the board in parallel with the 10 mfd coupling capacitor, C_{16}. This simulates a leaky coupling capacitor. Energize the receiver and test its operation. Measure voltages in the audio stages, Q_4 and Q_5. Compare your readings with those you recorded for normal operation in the voltage chart.

As you would expect, the leaky capacitor allows the positive dc potential present in the detector circuit to be applied to the base of the audio driver, Q_4. This increased positive bias reduces the conduction of Q_4 and lowers the collector voltage. Since the collector of Q_4 is directly coupled to the base of Q_5, the forward bias for Q_5 is reduced.

This in turn reduces the conduction of Q_5 and causes increased collector voltage for Q_5. The circuit distorts the audio signal because the transistors are not operating at the correct point on their transfer curves. You can increase the distortion by replacing the 680-ohm resistor with a direct short.

The voltage readings in the audio stages do not tell you for sure that the capacitor is leaky. Perform this additional test. Tune the receiver to a point between stations. Hold your meter probe on the base of Q_4 and observe the meter reading. Take a dc voltage reading with the volume control at minimum and another reading with the control set to maximum. You should observe a change of at least a volt or more.

Examine the schematic diagram to see why the base voltage changes when the coupling capacitor is leaky or shorted. Normally, no direct current flows through the volume control pot. A leaky or shorted C_{16} completes a dc path from the pot slider to the resistor network in the base of Q_4. DC from the B+ line can now flow through the pot, through C_{16} leakage, and through R_{12} to B-. Changing the setting of the volume control pot changes the drop across its resistance, and therefore changes the voltage reading at the base of Q_4. The results of this test are a pretty good indication that C_{16} is defective.

Unsolder and remove the 680-ohm resistor and/or the short circuit that you bridged across capacitor C_{16}. Operate the receiver and test it for proper operation.

Step 3: To show the effects of increased forward bias on the audio driver stage.

In this step you simulate a condition where a resistor in the base bias network for Q_4 changes resistance. Tack-solder a 22k-ohm resistor from the foil at the base of Q_4 to B-. Energize the receiver and test its operation. Tune to a point between stations and take voltage readings. Record your readings in the chart of Fig. 68-1.

Q4	NORMAL READINGS	R12 WITH 22K IN PARALLEL
BASE TO B-		
EMITTER TO B-		
COLLECTOR TO B-		

Fig. 68-1. Chart for recording voltage readings in Step 3.

Examine the schematic diagram of the receiver and relate the voltage readings to the circuit conditions. Reducing the resistance of R_{12} lowers the normally positive voltage on the base of Q_4. Since this is a PNP transistor, the less positive base voltage means an increase in forward bias.

Your voltage readings reveal that the emitter and the collector are at almost the same potential. This indicates that the transistor is conducting very heavily. These facts should tell you why you have audio distortion. Since the bias very nearly saturates the transistor, it is operating close to one end of its transfer curve and cannot provide linear amplification of the applied audio signal. In fact, the negative portion of the audio signals drives the transistor even further into saturation. Only the positive portions of the audio signals are capable of producing reasonable amplification. The result is a clipped and distorted audio signal.

This defect also increased the forward bias on Q_5 and thereby increased its conduction. The base bias for Q_5 is determined by the voltage drop across R_{15} and R_{16}. The current through these two resistors is determined by the amount of conduction of Q_4. Increased conduction of Q_4, caused by the defect, increased the drop across R_{15} and R_{16} and thereby increased the forward bias for the NPN transistor Q_5.

Step 4: To show the effects of an open capacitor in the emitter circuit of the power output transistor.

Energize the receiver, tune to a local station and adjust volume for normal listening level. Unplug the receiver, being careful not to change the setting of the volume control. Unsolder and remove the 10 mfd electrolytic capacitor, C_{19}, from the emitter circuit of the transistor, Q_5. Energize the receiver and listen to the station with the same setting of the volume control.

The sound will have reduced volume. Now listen to the quality of the program material. It sounds flat even with the volume turned up. The sound seems to lack the low frequencies.

Examine the schematic diagram to see the effect of capacitor C_{19}. This capacitor provides a feedback path from the emitter through R_{15} to the base of Q_5. Since the signals at the base and emitter are in phase (the emitter signal follows the base signal) the feedback is a form of positive feedback. This type of positive feedback increases the gain of the stage and, more important, the feedback increases the input impedance of the stage. The .05 mfd capacitor, C_{17}, is shunted from the base of Q_5 to ground. The effect of this capacitor is to reduce the frequency response of the circuit to high frequencies (especially noise). When C_{19} is removed from the circuit, the middle low frequencies, 200 to 600 Hz, receive much less amplification, causing the "flat" sound of the reproduced program material.

Install the 10 mfd electrolytic capacitor, C_{19}, on the circuit board. Be sure to match the polarity markings on the capacitor with the corresponding markings on the circuit board. Solder the capacitor in place. Test the receiver.

Instructions for Statement 68: For this statement you will change the resistance in the base bias network for the audio output transistor, Q_5, and observe the results. Tack-solder a 220-ohm resistor from the foil at the base of Q_5 to B−. Turn on the receiver and test its operation. Take voltage readings and other tests as necessary to answer the statement.

Unsolder and remove the 220-ohm resistor that you tack-soldered from the base of Q_5 to B−. Test the receiver.

Statement No. 68: When I paralleled R_{15} and R_{16} with a 220-ohm resistor and tested the receiver,

(1) the increased forward bias on Q_5 caused increased gain and badly distorted audio.

(2) the reduced forward bias on Q_5 nearly cut off Q_5, causing clipping of the audio signal and badly distorted audio output.

(3) the reduced forward bias on Q_5 caused loss of audio gain and some distortion.

EXPERIMENT 69

Purpose: To show how the mixer and oscillator functions of the receiver can be combined into a single stage.

Introductory Discussion: Most small inexpensive transistor receivers use a single stage as an oscillator-mixer. The advantages of a separate oscillator stage are improved oscillator stability, a better noise figure, and usually more gain in the converter (mixer) stage. These advantages do not necessarily outweigh the economy of one less transistor. As you know, your receiver has a separate local oscillator stage. In this experiment you rearrange the receiver so transistor Q_2 acts as both the oscillator and the mixer stage.

The simplified schematic diagram in Fig. 69-1 shows the circuit for the combined mixer-oscillator stage. Transistor Q_1 is completely out of the circuit. The emitter circuit for Q_2 is completed through the 5-3 winding of the oscillator transformer, T_1. The B+ dropping resistor, R_{19}, has been paralleled by a resistor to provide enough supply voltage for Q_2. A feedback signal from terminal 4 of the oscillator transformer is coupled through C_7 to the base circuit of Q_2. The signal fed back to the base circuit is of the correct polarity to cause the circuit to oscillate.

The rf signal is fed to the base circuit of Q_2 in the usual manner, and the two signals are mixed in the transistor. Transformer T_2 is tuned to the intermediate frequency to select the difference frequency between the incoming rf and the local oscillator frequency. In this way transistor Q_2 powers the local oscillator and performs the mixing function.

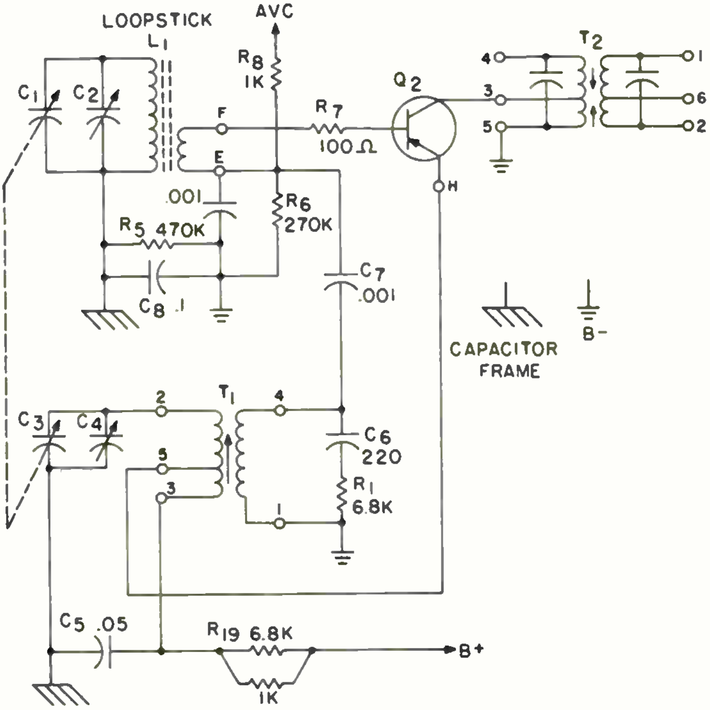

Fig. 69-1. Schematic diagram showing the circuit wired so Q_2 acts as a combined mixer-oscillator stage.

Experimental Procedure: For this experiment you need your operating receiver, voltmeter, hand tools, and the following parts:

1 .001 mfd capacitor
1 1k-ohm resistor

Step 1: To wire your receiver so transistor Q_2 functions as both oscillator and mixer.

Unsolder and remove transistor Q_1 from the circuit board. Unsolder and remove the short jumper wire connected between holes H and I on the circuit board. Unsolder and remove the .005 mfd disc capacitor, C_9, from the circuit board. In its place, tack-solder a .001 mfd disc capacitor. Tack-solder a 1k-ohm resistor in parallel with the 6.8k-ohm resistor, R_{19}, on the foil side of the board. Tack-solder a 1/2" jumper wire from hole H on the circuit board to terminal 5 of T_1 (use the hole where the emitter of Q_1 was connected). Your circuit should now be wired as shown in the schematic in Fig. 69-1.

Energize the receiver and test its operation. You may notice a reduction in sensitivity of the receiver. Also the stations do not come in at the correct place on the dial. The circuit changes have changed the operating characteristics of the oscillator so it does not track the tuned rf circuit of the antenna.

Step 2: To adjust the frequency of the local oscillator so the stations will come in at correct points on the dial.

Tune the receiver to a known frequency station at the low frequency end of the dial. Use a small screwdriver to adjust the core of the oscillator transformer, T_1, to bring the station in at the correct setting of the tuning dial. Next, tune the receiver to a known frequency station near the high frequency end of the dial. Adjust the trimmer capacitor, C_4, on the oscillator section of the tuning capacitor to tune in the station at the correct setting of the tuning dial. Check the reception of the station at the low frequency end of the dial. If necessary, repeat the adjustments until no further improvement is obtained.

Tune the receiver to a station at the high end of the band and adjust the trimmer capacitor, C_2, on the rf section of the tuning capacitor for maximum volume of the received station. Test the receiver and compare its operation now with the operation you experienced when the separate oscillator circuit was in use. You may notice slightly reduced sensitivity but otherwise very little difference. Any difference in the noise figure is probably too small to be noticed.

Step 3: To measure the operating voltage on the combined mixer-oscillator stage.

For this step you measure the voltages in the circuit of transistor Q_2 with it connected as a mixer-oscillator stage. Energize the receiver and tune in a strong local station. Measure the dc voltage between B- and the junction of R_6, C_7, and C_9. Look for a voltage change as you tune across the station.

The positive dc voltage increases when you are tuned exactly on the station, indicating that avc voltage is reducing the forward bias on Q_2 and limiting the gain of the stage. For this hookup, avc is not applied to the base circuit of Q_3.

Next measure the emitter voltage and the B+ voltage. As you can see from the readings, there is very little drop across R_{19} (with the 1k-ohm resistor in parallel). This indicates that the transistor is drawing very little current. Measure the dc voltage between the base and emitter. A typical reading is -.15 volt, indicating that the transistor has only a small forward bias.

Measure the ac voltage at the capacitor terminal of the oscillator section of the tuning capacitor. The probe will detune the oscillator but you should get a reading. Observe the reading as you tune across the band. The output may drop to zero at some points because of the loading of the voltmeter probe.

Leave your circuit wired as it is because you will use it again for the statement of this experiment.

Instructions for Statement 69: For this statement you will change the supply voltage to the mixer-oscillator stage and determine the effect on the operation of the receiver.

Unsolder and remove the 1k-ohm resistor that you tack-soldered in parallel with the 6.8k-ohm resistor, R_{19}. Energize the receiver and test its operation. Take voltage measurements and other tests as necessary to answer the statement.

Turn off the receiver. Unsolder and remove the .001 mfd disc capacitor that you tack-soldered in place of C_9 on the circuit board. Install the .005 mfd capacitor for C_9 on the circuit board. Solder the capacitor in place. Unsolder and remove the 1-1/2" jumper wire that you connected from hole H on the circuit board to terminal 5 of transformer T_1 (terminal 5 connects to the foil at the hole for the emitter lead of Q_1).

Reinstall transistor Q_1. Carefully solder the transistor leads to the foil on the foil side of the circuit board. Install the 3/4" jumper wire from hole H to hole I on the circuit board. Solder the jumper in place. Your receiver is now correctly wired. Energize the receiver and test it for proper operation. Readjust the oscillator frequency and the rf tank circuit as necessary for best operation.

Statement No. 69: When I removed the 1k-ohm resistor that was in parallel with R_{19}, the receiver,

(1) operated normally, with no noticeable change.

(2) operated only on stations at the low end of the broadcast band.

[✓ *(3)*] *failed to operate because the local oscillator dropped out of oscillation.*

EXPERIMENT 70

Purpose: To show receiver alignment problems; and

To show how a receiver can be satisfactorily aligned using only received radio stations.

Introductory Discussion: In the test section of this manual you were shown how to touch up the alignment of your receiver. In an earlier experiment you changed some of the alignment adjustments. Therefore your receiver may not be perfectly aligned at this time. In this experiment you perform various alignment procedures. As a final step you will perform complete alignment to put the set in top operating condition.

Alignment is a regular procedure in repairing radios. After repairing a radio, the least you should do is check to see if the receiver picks up the entire broadcast band and if the stations are received at the indicated points on the dial.

If the receiver seems to lack sufficient sensitivity, you should check the i-f alignment. Making these simple checks will assure customer satisfaction. A touch-up alignment will usually make the receiver operate better then before it developed the defect that you repaired.

Don't expect perfect results when you check the alignment of inexpensive transistor receivers. The tuning dial markings are usually very coarse so you cannot read them accurately. Many receivers will not cover the complete broadcast band from 540 kHz to 1600 kHz. Naturally you should not try to redesign a receiver that does not cover the entire band. Likewise, circuit design or the reception area may produce low sensitivity at some frequencies.

When you touch up the i-f alignment you may find the i-f amplifier oscillates when a certain adjustment is peaked. This condition may have existed since the set was manufactured. The value of your time required to correct this condition could easily exceed the purchase price of the receiver. Again, as a service technician, your repair job should put the receiver back in its original operating condition. If you can improve operation with a touch-up alignment job, you should do it; but you cannot profitably make the alignment perfect on every inexpensive receiver that you repair.

In this experiment you perform alignment using received radio stations. An alignment generator is a real convenience and enables you to do the job quicker. Also, the generator can be used as a troubleshooting tool, but a generator is not absolutely necessary for performing satisfactory alignment on the average radio.

Receiver alignment consists of adjusting the response of three sections of the receiver. These include the i-f amplifier, the local oscillator, and the rf section of the receiver. As you know, the i-f amplifier is a fixed frequency amplifier that provides most of the gain and selectivity of the receiver. In your receiver, the i-f frequency is centered at 455 kHz. The tuned circuits in the i-f amplifier are adjusted to passing a narrow band of frequencies centered around 455 kHz.

The local oscillator is designed to operate above the incoming rf by an amount equal to the i-f amplifier frequency. With this arrangement, the difference between the rf and the local oscillator frequency equals the intermediate frequency.

In your receiver, two adjustments are provided for changing the local oscillator frequency. The core of the oscillator transformer is adjusted to set the frequency of the local oscillator at the low end of the band. A trimmer capacitor in parallel with the local oscillator tuning capacitor is provided to adjust the local oscillator frequency at the high end of the band.

These two adjustments interact to some extent. Adjusting the core of the transformer has a large effect at either the high end or the low end of the band. Adjusting the trimmer capacitor has a small effect at the low end and a large effect at the high end.

At the low end of the band, the tuning capacitor is fully meshed and inserts maximum capacitance in the tuned circuit. In this position a change in the trimmer capacitor represents only a small change in the total capacitance in the circuit.

However, at the high end of the band the tuning capacitor is open, providing minimum capacitance in the tuned circuit. In this position a small change in the trimmer capacitor represents a large percentage change in the total capacitance in the circuit.

Edge capacitance increases the tuning capacitance at the extreme unmeshed position of the tuning capacitor. As the tuning capacitor rotor is rotated counterclockwise, the rotor plates unmesh from the stator plates, causing the circuit capacitance to decrease. However, when the stator plates approach the full unmeshed position, the edges of the rotor plates approach the opposite edges of the stator plates.

This proximity of the plate edges causes the circuit capacitance to increase for the last few degrees of rotation as you reach the high frequency end of the dial. As a result, you may receive the high-frequency station at two points near the high frequency end of the dial. For example, a station at 1600 kHz may be received with the plates fully unmeshed. Then as you rotate the tuning capacitor a couple of degrees clockwise, you will again receive the same station.

Edge capacitance causes the oscillator to produce the correct local oscillator frequency at both positions of the tuning dial. This condition is normal. Simply disregard the last few degrees of rotation near the fully unmeshed position of the tuning capacitor.

The rf section of the receiver consists of only the tuned tank circuit of the antenna. This is the usual arrangement for receivers. Very few broadcast receivers have an rf stage. A trimmer capacitor on the rf section of the tuning capacitor is provided for adjusting the frequency of the rf tank circuit. The trimmer has the greatest effect at the high end of the band and is usually adjusted for maximum response to a frequency near the high end of the band.

Experimental Procedure: For this experiment you need the operating receiver and your hand tools.

Step 1: To demonstrate improper tracking due to a misadjusted trimmer capacitor on the local oscillator circuit.

For this step you misadjust the trimmer capacitor on the local oscillator section of the tuning capacitor and observe the effect.

Tune the receiver to a local station near the upper end of the band. Try to select a station between 1400 and 1200 kHz for best results.

Suppose you select a station at 1240 kHz. Since your tuning dial is only roughly marked, it reads only the approximate frequency of the station you are tuned to. Now tighten the oscillator trimmer capacitor a small fraction of a turn. Readjust the tuning capacitor toward the high end of the dial to again receive the station at a frequency of 1240 kHz. Repeat the above process until you have the trimmer capacitor adjustment nearly tight, and you are receiving the 1240 kHz station at or near the full open position of the tuning capacitor.

What you have done is increase the capacitance by tightening the trimmer capacitor and decrease the capacitance by opening (unmeshing the plates of) the tuning capacitor. You are receiving a station of 1240 kHz, and the tuning dial is indicating nearly 1600 kHz. The loudness of the station probably decreased considerably as you changed the adjustment. The reason for the reduced sensitivity is the loss of rf tracking. That is, the rf section of the tuning capacitor is adjusted for receiving stations close to 1600 kHz when the plates of the tuning capacitor are nearly open.

The fact that you can still receive the 1240 kHz station indicates that the rf section of your receiver is rather broadly tuned. Receiver selectivity is accomplished by the i-f amplifier rejecting those signals that do not fall in the i-f bandpass. Tune your receiver to other stations toward the low end of the band. You will find that all the stations you receive come in at points higher on the dial than they should.

Readjust the local oscillator trimmer capacitor so that the stations track the dial markings. Since you are adjusting only the trimmer, it is easiest to do it on the highest frequency station that you can receive. Simply set the dial to the correct point where you should receive the highest frequency station. Then adjust the oscillator trimmer until you hear that station.

Step 2: To demonstrate improper tracking due to a misadjusted oscillator transformer core.

For this step you again change the frequency of the local oscillator, but you do it by changing the inductance of the tuned circuit. As you know, the oscillator transformer has an adjustable core. Changing the setting of the core changes the inductance of the transformer, and thereby changes the frequency of the local oscillator. This, in turn, will change the point on the dial where you receive a given station.

Tune the receiver to a station near the low end of the broadcast band. Locate the oscillator transformer, T_1, on your circuit board. Use a screwdriver to adjust the slotted core in the top of the transformer. Tune the core a fraction of a turn counterclockwise.

Adjust the tuning dial so that you again receive the same station. Notice that you have to tune to a lower frequency to receive the station. Turning the adjustment counterclockwise in T_1 decreased the inductance and increased the frequency of the local oscillator. To correct for this you had to insert more capacitance into the circuit by moving the tuning dial toward the lower end. Readjust the core of T_1 so the station comes in at the proper place on the dial.

Next, tune to a station near the high end of the broadcast band. Adjust the core of the oscillator transformer slightly clockwise. Adjust the tuning capacitor to again receive the same station. Notice that you have to tune toward the high frequency end of the dial to receive the station. Readjust the core, T_1, so that the station comes in at the correct place on the dial.

In Step 1 of this experiment, you found that adjusting the oscillator-trimmer capacitor had the greatest effect at the high end of the band. This is because a change in the trimmer capacitance represents a larger percentage change in the total capacitance at the high frequency end of the band.

In this step you found that a change in the inductance of the oscillator transformer had about the same effect at either the high or the low end of the band. This is what you would expect because the inductance is not varied when you tune across the band. You will take advantage of these facts when you perform receiver alignment.

Step 3: To show the effects of aligning the i-f amplifier to the wrong frequency.

In this step, you align the i-f amplifier to a frequency lower than 455 kHz, and observe the effect on the operation of your receiver.

Tune your receiver to a local station that you can readily identify. Note the exact position of your tuning dial. Since the dial is only coarsely graduated with the approximate station frequency, you'll have to mark the dial. Use a crayon or a piece of tape to temporarily mark the exact position of the dial. For example, tune the receiver exactly to the selected station and place a small piece of tape on the tuning dial so that the edge of the tape lines up with one edge of the red line behind the dial. Leave the tape in place for now.

Use your alignment tool to change the adjustments in the i-f amplifier transformer, T_2. Turn the top slug of T_2 two full turns clockwise. Next reach through the hole in the circuit board at the center of T_2 and adjust the bottom slug of T_2 two full turns clockwise. Now use a screwdriver to adjust the slug of the transformer T_3 about one-half turn clockwise. These adjustment changes have tuned the i-f amplifier to a lower frequency of approximately 400 kHz. Without a signal generator, you have no way of knowing the exact frequency. Also, the adjustments are not peaked to the new intermediate frequency.

To peak the i-f adjustments, tune the receiver to a weak station and readjust the i-f transformers. Move each slug as necessary to increase the volume of the station that you are tuned to. Go over the adjustments two or three times in order to get the greatest possible response.

Tune your receiver to the station that you marked with the tape on the dial. Definitely identify the station and set the tuning dial until you are tuned exactly on the station.

Now observe the mark that you put on the dial in relation to the red line. You will find that you had to move the dial about 1/16" clockwise to receive the station with the i-f amplifier tuned to a lower frequency.

To understand why the dial position shifted for receiving the selected station, think through the operation of your receiver. Suppose the selected station transmitted at a frequency of 1000 kHz. When your i-f was tuned to 455 kHz, you had to tune your receiver until the local oscillator produced a frequency of 1455 kHz. The difference between the incoming rf signal of 1000 kHz and the local oscillator frequency of 1455 kHz was 455 kHz, which is also the frequency that your i-f amplifier was tuned to. This setting enabled you to receive the station.

Let's see just what happened when you realigned your i-f amplifier to 400 kHz. To receive the 1000 kHz station you had to produce a local oscillator signal that was 400 kHz above the incoming rf signal. Or you need a local oscillator signal of 1400 kHz.

To get the local oscillator frequency down to 1400 kHz, it was necessary to adjust the tuning dial to a point where it would increase the capacitance in the oscillator circuit. The increased capacitance tuned the oscillator to a lower frequency of 1400 kHz. Now the difference is 400 kHz, and you receive the selected station but at a different point on the dial.

Steps 1, 2, and 3 of this experiment should help you to understand alignment procedures. As you know, the i-f amplifier processes only those signals having the frequency to which the amplifier is tuned. Therefore, to receive a certain station, you must generate a local oscillator frequency that is above the incoming rf signal by an amount equal to the i-f. Also, the tuning dial should be calibrated to indicate the received station frequency when the dial is in the correct position to produce the required local oscillator frequency. Likewise, the rf section should be tuned to the indicated frequency.

Step 4: To show how to perform touch-up alignment on your receiver using only received radio stations.

A signal generator is a real convenience for quick, accurate alignment of a radio receiver. If you are used to using a signal generator for alignment, you will probably find this step slow and clumsy. You should perform the step anyway. What you learn will be useful for touch-up alignment of receivers when you do not want to go to the trouble of setting up a signal generator.

At the present time, your receiver has the i-f amplifier aligned to approximately 400 kHz. First we will retune it to approximately 455 kHz. Use your alignment tool to adjust slugs in the transformer, T_2. Tune the top slug two turns counterclockwise. Reach through the hole in the circuit board and turn the bottom slug of T_2 two turns counterclockwise.

Use a screwdriver to turn the adjustment on transformer T_3 one-half turn counterclockwise. Set your tuning dial to the position you marked with the tape so you receive the selected station. The station may come in very weak or you may have to tune slightly off the correct point to hear it at all.

Readjust the top and bottom slug in T_2, and the screwdriver adjustment on T_3 to get maximum volume. Recheck the setting of the tuning dial. If you had to offset is slightly before, you should now be able to set it exactly on and still be able to hear the station. Readjust the preceding three adjustments for maximum volume.

These adjustments should have returned your i-f to 455 kHz, but you may be able to improve the alignment. Tune your receiver to the weakest available station. If all available stations are strong, connect a clip lead from the trimmer capacitor terminal on the rf section of the tuning capacitor to the ground lug on the capacitor frame.

The clip lead shorts out the rf section of the antenna and greatly attenuates the received signals. Again, tune the receiver to a weak station. Make sure you are tuned to the exact center of the received signal. Now readjust the slugs of T_2 and T_3. Tune each slug for the maximum received signal. Your i-f amplifier is now peaked at approximately 455 kHz. Remove the clip lead you used to short out the antenna.

Tune your receiver to the lowest frequency station available in your area. Identify the frequency of the station and check the tuning dial to see if the station comes in at the correct point on the dial.

Since the dial is only roughly graduated, you have to estimate the correct position. If necessary, set the tuning dial to the correct position and adjust the slug in the local oscillator transformer, T_1, to bring in the station. Clockwise rotation of the slug increases the inductance and lowers oscillator frequency.

Next, tune the receiver to the highest frequency station available in your area. Again check the tuning dial reading to see if the station is received at the correct position on the dial. If not, set the dial to the correct point and adjust the trimmer capacitor on the oscillator section of the tuning capacitor to bring in the station.

Recheck reception at the low end of the band. If you made large changes in either adjustment, it may be necessary to repeat both adjustments until no further improvement is possible.

Peak up the adjustment on the rf section. Tune the receiver to a weak station at the high frequency end of the dial. Adjust the trimmer capacitor on the rf section of the tuning capacitor for maximum volume.

This procedure may not produce perfect alignment, but it is satisfactory for all practical purposes. For example, your i-f amplifier is probably not aligned to exactly 455 kHz. Your receiver may not tune to the extremes at both ends of the band. The stations may not come in at exactly the correct point on the tuning dial, and the rf section may not track across the entire band. But you receive all available stations with adequate volume.

Step 5: To perform complete alignment procedures using only the received radio stations.

In this step we assume that your receiver is completely misaligned so that you are unable to receive stations at all. This could happen if you failed to identify adjustments before you moved them, or you may have had a defect in the receiver and thought the problem was alignment. The procedure we give here will enable you to realign the receiver using only received radio station signals. Some steps in this procedure will involve trial and error before you get all sections of the receiver tracking properly. The following adjustments steps, (a) through (e), are followed by a discussion of what to do if you are unable to get satisfactory results from some steps.

(a) Preset all adjustments. Do not force any adjustment beyond its limit, or point where the adjustment moves easily. The preset positions we give here are a starting point from which you will perform the alignment. Tighten the trimmer capacitors on the tuning capacitor. Then turn each trimmer screw one-half turn counterclockwise. Adjust the slug of the oscillator transformer, T_1, to its mid-position. The full adjustment range of the slug is about two turns, so tighten the slug and then turn it counterclockwise one full turn. Do the same for the i-f output transformer T_3.

Preset the slugs in the i-f transformer, T_2. Start by moving the slugs to the ends of the coils so that there is maximum separation between the slugs. Next, adjust the top slug about four full turns clockwise so the top of the top slug is about 3/8″ from the top of the can. In the same way, adjust the bottom slug four full turns into the coil, so the bottom slug is 3/8″ up from the circuit board.

All alignment adjustments are now preset to an approximate position, so you should be able to receive at least one station, although it may come in weak. Move the tuning knob slowly across the band until you pick up a station. Disregard the frequency of the station or where it comes in on the dial.

(b) Align the i-f amplifier for maximum signal on a received station. Adjust the top and bottom slugs in T_2 and the single slug in T_3 for maximum signal. If the station becomes too strong, tune to a weaker station. Most accurate adjustments are made on the weakest signal that you can hear. Readjust all three i-f adjustments until no further improvement is possible. The i-f amplifier is now aligned, although it may not be aligned to exactly 455 kHz.

(c) Adjust the oscillator frequency at the low end of the broadcast band. Identify the lowest frequency station that you can receive. Set the tuning dial to the correct point where the station should be received. Adjust the slug in the oscillator transformer, T_1, to bring in the station.

(d) Adjust the oscillator frequency at the high end of the broadcast band. Identify the highest frequency station you can receive. Set the tuning dial to the correct point where that station should be received. Adjust the trimmer capacitor on the oscillator section of the tuning capacitor to bring in the station. Repeat steps (c) and (d) until no further improvement is obtained.

(e) Adjust the trimmer capacitor on the rf section of the tuning capacitor. Tune the receiver to the highest frequency station you receive. Be sure you are tuned exactly to the station. (Tune for maximum volume.) If you have a choice of several stations near the high end of the band, select the weakest station. Adjust the trimmer capacitor on the rf section of the tuning capacitor for maximum received signal.

If you were able to complete each of the five steps listed above, your receiver is probably satisfactorily aligned. Check the receiver operation to see if all available stations are received at the correct points on the dial.

Since the dial is only roughly calibrated, you have to estimate the exact frequency readings. Unsatisfactory alignment may show up as inability to receive stations at the high end or the low end of the band, low sensitivity, stations received at the wrong points on the dial, or i-f oscillation.

Try repeating steps (b) through (e). Examine the position of each adjustment to see if it is very far from the preset position. You should be able to hear the response fall off each side of the correct adjustment point when making each adjustment.

In step (d), if you turn the trimmer capacitor much more than one full turn counterclockwise, the adjustment screw becomes quite loose and has little effect. To correct this, readjust the slug in T_1 a fraction of a turn counterclockwise. This reduces the inductance and increases the oscillator frequency.

The trimmer adjustment point will be reached with the screw closer to the tightened position. Changing the oscillator slug will move the lowest frequency station down on the tuning dial. You may have to compromise to get a satisfactory adjustment in both steps (c) and (d).

Low sensitivity can be caused by the i-f amplifier being improperly aligned. Peak each adjustment in step (b) on the weakest available station signal. Be sure that the response falls off either side of the final adjustment point of each slug. Be sure that the slugs are somewhere close to the preset positions given in step (a).

If you are unable to receive the highest frequency stations or the lowest frequency stations, your i-f may be aligned to a frequency far from 455 kHz. As a result, you may be unable to adjust the oscillator adjustments far enough to receive some stations. Try changing the alignment frequency of the i-f amplifier. To lower the frequency, turn each slug in transformer T_2 one-quarter turn clockwise (move both slugs toward the center of the coil). Turn the slug on T_3 one-eighth turn clockwise. Tune to a weak station and perform step (b). This will align the i-f at a lower frequency. Now repeat steps (c),(d), and (e).

You can raise the i-f amplifier alignment to a higher frequency by moving the i-f transformer slugs counterclockwise. Adjust each slug in T_2 one-fourth turn counterclockwise. Move the slug in T_3 about one-eighth turn counterclockwise. Tune to a weak station and peak up the i-f adjustment as outlined in step (b). This will align the i-f amplifier to a higher frequency. Again perform steps (c), (d), and (e). By repeating these steps you should be able to find an i-f amplifier frequency that will enable your receiver to track satisfactorily.

Instructions for Statement 70: For this statement you will change the frequency of the local oscillator by paralleling the oscillator section of the tuning capacitor with a 27 pf capacitor and observing the results.

Tack-solder a 27 pf disc capacitor from the terminal on the oscillator section of the tuning capacitor to the solder lug on the frame of the tuning capacitor. Energize the receiver and test its operation as necessary to answer the statement.

Unsolder and remove the 27 pf capacitor that you tack-soldered from the terminal of the oscillator section of the tuning capacitor to the ground lug on the frame of the tuning capacitor. Test the receiver for proper operation.

Statement No. 70: When I placed a 27 pf capacitor in parallel with the oscillator section of the tuning capacitor,

(1) all stations that I could receive were received at a lower frequency setting of the tuning capacitor.

[✓ *(2)*] *all stations that I could receive were received at a higher frequency setting of the tuning capacitor.*

(3) the receiver failed to operate because the local oscillator failed to oscillate.

Installing the Receiver In the Cabinet

Now that you have completed the experiments, you will want to install the receiver in its cabinet for normal use. In the final experiment you performed alignment. Your receiver should now be in tip-top operating condition. Examine the circuit board and other parts carefully.

Look for poorly soldered connections or bits of wire that could short out the circuits. See that the wiring, especially around the loopstick antenna and on the volume control potentiometer, is dressed close to the panel so that the wires will clear the cabinet. When you are satisfied with the condition of the receiver, perform the following steps to install it in the cabinet.

Remove the power cord from both the receiver and from the ac outlet.

Insert the interlock end of the power cord through the rectangular cutout marked "Interlock" . . . . ( )

Slip the power cord clamp on the interlock connection, as shown in Fig. 23. . ( )

Pull the cord through the rectangular cutout until the interlocking portion of the cord extends through the rectangular cutout, as at "1" in Fig. 24. The power cord clamp is now positioned against the inside of the cabinet at the cutout . . . .( )

With the cabinet right-side up, position the receiver so the circuit board rests in the guide strips on either side of the inside of the cabinet . . . . ( )

Slowly slide the receiver into the cabinet. Position the interlock connector so the interlock prongs on the circuit board fit into the female connector on the power cord . . . . ( )

To make sure that the interlock is correctly seated, plug in the receiver and turn it on. If it operates, the interlock is

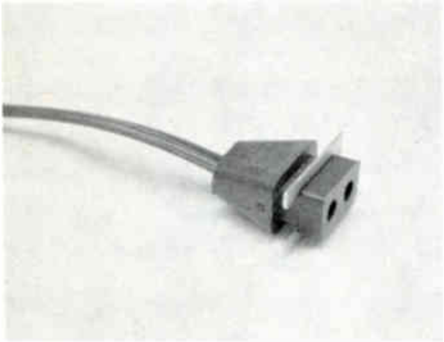

Fig. 23. Placement of the cord clamp on the interlock.

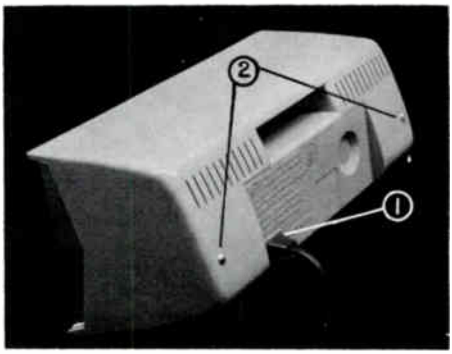

Fig. 24. Mounting the receiver in its cabinet for normal use.

properly connected. If it does not operate, pull the receiver forward and reseat the interlock connector . . . . ( )

Place the two 4-1/4" screws through the two holes in the rear of the cabinet as shown at "2" in Fig. 24. Tighten the screws evenly . . . . ( )

Your receiver is now completely assembled and installed in its cabinet ready for normal use.

NOTES

WHY DO YOU WANT TO SUCCEED?

There are several answers to this question. You may want to succeed for the very human reason that you want more money with which to enjoy life, or you may have a family for whom you want to provide those comforts they deserve – a home, a new car, good clothes, life insurance, and financial security.

Your ambition to succeed may be promoted by the desire to bring happiness to an aged father, mother, or relative whose chief hope in life is to see that you enjoy prosperity and prestige, to see you on the pinnacle of success.

Pause for just a minute and think – what is your reason for wanting success? With this reason in mind, resolve firmly that you will never allow your ambition to weaken. Resolve that you will never swerve from the direct path of your goal. Make this resolution now and keep it, so the years to come will be happier and more prosperous for you.

INSTRUCTIONS FOR EXPERIMENTS 61 TO 70

In this kit you build a complete 5-tube ac-dc receiver and conduct experiments on it. This is an excellent receiver that you can use in your home or in your shop.

NATIONAL RADIO INSTITUTE, WASHINGTON, D.C. 20016

CEC5C176 1976 EDITION Litho in U.S.A.

Instructions for Performing Experiments 61 to 70

The experiments that you have carried out so far have shown how certain stages in a receiver operate, but you have not yet worked on a complete receiver.

Before you carry out any of the experiments in this manual, you will assemble a complete 5-tube ac-dc radio receiver. This is the type of table model radio most commonly used today, and ac-dc TV sets are also quite common.

You will then learn the correct troubleshooting procedures for locating the cause of a dead receiver, a receiver with hum, and af and i-f oscillations. You will show how important i-f alignment is for tracking and sensitivity of superheterodyne receivers. You learn three different methods of troubleshooting radio receivers; the voltage measurement, resistance measurement, and circuit disturbance methods. You see where each of these methods should be used and learn the limitations of each.

Building a complete receiver and then making standard servicing checks on it will give you valuable practical training. When you finish the experiments, you will have an excellent receiver complete with modern cabinet that you can use in your home, as a shop set, or as a set to lend out to customers while their sets are in your shop.

You will wire the set in steps. When you finish each step, you should check your work carefully. After you have completed the receiver, carry out each test procedure carefully and completely. If you fail to get the correct results, recheck your work and correct the trouble before you go on to the next step. If you cannot locate the trouble, write to NRI on a regular Experiment Consultation Blank. When you write for help, be sure to give complete details, because the only information we will have is what you send in your letter.

Even if the set is completely dead, take the voltage and resistance measurements indicated on pages 22 and 23, and let us know the results. This information will help us locate your trouble.

CONTENTS OF THIS KIT

In this kit you will receive two new tubes, a 50C5 power output tube, and a 35W4 rectifier tube. You will also receive a loudspeaker, a two gang tuning capacitor, a dual section electrolytic capacitor, and various resistors and capacitors.

IMPORTANT: The i-f transformers sent in this kit have been pretuned at the factory. Do not turn the adjustments on these i-f transformers until you are told to do so. If you do, you may get them so badly out of adjustment that you will not be able to align the set without a signal generator.

The parts included in this kit are illustrated in Fig. 1, and are listed in the caption below it. Check the parts you received against this list to be sure you have all of them.

If any part of this kit is obviously defective or has been damaged in shipment, return it to NRI immediately as directed on the packing slip included in this kit.

Assembling Your Experimental Receiver

In all the assembly instructions, read the entire sentence or paragraph of each step before you proceed with the actual construction. Position each part and lead according to the description and illustrations. Be sure and cut the leads of all parts to the proper length for neat assembly. You will not be using any of these parts in later kits. Solder carefully. Above all, take your time. The few extra minutes it takes for careful construction may save you hours of checking to find a mistake. As you complete a step, put a check in the space provided.

MOUNTING THE PARTS

Before you do any wiring, you will mount most of the parts on the chassis and front panel. Gather the following parts from those you had left over from your other kits and from those you received in this kit.

1	Front panel
1	Round dial plate with red line
1	Plain round dial plate
1	Gray edge molding
2	Chassis support brackets
2	6-32 X 1/4" spade bolts
4	No. 6 X 1/4" self tapping screws
1	Chassis
2	I-F transformers
5	7-pin miniature tube sockets
1	Oscillator coil
2	4-lug terminal strips
1	3-lug terminal strip with ground lug
1	2-lug terminal strip
1	Audio output transformer
1	Dual 50/30 electrolytic capacitor
12	4-40 X 1/4" screws
12	4-40 hex nuts
5	6-32 X 1/4" screws
4	6-32 X 3/8" screws
12	6-32 hex nuts
22	No. 6 lockwashers
1	Male chassis interlock connector
1	Volume control bracket
1	Tuning capacitor
1	500k-ohm potentiometer with switch, lockwasher and mounting nut
1	Potentiometer ground lug
1	Ferrite antenna rod
1	Antenna coil
1	Fiber antenna mounting bracket
3	1/4" spacers

Decorative Trim. Refer to Figs. 2(A) and 2(B) as you mount the decorative trim on the front panel.

Position the dial plate with the red line so that the red line is pointing straight up. Put the dial plate in the upper recess of the panel after bending the three tabs so they pass through slots 1, 2, and 3 of the panel as shown in Fig. 2(A). The red line should be between slots 1 and 2. . . (✓)

Put the plain round dial plate in the lower recess after bending the three tabs so they pass through slots 4, 5, and 6. (✓)

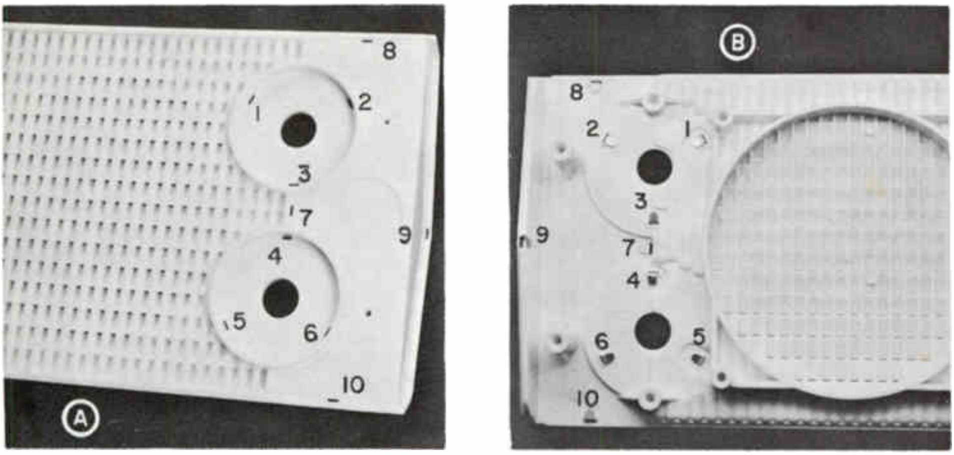

Fig. 2. (A) Mounting slots for panel trim, (B) bending mounting tabs of panel trim.

Mount the gray edge molding so the four mounting tabs pass through slots 7, 8, 9, and 10. Slot 9 is on the rear edge of the panel. . . . . (✓)

With the three trim pieces pressed firmly against the front panel, bend the ten mounting tabs as shown in Fig. 2(B). (✓)

Chassis Support Brackets. The next step will be to prepare the chassis support brackets and fasten them to the front panel. This step is shown in Figs. 3 and 4.

Fasten one of the 6-32 spade bolts in hole B of one of the chassis support brackets as shown in Fig. 3. Position the "spade" part parallel to the short dimension of the bracket, and secure with a No. 6 lockwasher and a 6-32 hex nut. . . . ( )

In a similar manner, fasten the other 6-32 spade bolt in hole B of the other chassis support bracket. . . . . ( )

Place the front panel face down on a cloth in front of you. Position the two large holes in the panel to your left, as shown in Fig. 4. . . . . ( )

Place one of the two chassis support brackets over the two posts on the left of the panel: Position the bracket so that holes A and D are over the holes in the ends of the posts. The "spade" part of the spade lug should be nearest you and pointing straight up. . . . . ( )

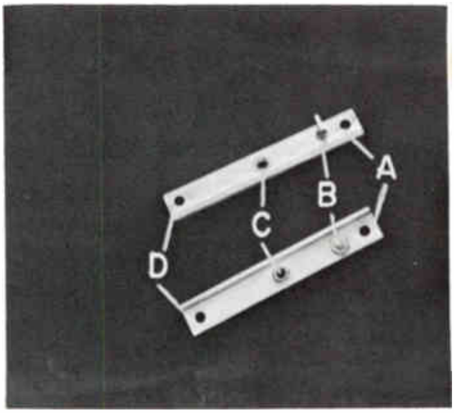

Fig. 3. Chassis support brackets.

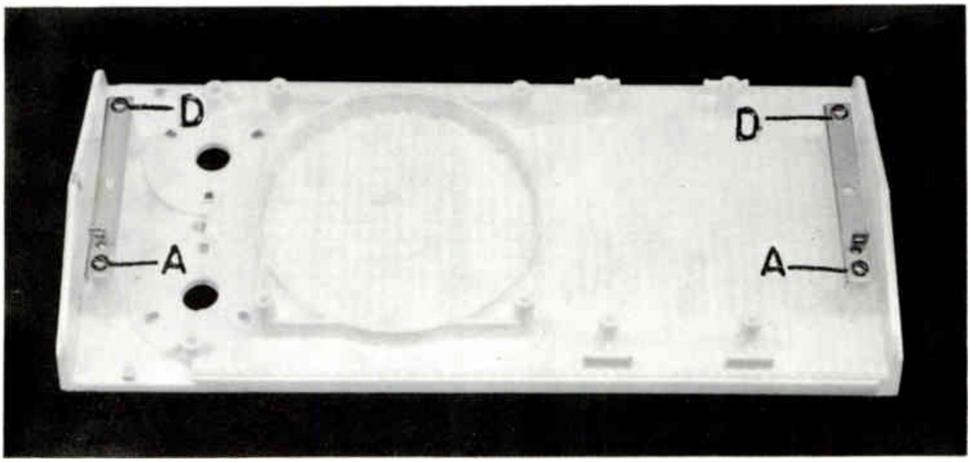

Fig. 4. Rear of front panel.

Fasten the bracket to the front panel with two No. 6 X 1/4" self-tapping screws. It is important that you tighten these screws very slowly and that you do not overtighten them. The plastic posts, while strong, may crack if too much force is used in tightening these screws. . . . ( )

In a similar manner, fasten the other chassis support bracket to the two posts on the right end of the front panel. Figure 4 shows the chassis mounting brackets in place. . . . . ( )

Mounting Parts On The Chassis. Figure 5 identifies the various holes in the chassis as viewed from the bottom. You can mark the chassis with a marking crayon if you wish. Refer to Figs. 5, 6, and 7 as you mount the parts.

Position the chassis in front of you as shown in Fig. 5. . . . . ( )

Place a 7-pin socket in hole B. Pass a 4-40 X 1/4" screw through hole B1 from the top of the chassis and fasten with a

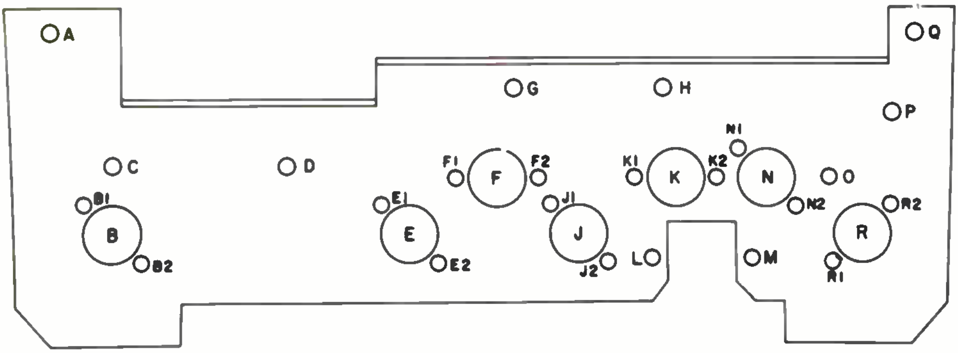

Fig. 5. Bottom view of receiver chassis with holes identified.

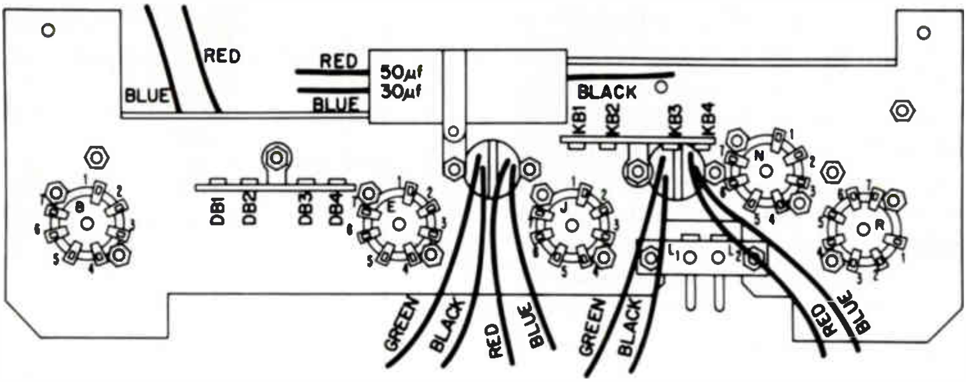

Fig. 6. Parts mounting on bottom of chassis.

No. 6 lockwasher and a 4-40 hex nut. Secure the socket with another 4-40 X 1/4" screw, lockwasher, and nut in hole B2. Be sure the socket is positioned with the space between pins 1 and 7 as shown in Fig. 6. This socket will be referred to as "socket B." . . . . ( )

In a similar manner, mount sockets in holes E, J, N, and R. Position these sockets as shown in Fig. 6. . . . . ( )

Using two 6-32 X 1/4" screws, two No. 6 lockwashers, and two 6-32 hex nuts, mount the male interlock connector in the space between holes L and M. . ( )

Mount the oscillator coil on top of the chassis with two 6-32 X 1/4" screws, two No. 6 lockwashers, and two 6-32 hex nuts in holes O and P. Position the lugs with the red, black, green, and orange dots as shown in Fig. 7. . . . . ( )

Mount the output transformer on top of the chassis with a 6-32 X 1/4" screw, No. 6 lockwasher, and 6-32 hex nut in hole C. Position the transformer so the red and blue leads are shown in Figs. 6 and 7. . . . . ( )

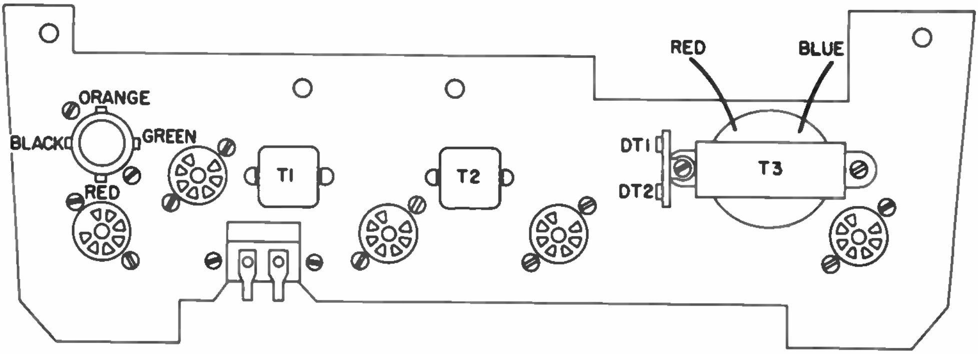

Fig. 7. Parts mounting on top of chassis.

Pass a 6-32 X 3/8" screw through the mounting foot of the 2-lug terminal strip, then through the remaining mounting hole of the output transformer from the top of the chassis over hole D. Place a 4-lug terminal strip on the projecting end of this screw and fasten with a No. 6 lockwasher and a 6-32 hex nut. Position the lugs of the two terminal strips as shown in Figs. 6 and 7 and tighten the nut securely. . . . . ( )

Next, you are to mount the two i-f transformers on top of the chassis. Pass the leads of one of the i-f transformers through hole K from the top of the chassis. Turn the transformer so the red and blue leads will be in the position shown in Fig. 6. Run the spade bolts on the shield can through holes K1 and K2. . . . . ( )

Place a No. 6 lockwasher and a 6-32 hex nut on the spade bolt projecting from hole K2 and tighten just enough to securely hold the transformer. Too much force may pull the spade bolts from the can. . . . . ( )

Position the other 4-lug terminal strip over the spade lug projecting from hole K1 as shown in Fig. 6 and secure with a No. 6 lockwasher and 6-32 hex nut. . ( )

Mount the other i-f transformer in hole F. Position the leads as shown in Fig. 6 and secure with one No. 6 lockwasher and one 6-32 hex nut at F2. . . . . ( )

Mount the dual electrolytic capacitor on the remaining spade lug at F1 with a No. 6 lockwasher and a 6-32 hex nut. Position the red, blue, and black leads as shown in Fig. 6. . . . . ( )

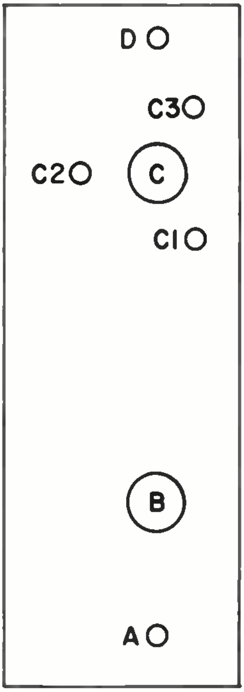

Fig. 8. Rear view of volume control bracket.

Mounting Parts On The Volume Control Bracket. Figure 8 shows the rear of the volume control bracket and identifies the holes.

Place a lockwasher and then the potentiometer ground lug over the shaft of the 500k-ohm potentiometer with the bent lug pointed to the rear of the control. ( )

Push the shaft of the potentiometer through hole B of the volume control bracket. Position the lugs as shown in Fig. 9 and fasten with the potentiometer mounting nut. . . . . ( )

Place three 6-32 X 3/8" screws through holes C1, C2, and C3 from the front of the bracket. . . . . ( )

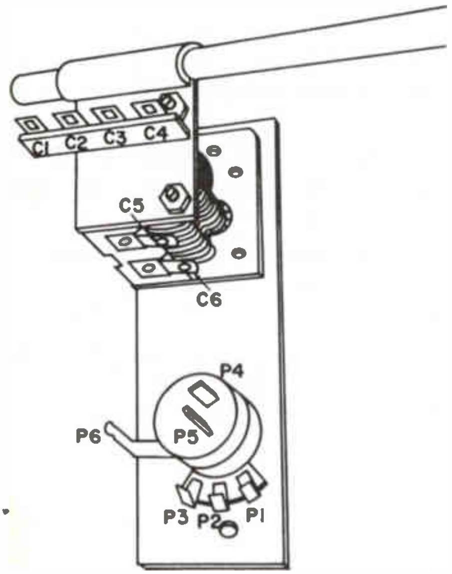

Fig. 9. Parts placement on volume control bracket.

While holding the heads of the three 6-32 screws, slip a 1/4" spacer over the end of each screw. . . . . ( )

Carefully position the tuning capacitor, as shown in Fig. 9, with the two trimmer capacitors nearest hole D. The shaft of the capacitor goes through hole C. . . ( )

Line up the ends of the three screws with the corresponding tapped holes on the front mounting plate of the tuning capacitor. Move the capacitor and bracket together and tighten the three 6-32 screws. . . . . ( )

Make sure the plates of the tuning capacitor are fully meshed. . . . . ( )

To insure safe arrival, the ferrite rod antenna has been shipped to you in three separate parts: the fiber mounting bracket, the ferrite rod, and the antenna coil itself. You will now assemble the three parts of the antenna.

Slip one end of the ferrite rod into the sleeve of the mounting bracket. Position the rod as shown in Fig. 10. . . . . ( )

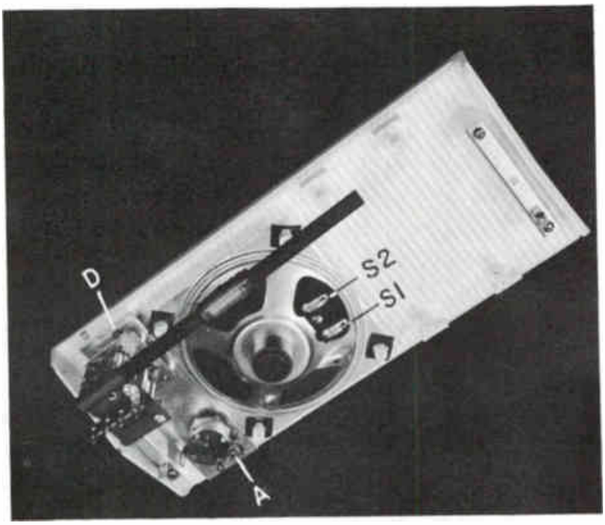

Fig. 10. Parts mounted on front panel.

Examine the antenna coil and notice that there are two separate windings: a small winding and a large winding. Slide the antenna coil onto the ferrite rod with the larger winding nearest the fiber mounting bracket. Figure 10 shows the relative positions of the three parts of the assembled antenna. . . . . ( )

Mount the assembled antenna and four-lug terminal strip to the rear plate of the tuning capacitor as shown in Fig. 9. These parts are fastened with two 4-40 X 1/4" screws and two 4-40 hex nuts in the two small holes near the edge of the rear frame of the tuning capacitor. . . ( )

Final Mounting of Parts on the Front Panel. You will need the following parts in this step of the assembly:

1	Loudspeaker
1	Volume control bracket with parts mounted.
2	No. 6 X 1/4" self tapping screws
4	Loudspeaker mounting clips.
1	Front panel assembly

Place the front panel in front of you on a soft cloth and position the loudspeaker with the speaker lugs S1 and S2 as shown in Fig. 10. . . . . ( )

Push one of the loudspeaker mounting clips over each of the four loudspeaker mounting posts on the front panel. . . ( )

Position the volume control mounting bracket as shown in Fig. 10. . . . . ( )

Fasten the bracket to the front panel with a No. 6 X 1/4" screw in hole A of the bracket. Again, do not overtighten this screw or you may break the plastic mounting post. . . . . ( )

Slip the other No. 6 X 1/4" screw between the tuning capacitor frame and the mounting bracket at hole D. . . . . ( )

Push the screw through hole D and fasten to the front panel. Use a thin-bladed screwdriver to tighten this screw. This will make it easier to clear the capacitor frame. . . . . ( )

You have now completed mounting the parts. Compare your work with Figs. 6, 7, 9, and 10. You are now ready to go ahead with the wiring.

WIRING
THE FILAMENTS
AND B−

In doing the wiring, follow the techniques you have learned. Keep your soldering iron clean and well-tinned, and be sure it is hot when you use it. In connecting hookup wire, remove just enough insulation from the ends to make a hook, and hook the bare end through the terminal lug. Use temporary hook joints in all your connections so that, if you have to disconnect them in the experiments, it will not be so difficult. You will be given instructions on when to solder each connection. Cut the leads of the parts to the proper length, make your wiring neat, and keep the wires and leads short.

For this step you will need black and white twisted wire and hookup wire.

First, prepare two lengths of black and white twisted wire as shown in Fig. 11 and the following instructions.

Cut off a 9" length of twisted wire. ( )

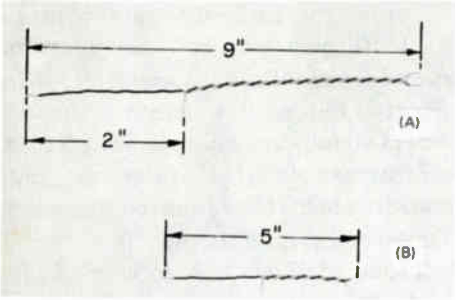

Fig. 11. Twisted filament wires.

Carefully cut only the WHITE wire 2″ from one end. Untwist and remove the short length of white wire and straighten the remaining black wire. . . . . ( )

Cut a 5″ length of twisted wire. . . ( )

Carefully cut only the WHITE wire 2″ from one end. . . . . ( )

Untwist and remove the short length of white wire. . . . . ( )

Now wire the filaments and B– according to the instructions in Table I and the layout of Fig. 12. As you finish each connection, put a check mark in the last column.

PRELIMINARY I-F AND RF WIRING

Next, you will wire the i-f amplifier and parts of the detector and converter stages. Follow the instructions in the layout of Fig. 13 and Table II.

2.200.000

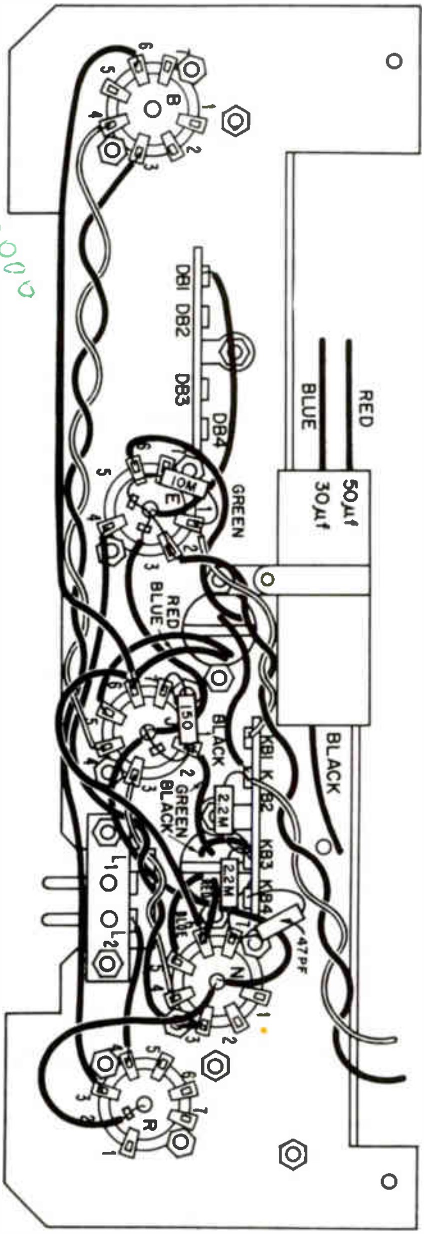

Fig. 13. Pictorial diagram of i-f amplifier and rf wiring.

Before you begin the wiring steps in Table II, you will have to prepare a special length of twisted wire as shown in Fig. 14. Cut a 7-3/4" length of twisted wire. Carefully cut only the white lead at a distance of 2-1/2" from one end. Untwist about 1/2" from both sides of the cut and strip all six ends.

Figure 15 shows how to connect one lead of the 10 meg resistor. Notice that the lead goes through terminal 5, the center post, and terminal 2 of socket E. Also, be sure to leave 1/4" from the body of the resistor to terminal 5.

You will need the following:

1 150-ohm, 1/2-watt resistor
2 2.2-meg, 1/2-watt resistors
1 10-meg, 1/2-watt resistor
1 47 pf capacitor

PREPARING THE FRONT PANEL

For this step you will connect some leads to the antenna, switch, and loudspeaker to make final assembly of the receiver easier.

You will need:

- The front panel assembly
- Hookup wire
- Twisted wire

FINAL ASSEMBLY

In this step you will join the front panel and the chassis and complete the wiring. You will need the following:

Partially wired chassis
Front panel

1	100 pf capacitor
1	0.01 μf capacitor
1	0.05 μf capacitor
1	0.1 μf capacitor
1	No. 6 solder lug
2	6-32 X 1/4" screws

Figure 20(A) shows how the chassis and panel go together, as well as the placement of wires and parts under the chassis. Figure 20(B) shows the wiring on top of the chassis.

Insert one of the 6-32 X 1/4" screws through hole A of the chassis from the bottom. Position the chassis and panel as shown in Fig. 20(A). Push the 6-32 screw on through the hole in the protruding spade bolt on the chassis support bracket and fasten with a No. 6 lockwasher and one of the 6-32 hex nuts. .... ( )

Insert the other 6-32 X 1/4" screw through the large hole in the No. 6 solder lug. .... ( )

With the solder lug facing toward the volume control, push the 6-32 screw through hole Q of the chassis and the hole in the spade bolt on the chassis support bracket. .... ( )

Fasten in place with a No. 6 lockwasher and the remaining 6-32 hex nut. ( )

Bend the solder lug so it is touching the ground lug P6 of the volume control. Both lugs together are now P6. ..... ( )

Next, complete the assembly of your receiver following the instructions in Table VI. Figure 20 shows parts placement.

This completes the wiring of your receiver. Before plugging in the tubes and turning the set on, carefully inspect all connections on the chassis. Every connection should be well soldered, with no

stray wires shorting to other terminals. Lug DB4 should be the only lug which has no connections made to it. Compare your wiring with that in the figures. Parts must be positioned exactly as shown in order for the chassis to fit easily inside the cabinet. One of the best ways of checking your wiring is to have someone else go over it.

When you are certain that you have made no mistakes and that all connections are securely soldered, insert the five tubes in the following sockets:

Testing and Analyzing the Receiver

Before you start your experiments, you will make tests on your receiver to see that it is operating properly. Refer to the complete schematic diagram shown in Fig. 22 to locate terminals and parts.

PRELIMINARY TESTS

Receivers brought to the shop for repair work, as well as new equipment such as the receiver you have just constructed, should be tested before being placed in operation. Defects in the receiver may ruin parts if the set is plugged in and turned on without these preliminary tests.

If you have faithfully followed all instructions and the quality of your workmanship is good, it would probably be safe to turn on the set. However, you should not take a chance that everything is all right. A simple test and an inspection lasting a few minutes will tell you if it is safe to apply power to the set, so wait until you have carried out the tests suggested in this section.

The greatest danger is from a short in the B supply system, which might damage the rectifier tube.

The easiest way to work on the receiver so that you can perform the following experiments is to stand it up on one end with the tuning capacitor and volume control nearest the work table. You will then have easy access to both the top and bottom of the chassis.

First, set your tvom for high-range ohmmeter measurements, and connect the ground clip to pin 1 of the 35W4 and the probe to the cathode, pin 7 of the 35W4 tube socket. The meter pointer will indicate a low resistance because the filter capacitors are discharged. As the 1.5-volt cell in the ohmmeter section of the tvom gradually charges up the capacitors, the pointer will rise, indicating higher and higher resistance. In about two minutes the reading will reach its maximum. The resistance measured should not be less than 150,000 ohms. If the reading is lower than 100,000 ohms, there is certainly a short in the B+ circuit which you must locate and remove before trying the set out; otherwise the 35W4 may be ruined.

If you do measure abnormally low resistance, look for bare parts leads that are shorting to other terminals or leads, look for solder that has dropped from one terminal to another or to the chassis, and then check the wiring against Fig. 22. If you don't find anything wrong, disconnect the positive leads of the electrolytic capacitors one at a time. If the reading goes up when a capacitor lead is disconnected, that capacitor is leaky and must be replaced.

If your test shows that the resistance is normal, it is safe to try out the set.

Notice that there is a trimmer capacitor on top of each tuning capacitor section. The one toward the front (nearest the front panel) is the rf trimmer; the other is the oscillator trimmer. Before turning on the receiver, use a screwdriver to tighten the screw on each trimmer as far as it will go in the clockwise direction.

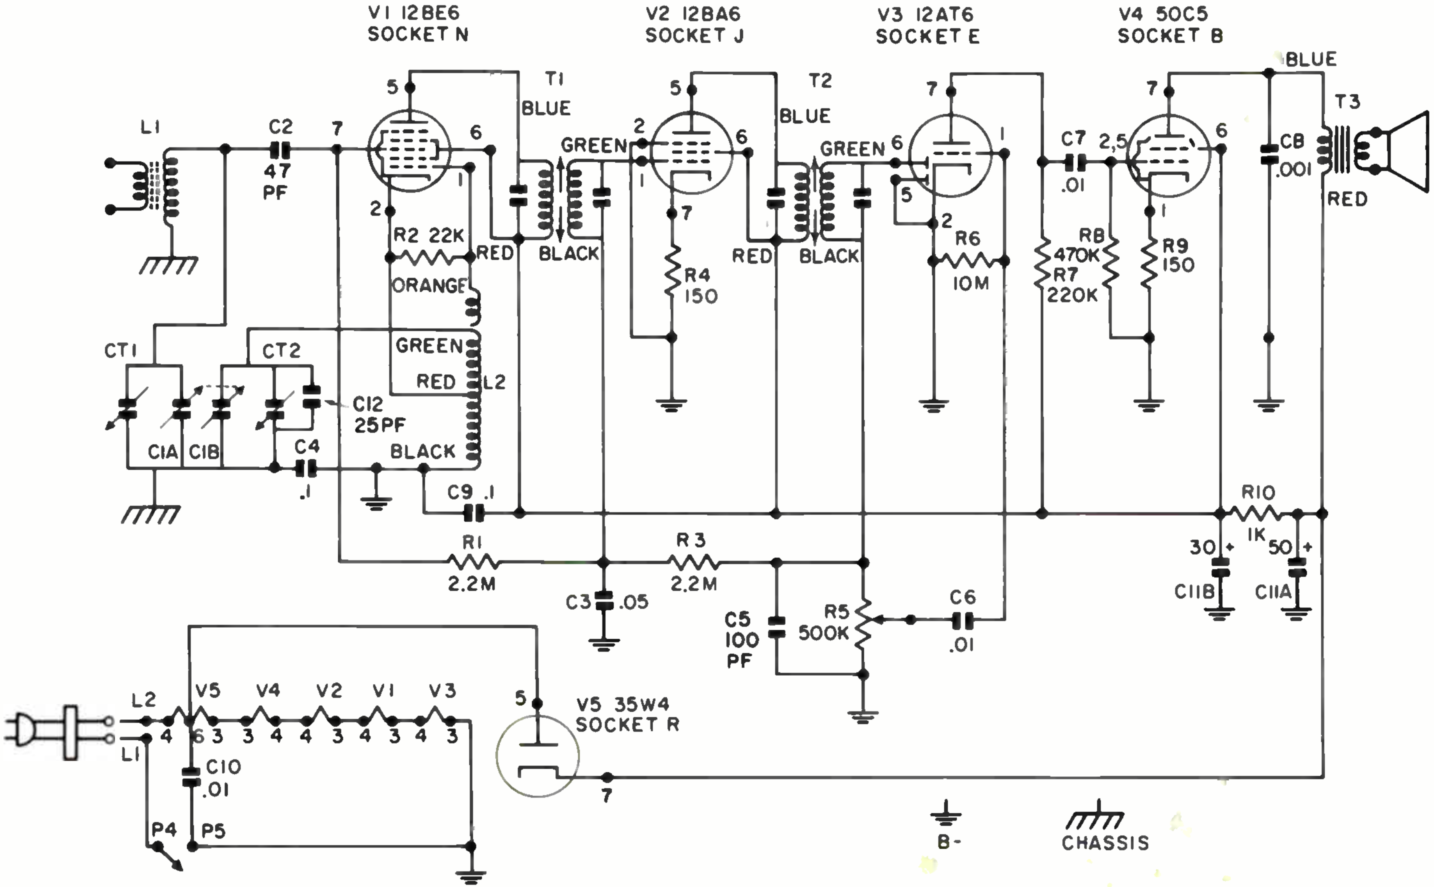

Fig. 22. Schematic diagram of the 7YY receiver.

Insert the power plug into the wall outlet and turn the set on. Turn the volume control all the way clockwise, and tune the receiver across the dial. If you are near stations, you should be able to pick one up somewhere near the high-frequency end of the dial around 1400 kHz or 1500 kHz. (Notice that the final two zeros have been omitted from each of the dial numbers; for example, 1400 kHz is at 14 on the dial.) The station will probably not come in at the proper dial setting. Identify the station by picking it up on another receiver, or by waiting for a station announcement. Then, tune your receiver to the correct dial setting for that station.

Adjust the oscillator trimmer CT2 very carefully until you receive the station again, this time at the proper dial setting. CT2 is the trimmer on top of the tuning capacitor farthest from the front panel. CT1 is the trimmer closest to the font panel. Next, adjust the rf trimmer CT1 for maximum volume. You should then be able to pick up a number of stations at their correct dial settings.

To get a better adjustment of the rf trimmer, connect your dc voltmeter across the volume control, with the ground clip to terminal P1 and the probe to terminal P3 of the volume control. Set the Function switch for -DC voltages, and choose a range setting that gives an appreciable reading when the set is tuned to a station near the high-frequency end of the dial. Now adjust the tuning dial for maximum voltage, even though you have to shift the dial setting slightly. Now, adjust the rf trimmer for maximum voltage across the volume control. You should be able to pick up stations at various points on the dial.

Tune in a station near the middle of the dial. Slowly slide the antenna coil up and down on the ferrite rod until the signal is maximum. This adjustment will increase the sensitivity of your receiver by correctly matching the antenna to the input circuits of the receiver.

The i-f transformers have been preset at the factory, and should need little adjustment. However, because of variations in parts values and tube characteristics in the diode detector circuit, the second i-f transformer may need some adjustment. Follow the procedure very carefully, making only the adjustments you are told to make.

Leave the tvom connected between terminals P1 and P3 to measure the avc voltage, and tune the receiver to a station near the high-frequency end of the dial. Now, refer to the top view of the chassis, Fig. 7, and find the second i-f transformer, T_2. You are to peak each slug for maximum avc voltage as indicated on the meter. Use the alignment tool (AT3) provided. Note that there are two slugs in each of the i-f transformers; one adjusts the resonant frequency of the primary winding, and the other affects that of the secondary. Turn the top slug from the top of the chassis, and the bottom slug from the wiring side. Insert the alignment tool only far enough to reach the closer slug.

DO NOT ADJUST THE SLUGS IN THE FIRST I-F TRANSFORMER. You will make these adjustments later when you do the experiment on alignment. If you adjust them now, you may get the receiver so far out of alignment that you will need a signal generator to realign it.

Carefully turn each slug a very small amount to the right and to the left of its original setting, until the avc voltage is at maximum. This adjustment is critical; usually a fraction of a turn is enough.

When you have peaked the top slug for maximum avc voltage, repeat the adjustment on the bottom slug in the same way. Your receiver should now operate satisfactorily. Do not attempt to make any further adjustments until you are told to do so.

If your set does not work and you write for help, let us know if the tubes light, and if there is a loud buzz from the speaker when you touch the control grid of the 12AT6 tube with your finger. Even if your set does not work, take the voltage and resistance measurements as instructed in the next section, and let us know the results. This will help us to diagnose your trouble.

TAKING VOLTAGE AND RESISTANCE MEASUREMENTS

Point-to-point voltage and resistance values are given in most manufacturers' service diagrams. If you cannot diagnose a defect by observing the symptoms, or cannot localize it, you can sometimes find the trouble by checking the resistance and voltage values and comparing them with the published values. Your values and those given by the manufacturer will not necessarily match, but with experience you will be able to decide if the variations are normal.

Fig. 24. Resistance values for the 7YY receiver. Record your values beside the typical ones.

Typical voltage values for the 7YY receiver are given in Fig. 23 and typical resistance values are given in Fig. 24. Make your own measurements and record them regardless of whether your set is working properly or not.

Remember that for voltage measurements, the set must be plugged into the power line. Since this is an ac-dc set, connect the meter ground clip to pin 1 of the 35W4, which is at B−. Do not connect it to the chassis. Tune the receiver to the high-frequency end of the dial at a point where no station is coming in when you take the voltage measurements.

When taking resistance readings, be sure that the receiver is disconnected from the power line. Notice that for some resistance measurements the ground clip is to be connected to B−, and for some it is to be connected to B+. Use pin 7 of the 35W4 as the B+ connection. Measure your resistances, and record them in Fig. 24 so you will have them for future use. If you were servicing a receiver, you would not write down your results, but would compare each measurement with the manufacturer's listed reading as you made it.

The charts in Figs. 23 and 24 show where to place the probe for each measurement, and the typical value indicates which range to use. Note that some of the voltages measured are negative, some positive, and some ac. In the resistance measurements, an infinity reading means that the resistance is too high to be measured. The reading from B− to pin 7 of V5 depends upon the condition of C11A and C11B, and how long the test leads are attached to the circuit.

In your service work, you may notice some unusual effects when taking resistance measurements in a radio or TV set. As you have learned, resistance measurements are always made with the receiver disconnected from the power line. Sometimes, if a resistance measurement is made immediately after the equipment being tested is unplugged from the line, the cathodes of the tubes will still be hot and will still be emitting electrons. This will affect the ohmmeter readings and will cause completely erroneous results. You can easily demonstrate this.

With the receiver operating, connect the ground clip of your tvom to B–, and set up the tvom for ohmmeter measurements. Remove the plug from the wall outlet, and quickly touch the probe to mixer grid pin 7 of the 12BE6 tube. Again notice that the reading is very low. Leave the probe connected and watch the meter pointer. The pointer will gradually rise until you measure approximately 5 megohms. The reason for these peculiar results is that the cathode of the 12BE6 tube was still hot and was continuing to emit electrons. When the tvom is used as an ohmmeter, the probe is positive, and connecting it to the mixer grid made the mixer grid positive, and electrons flowed from the cathode to the mixer grid and through your tester.

If you had reversed the meter connections, placing the ground clip on pin 7, and the probe on B–, you could have measured the true circuit resistance before the tube cooled off. It is not necessary to do this, however, because tubes will cool rather quickly. In servicing radio or TV receivers, be on the lookout for the ohmmeter actions that you have just demonstrated so that you will not be confused by them.

ANALYZING THE RECEIVER

The i-f transformers between the 12BA6, 12BE6, and 12AT6 tubes, and the oscillator circuit used with the 12BE6 tube, identify this set as a superheterodyne.

The Power Supply. The diagram shows that this is an ac-dc receiver. We know this because there is no power transformer. Since there is a half-wave rectifier connected to the power line, a B supply voltage could be obtained from either an ac or a dc power line. On dc, the plug must be inserted so that a positive voltage is applied to the plate of the rectifier. The tube filaments in series across the power line can also be supplied from either an ac or a dc source.

In the filament circuit, the sum of the filament voltages required by the various tubes is 12 volts + 12 volts + 12 volts + 50 volts + 35 volts, or 121 volts. Since the average power line will furnish between 112 and 120 volts, each tube will receive approximately its rated filament voltage. Even a large variation in line voltage will have little effect on cathode heating, since the tube filament voltages are not at all critical.

The 35W4 tube functions as a half-wave rectifier. However, the plate of the tube, instead of being connected directly to one side of the power line, is connected to a tap on its own filament. This means that the plate current of the 35W4 flows through the top part of the filament, connected to pins 4 and 6. The resistance of this filament section will protect the B supply in case of a short by limiting the plate current of the tube. Excess current, however, will burn out the filament between pins 4 and 6.

Signal Circuits. Let us follow a signal through the receiver. Radio signals in the air induce a voltage in the ferrite rod antenna, L1. At the resonant frequency (the frequency to which the receiver is tuned), determined by the values of L1 and tuning capacitor C1A, resonance step-up occurs, and a large signal appears across the tuning capacitor C1A. This signal is applied through C2 to the mixer grid, pin 7 of the 12BE6 tube, and through capacitor C4 and the red and black taps on the oscillator coil to the cathode. This signal, acting between the mixer grid and the cathode, modulates the electron stream flowing from the cathode to the plate. At the same time oscillation occurs in the 12BE6, and the oscillator signal at oscillator grid 1 also modulates the plate current electron stream.

The oscillator circuit that is used is standard. It is the same one you have used before. Coil L3 is not actually an inductance, but serves to give capacity coupling between the oscillator grid (pin 1) and L2 which is the oscillator tank coil. An actual capacitor could have been used just as well. The frame of the tuning capacitor is connected to the chassis, and in order to complete the circuit from the black lead of the oscillator coil to the tuning capacitor, we install capacitor C4. This also completes the path in the resonant circuit of L1 and C1A. The fact that the capacitor is common to both resonant circuits is of little importance. If some of the oscillator signal is injected directly into the mixer grid circuit, no harm will result. The two signals are mixed in the tube and the resulting beat signals and the original signals flow through the primary of the first i-f transformer, T1. The primary winding is tuned to the intermediate frequency, which is the difference between the incoming signal and the local oscillator signal. Since the reactance is low at off-resonance frequencies, such signals pass through the transformer primary without inducing an appreciable voltage in the secondary, and are bypassed to B− through C9 and C11B. Ordinarily C11B would be all the bypass required, but it is an electrolytic capacitor, and because of its construction, not effective for bypassing high-frequency signals, particularly when it has been in use for a long time. C9, on the other hand, is an excellent rf bypass, and is ready to take over if C11B (because of an increasing power factor) does not bypass the rf signals.

The secondary of T1 is tuned to resonance at the desired frequency so that when the desired signal is applied to the primary, a corresponding signal is induced in the secondary. It is applied directly to the control grid of the 12BA6, and through C3 and R4 to the cathode of the tube. Remember that a signal must always be applied between the control grid and the cathode. Just tracing the signal to the grid is not enough.

Resistor R4 has a value of only 150 ohms, so very little voltage is developed across it. However, the resistor is not bypassed, and the voltage developed across it will be of such a polarity as to oppose the signal voltage. The resulting degeneration tends to make the stage stable and to prevent oscillation.

The 12BA6 tube amplifies the signal, and the amplified signal appears across the primary of the second i-f transformer, T2. The action of this resonant circuit is to boost the i-f signal and remove all others that may still be present in the plate circuit of the 12BA6. The signal induced in the secondary undergoes further selection, and is applied to diode plate, pin 6, of the 12AT6, and through C5 to the cathode.

When the i-f signal makes the diode plate negative, no current flows through the tube, but when the i-f signal makes the diode plate positive, electrons flow from the cathode to diode plate 6, through R5 and back to the cathode. A voltage drop appears across R5. Since the current flows only when the plate is positive, rectification or detection results, and we have the audio across resistor R5.

The dc component across R5 is used for avc purposes. To get a pure dc voltage, the audio voltage that is also present across the volume control must be filtered out. This is done by means of R3 and C3, and only the dc voltage appears across C3. The dc voltage is applied to the mixer grid of the 12BE6 and the control grid of the 12BA6. If the signal increases, the voltage across R5 also increases, and the gain of the 12BE6 and 12BA6 tubes decreases. On the other hand, if the signal tends to fade, less voltage will appear across R5, and the gain of the 12BE6 and 12BA6 tubes will increase. Any part of the available audio voltage across R5 can be applied to the control grid and cathode of the 12AT6 tube. The part that is applied depends upon the setting of R5, which is the volume control. The connection to the control grid is through C6, and the cathode connection is direct, since the lower end of the volume control is in electrical contact with the cathode.

The 10-megohm resistor R6 is used to bias the control grid of the 12AT6 tube. The tube amplifies the signal applied to its control grid-cathode, and the amplified signal appears across the plate load resistor R7. This signal is applied to the control grid -- pin 2 or pin 5 of the 50C5, and through output filter capacitor C11B and resistor R9 to the cathode of the 50C5. Again amplification occurs, and this time large amounts of power are developed across the primary of output transformer T3. Voltage is induced in the secondary, and the resulting current flow through the voice coil sets the cone in motion, thus reproducing the sound waves which were picked up by the microphone at the broadcasting station.

The bias voltage for the output tube V4 is obtained from the voltage drop across the 150-ohm resistor, R9, in the cathode circuit. The bypass capacitor, C8, in the plate circuit is used to make the plate circuit capacitive so that the tube will not go into oscillation at high frequencies, which may be beyond the audible range. As long as the plate circuit is capacitive, oscillation will not take place.

Notice that capacitor C10 is connected directly across the power line. The purpose of this capacitor is to prevent rf signals from entering the receiver by way of the power line, and causing hum modulation. If there are poorly soldered connections somewhere in the power line, the 60 Hz power line signal could modulate the rf signal, resulting in an annoying hum, Bypassing the signal before it can get into the receiver circuit prevents hum modulation, because then only the signal induced in the loop will be amplified, detected, and reproduced by the loudspeaker.

Although the foregoing description is brief, it should give you an idea of how your receiver works and how the various parts work together. Study the several sections of the receiver carefully to become more familiar with the operation of the receiver.

Performing the Experiment

The ten experiments in this manual are designed to give you practical experience in servicing all types of sets, not just ac-dc sets.

In the first two experiments, you will learn to isolate trouble to one section of the receiver. In the later experiments you will demonstrate symptoms produced by defects you will frequently find, and you will learn the test procedures to follow in finding each defect. You will conduct experiments covering the following major defects:

1. Dead receiver.
2. Hum.
3. Noise.
4. Oscillation.
5. Distortion.
6. Weak reception.
7. Misalignment.

EXPERIMENT 61

Purpose: To show that a meter can be used to indicate the presence or absence of signals in certain stages of the receiver.

Introductory Discussion: When a set is dead, the expert serviceman will need to make only a few tests to find the defective section or stage. There are two basic methods of finding a stage that does not pass a signal. You can tune to a station so that a signal is applied to the input of the dead stage. If the signal is strong enough, you can use the tvom to see if the signal is present at both the input and the output of the stage. In receiver stages where the signal is too weak to be identified with a tvom, the technician must use a more sensitive instrument, such as a signal tracer (described in your regular lessons), or he must use some other method of testing the suspected stage.

In this experiment, we will deal with the first method: identifying the signal with the tvom where possible. We will also point out where it is not possible to use the tvom. The experienced technician will know the limitations of various instruments and will know when it is necessary to turn to other methods of diagnosis. These experiments will give you valuable experience in using test instruments and in carrying out standard troubleshooting procedures. Refer to the schematic diagram in Fig. 22 as you carry out the various tests so that you will become more familiar with the receiver and get more experience in reading diagrams of this type.

Experimental Procedure: To conduct the steps in this experiment, you need only the receiver in operating condition and the tvom.

Step 1: To show how the tvom can be used to localize a defect causing a dead set to one section of the receiver.

As you know, there are two signal-handling sections in a radio receiver -- the rf and the af sections. The dividing point is the output of the second detector, which is considered a part of the rf section.

Tune in a strong local station, and short the loudspeaker voice coil to kill reception by soldering a short piece of bare hookup wire across the voice coil terminals. Now turn the volume control all the way clockwise. If you hear any of the program, it will be extremely weak.

Now connect the ground clip of the tvom to B- and set the Function switch for -dc voltage. Touch the probe to terminal P3 of the volume control. You should measure a small voltage. Adjust the tuning knob throughout its range. Notice that the voltage drops as you tune away from the station, and that it reappears as you tune past other stations. The presence of this voltage proves that a signal is reaching the second detector, so you know the rf section is working normally. The fact that the rf section works is also proof that the power supply is all right.

Step 2: To trace the signal through the af system with the tvom.

First tune to a point on the dial where a large diode load voltage, measured across the volume control as in Step 1, is produced. Now switch the tvom for ac voltage measurements, and leave the ground clip on B-. Touch the probe to terminal P3 of the diode load resistor (the volume control).

There will be a very small voltage, which can be identified as an audio signal, by noting that it disappears when you tune away from the station. Also, notice that the meter pointer fluctuates. Tune the signal back, and touch the probe to the control grid, pin 1 of the 12AT6 tube. You should measure as much signal here as at the diode load. Lack of signal would indicate an open in coupling capacitor C6.

Move the probe to plate socket pin 7 of the 12AT6 tube; reset the Range switch if the meter pointer goes off scale. You should measure an increased voltage. If the voltage is not larger here than it was on the grid, or if there is no voltage at all on the plate, you know that there is a defect somewhere in the 12AT6 tube circuit. Move the probe to the grid of the 50C5, pin 2. You should measure as much voltage as at the plate of the 12AT6. Lack of signal voltage at the 50C5 grid would indicate an open in coupling capacitor C7.

To see if the signal is present at the output of the 50C5, touch the probe to plate pin 7. You will have to switch to a higher voltage range, because a large signal voltage is present at this point. Since we have a signal at the plate of the 50C5, but no reception, the defect would have to be in the voice coil-output transformer secondary circuit.

In service work, you will probably never find a defective output transformer secondary or a shorted voice coil. Most defects in this part of the receiver are caused by open voice coils. Since the voice coil is in parallel with the transformer secondary, it is necessary to disconnect one lead of the transformer secondary to check the secondary and voice coil individually for continuity. If there is no continuity, there is an open in the part under test.

Let us see why it is necessary to disconnect one of the leads. Turn off the receiver, and remove the piece of wire you soldered across the voice coil terminals. Then, set up your tvom for ohmmeter measurements, using the lowest range. Connect the test leads across the voice coil terminals. You will measure about 0.4 ohm. Now disconnect one of the transformer secondary leads from the voice coil, and check directly across the secondary winding. Move the transformer lead back to the voice coil connection, and you will see that there is no appreciable change in resistance reading with the voice coil in or out of the circuit. These readings are definite proof that to check a voice coil for an open, you must disconnect one of its leads so it can be checked by itself.

Step 3: To show that the tvom is not satisfactory for tracing signals in the rf section.

Resolder the transformer lead to the voice coil terminal, tune in a strong station, and turn the volume control down.

Clip the ground lead of the tvom to B– and set the tvom for ac voltage measurements. Measure the i-f signal at plate pin 6 of the 12AT6 tube. Identify this as an i-f signal by tuning back and forth across the station frequency, noting that the signal voltage is at a maximum when you tune in the station. Now move the probe to the plate, pin 5, of the 12BA6. You should get a little more signal here than at the 12AT6 diode plate. The transformer coupling between the stages, of course, is the reason that the signal is reduced. If the signal is present at the 12BA6 plate, but not at pin 6 of the 12AT6, you would look for trouble in the second i-f transformer.

Now move the probe to the control grid of the 12BA6, pin 1. The signal at this point will be too weak to give a usable indication on the tvom. This means that the tvom is of little value as a signal tracer in the rf section of a receiver. As a matter of interest, however, touch the probe to plate pin 5 of the 12BE6. Since you measured practically no i-f signal voltage at the 12BA6 control grid, you wouldn't expect to measure an i-f signal at the 12BE6 plate. However, you will find a readable rf voltage at the 12BE6 output. This is not an i-f signal, but consists mainly of the oscillator signal, which is present in the mixer plate circuit. Its absence at the 12BA6 control grid shows the effectiveness of the i-f transformer in rejecting undesired signals.

Discussion: The fact that you can trace signals fairly well in the af section of a receiver does not mean that you should use this method to the exclusion of all others. Use it when you start doing service work, along with other test procedures. Then, you will be able to decide whether you like it well enough to use it every time you service a dead set, or whether to use it only on those occasions where other methods leave you in doubt as to the results.

As a matter of fact, an expert technician seldom uses one test procedure exclusively. He knows many test methods, and uses the one that he thinks from experience will best solve the particular problem at hand.

In this experiment, you did not get much output when you measured the i-f signal voltages because the capacity of the tvom probe detuned the circuit. If you were to tune the receiver first for maximum signal strength, then connect the probe, and reset the tuning slug of the i-f section in question, you would measure a larger signal. However, when you removed the probe, you would have to readjust the tuning slug for maximum output. If the set is dead to start with, adjusting the tuning slug might cause trouble. We do not suggest that you attempt it on your receiver, because if you get the i-f badly misaligned, you may have trouble in realigning it.

Instructions for Statement 61: In this experiment you saw that it was necessary to unsolder the output transformer secondary lead from the voice coil terminal to see if the voice coil was open. You did not measure the dc resistance of the voice coil, but from the effect you noted in checking the resistance of the transformer secondary with the voice coil in and out of the circuit, you should be able to complete the statement. If you are not sure, check the voice coil resistance with your ohmmeter. Then, answer the statement here and on the Report Sheet. Resolder the output transformer lead to the voice coil terminal before going on to the next experiment.

Statement No. 61: The resistance of the voice coil is:

[✓ *(1) more than*]
(2) less than
(3) the same as

that of the output transformer secondary.

EXPERIMENT 62

Purpose: To show how to use a circuit disturbance test to find the defective stage.

Introductory Discussion: A signal-injection test is based on the fact that if a signal injected into a certain stage produces a noise in the loudspeaker, you know that all stages between the point where the signal is injected and the loudspeaker must be in operating condition. There are several ways to carry out the test. You can start from the input of the receiver and work toward the loudspeaker, or you can start from the power output stage and work toward the input. In either case, the stage preceding the live point nearest the input is defective. A live point is one where an injected signal produces a sound in the loudspeaker.

When we speak of injecting a signal, we usually think of feeding an audio signal into the af section, and a modulated rf signal into the rf section. To inject such signals would require an af-rf signal generator. These are in common use and are found in most service shops. However, the experienced technician seldom uses them for signal injection when checking a dead receiver, because there is a faster, simpler way to do the job. This is the circuit-disturbance test, which requires only a screwdriver or no tool at all. Your body picks up some 60 Hz ac from the house wiring, so if you touch the input of a high gain audio amplifier with your finger, a 60 Hz signal will be heard in the loudspeaker.

Similarly, if you touch the input of an rf or i-f stage, there will be a slight change in the tube plate current. If there are tuned circuits, they will be shock-excited, and a signal voltage at the resonant frequency will be produced for a few cycles. The strength of this signal will fall off rapidly. This change in amplitude is a modulation on the signal, which can be detected and passed through the audio amplifier to the loudspeaker, where it produces a thud or click. By disturbing the circuit in this way, you can quickly localize trouble to a stage in the receiver, and then use your tvom to locate the defective part.

In this experiment, you will practice circuit disturbance testing.

Experimental Procedure: The only parts that you will require are your receiver in operating condition, your tvom, and your hand tools.

Step 1: To show that a sudden change in current through the output transformer primary will produce a click in the loudspeaker.

Unplug the receiver from the power line, and set up your tvom for low-range ohmmeter measurements. Clip the tvom ground lead to the screen, pin 6, of the 50C5 tube. Tap the probe against plate pin 7. This will cause a slight current to flow through the primary of the output transformer, and you will get a click from the loudspeaker each time the circuit is opened and closed. Use the lowest range of your ohmmeter when doing this, because on the higher ranges, the current flow will be limited, and you may not hear the click.

This shows that only a slight change in current through the transformer primary is necessary to produce a click in the loudspeaker. This procedure can be used to check output transformers and voice coils of pm loudspeakers. Now remove the ground clip from pin 6 of the 50C5 tube socket.

Step 2: To show that a change in the plate current of the output tube will produce a click in the loudspeaker.

Plug in the set, turn it on, and let it warm up. Have the volume control turned down all the way so radio programs will not interfere with the test.

Use a screwdriver that has a long thin blade, and hold it so that your hand is in contact with the metal blade. If you hold the screwdriver by its insulated handle, you may not get a click from the loudspeaker when you carry out the tests. Scrape the end of the blade across pin 2 of the 50C5 or on the lead of resistor R8 that is connected to pin 2. You will hear a noise in the loudspeaker. If you cannot definitely hear a noise or click, momentarily short pins 1 and 2 of the 50C5 together with the screwdriver blade. This will remove the bias from the 50C5, and the speaker will produce a loud click.

Move the blade of the screwdriver to plate pin 7 of the 12AT6 tube. You should again hear a click when the blade touches the plate terminal, if coupling capacitor C7 is in good condition. Do not touch the chassis or the other parts of the receiver when the blade touches the 12AT6 plate, or you will be shocked. However, be sure you have your hand in contact with the blade when you touch the tube socket pin.

Make sure that the 12AT6 is working by touching its control grid, pin 1, or any lead from pin 1. If your hand is in contact with the screwdriver blade, you will hear a hum from the loudspeaker. Hold the screwdriver by its insulated handle, and note that instead of the hum, there is only a click when you touch pin 1. For this test most servicemen use one finger instead of a screwdriver. Try this, being sure to touch only pin 1. Incidentally, this is the first check to make on a dead receiver. If you hear a signal from this point, you know that the audio system is operating, and that the trouble is between the second detector and the antenna. If you do not hear a click or hum, you know the trouble is in the audio system or power supply, and you can proceed accordingly.

Now, short the oscillator tuned circuit to kill reception, and turn the volume control completely on. You can short the tuned circuit by putting a screwdriver blade between terminal C5 of the tuning capacitor and the chassis. Arrange the screwdriver so that it will be self-supporting. Touch terminal P3 of the volume control with your finger. A hum indicates that everything from this point to the loudspeaker is working. If you get a hum at the 12AT6 grid, but not at terminal P3, sometimes called the "hot" terminal, of the volume control, coupling capacitor C6 might be open. Technicians usually touch this volume control terminal rather than the grid of the first audio tube because the volume control is easier to find.

Step 3: To show the effectiveness of a circuit disturbance test in localizing a defect.

Unplug the receiver and disconnect the B+ end of the 12AT6 plate load resistor R7 from the circuit. This removes plate voltage from the 12AT6 tube. Plug in the receiver and touch pin 2 of the 50C5, and then pin 7 of the 12AT6. Each of these will produce a click. Next, touch pin 1 of the 12AT6 tube. You will hear nothing, showing that the trouble lies between this point and the plate of the 12AT6 tube. It could be due to lack of plate voltage, as happens to be the case, or to a control-grid-to-cathode short in the tube. It could also be due to loss of emission in the tube. A few checks with your tvom and trying a new tube would enable you to make a quick repair.

Step 4: To show how the input of the rf and i-f stages can be disturbed to produce a click in the loudspeaker.

With the receiver unplugged, resolder the B+ end of R7 to the proper point in the circuit, but leave the screwdriver shorting out the oscillator section of the tuning capacitor in place. Plug in the receiver and turn the volume control on completely. Hold another screwdriver blade or your longnose pliers in your hand, and touch the free end to control grid pin 1 of the 12BA6 tube. You will hear a click in the loudspeaker. Now touch the mixer grid, pin 7 of the 12BE6; you will again hear a click.

Step 5: To show that the circuit-disturbance test is effective in isolating trouble to an rf stage.

Unplug the receiver and unsolder cathode bias resistor R4 in the i-f amplifier stage from pin 7. Remove the screwdriver that is shorting the oscillator tank circuit, turn up the volume control all the way, and try tuning in a station. The set should be dead.

You can tell that the af system is working by touching the hot terminal of the volume control with your finger. Now touch the diode plate, pin 6, of the 12AT6 tube. You should get the same amount of hum, showing that the secondary of the i-f transformer is not open.

Now, touch the plate of the 12BA6, pin 5, with the screwdriver blade. Since your hand is touching the blade, be sure your body is not grounded and does not touch any part of the receiver. You should hear a click in the loudspeaker when you touch the plate, showing that signals are capable of passing from this point, through the second detector-audio amplifier, and to the loudspeaker.

Now touch the control grid, pin 1 of the 12BA6 tube. Compare what you hear (which will probably be a very faint click if anything at all) with the click you heard when R4 was in the circuit. The faint click that you may have heard was due to the disturbance signal feeding back through the avc and power supply line to the audio section. The signal, however, did not go through the 12BA6 tube.

Thus, to locate the defect, you would check the tube, the operating voltages, and the component parts in the i-f amplifier stage.

Resolder resistor R4 back to pin 7 before going on to the next step.

Step 6: To show that touching the oscillator grid will also result in a loudspeaker noise.

Tune to a point on the dial where a station is not received, and touch the oscillator grid, pin 1 of the 12BE6, with your finger or the screwdriver blade. Note the noise produced from the loudspeaker.

Discussion: The circuit disturbance test is very useful in working on a dead receiver, or on a set that is so weak it is practically dead. Sometimes, because of interaction between stages, the circuit disturbance test is not effective. You probably noticed this when you touched the grid of the i-f amplifier stage in Step 5. However, there are other techniques that can be used, which you will learn later.

In making the circuit disturbance test, bear in mind that in some places, especially in the rf and i-f stages, touching the grid of a tube with an insulated screwdriver will produce a click. In the first audio stages, your hand should be in contact with the screwdriver blade. In still others, where the gain is low between the point of disturbance and the loudspeaker, you may have to make a radical change in plate current. You did this when you shorted the control grid of the 50C5 to the cathode. Removing all bias in this manner causes a very large change in plate current with a resulting loud click from the speaker. As long as you do not leave the short in the circuit for any length of time, there is no chance of damaging good parts as a result of the short.

Instructions for Statement 62: Although the circuit disturbance test is very useful, it may not always tell you what you want to know. Here you will compare its effectiveness to the effectiveness of measuring the dc bias voltage of the oscillator in deciding if an oscillator is operating.

First, tune to a point where a station is not received, and turn the volume control up completely. Touch the oscillator grid, pin 1 of the 12BE6, with your finger or a screwdriver blade. Now measure the dc voltage between pin 1 and B−.

Next, short the oscillator tank with your screwdriver as you did previously. Recheck the dc voltage on pin 1, comparing it with that obtained when the oscillator was working. With the tank still shorted, touch pin 1 with your finger, and compare the loudspeaker noise to that heard when the oscillator was working. You now have sufficient data to complete the statement.

Statement No. 62: If the oscillator is suspected of being dead, a circuit disturbance test:

(1) is a satisfactory
[✓ *(2) is not a satisfactory*]

method of determining if the oscillator is working.

EXPERIMENT 63

Purpose: To show the effects of some common filament defects.

Introductory Discussion: In servicing an ac-dc receiver, you may find any one of three filament circuit defects. These are:

1. No tubes light.
2. Tubes light intermittently.
3. Some tubes light -- others are dark.

This experiment illustrates still another filament circuit defect. Before going on, however, let us discuss the three defects listed above.

In a normally operating ac-dc receiver, the tube filaments are in series, and the same current flows throughout the entire filament circuit. You would expect an open anywhere in the circuit to prevent all of the tube filaments from lighting. This is why many technicians are puzzled when they find an ac-dc set where some of the tubes light and some do not. At first it would appear that if any of the tubes light, they should all light; and that if one does not light, none should light. However, both types of defects can occur in the filament circuit of an ac-dc set.

Experimental Procedure: For the following steps you will need:

2 120 ohm resistors
tvom
receiver

Step 1: To check filament circuit continuity with the ohmmeter.

When you have an ac-dc set where none of the tubes light, you know that either the wall outlet is not delivering power or that there is an open in the series filament circuit consisting of the power cord, the On-Off switch, and the tube filaments as shown in Fig. 63-1.

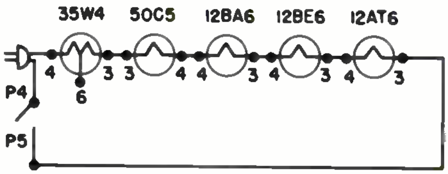

Fig. 63-1. Filament circuit of 7YY receiver.

The power outlet can be quickly checked, either directly or indirectly. A direct check is made either by plugging a piece of apparatus, such as a floor lamp, into the wall outlet and seeing if it lights, or by measuring the supply voltage. To check the voltage, you can push a thin-bladed screwdriver into either of the holes in the wall outlet and connect the ground clip of your tvom to the screwdriver blade. Push the probe into the other wall outlet hole, and measure the available voltage.

An indirect check of the outlet can be made by removing the receiver power plug from the wall outlet and connecting the ohmmeter across the prongs of the plug. Turn on the switch, and if you find continuity, you know that the filament circuit is not open. Therefore, the defect must be in the wall outlet. If you do not find continuity, you know the defect is in the receiver.

To see how to localize an open in the filament circuit, simulate an open by turning off the On-Off switch. Remove the power cord from the wall outlet, clip the ground lead to one prong of the plug, and touch the probe, using the R X 10 range, to pin 4 of the 35W4 tube. If you measure zero resistance, that side of the line cord is not open. If you get an open circuit reading, switch the ground clip to the other prong and repeat the measurement. If you get zero resistance, that side of the line cord is not open.

Now, leave the ground clip attached to the prong of the power cord where you measured zero resistance, and move the probe to pin 3 of the 35W4 tube. You will get a reading on the ohmmeter, indicating that there is continuity, and that the tube filament is not open. Now move the probe right around the circuit to pin 3 of the 50C5, 4 of the 50C5, 4 of the 12BA6, 3 of the 12BA6, 4 of the 12BE6, 3 of the 12BE6, 4 of the 12AT6, 3 of the 12AT6, terminal P5 of the On-Off switch, and finally to terminal P4 on the On-Off switch.

In each case, if you get a reading, you know there is continuity from the line plug to that point. You should get a reading each time, until you touch the probe to terminal P4 of the On-Off switch. This indicates that the tube filaments are not open, and you would suspect that the switch is defective. When checking continuity in this manner, remember that if you get a reading at one point but no reading at the next test point, you have located the circuit defect.

Instead of making point-to-point continuity measurements, you could remove the tubes and check their filaments individually with your ohmmeter. Try this on the 35W4 tube. Connect the clip of your tvom to pin 4, and touch the probe first to pin 6 and then to pin 3. In each case you should get a resistance reading.

This is the method to use if the receiver is in the cabinet so that you cannot get at the bottom of the tube sockets. Each tube should be checked individually. If all the tubes have continuity, then you know there is probably an open in the power cord or a defective On-Off switch. An open in the power cord is usually right at the power plug, and you can cut off the old plug and install another. Do not repair the power cord until you have checked the switch. You will have to remove the receiver from the cabinet to check it. These switches, however, seldom become defective.

Step 2: To check filament circuit continuity using ac voltage measurements.

You can check the filament circuit with your voltmeter instead of with the ohmmeter. The test procedure is almost the same.

To see how to do this, plug your receiver into the wall outlet, and remove the 12BE6 tube to simulate an open in its filament, and turn the set on. None of the tubes will light, since the filament circuit is open. Now connect the ground clip of your tvom to the power line side of the On-Off switch, terminal P4.

Set your tvom so that it will measure the full ac line voltage. Touch the probe to each of the filament pins of the tubes, working from the 12AT6 back toward the 35W4, as shown in Fig. 63-1. You will not get a reading when you touch pins 3 and 4 of the 12AT6 and pin 3 of the 12BE6 tube socket. When you touch pin 4 of the 12BE6 socket, you will measure the full line voltage. Since the circuit is open, normal current is not flowing through the tube filaments, and there is no voltage drop across them.

Reinsert the 12BE6 tube, and pull out the 50C5. Note that you do not get a reading as you work from the 12AT6 tube socket, until you again measure full line voltage when you touch pin 3 of the 50C5.

Turn the set off temporarily, and connect the ground clip of the tvom to pin 4 of the 50C5. Turn the set on, and touch the probe to pin 3. You will measure full line voltage just as you did when the clip was connected to the line. Now reinsert the 50C5 tube, and again touch the probe to pin 3. Note that in this case you measure approximately 50 volts, the normal filament voltage of the tube.

When you are looking for an open in the filament string, always remember to have the Range Selector switch set so that the tvom will measure full line voltage. If you have the Range switch set so that you can measure normal filament voltage, the meter will be overloaded when it is connected across the defective tube filament. Since this is a tvom the meter will not be damaged, but you should always get in the habit of using a range which will not cause the meter pointer to go off-scale.

Step 3: To show the effects of heater-cathode shorts.

To introduce a defect in which some tubes light and others are dark, temporarily connect a lead from pin 4 to the center post of the 12AT6 tube socket. This represents what would happen if a cathode-to-heater short developed in the 12AT6 tube.

Turn the receiver so that you can see the tubes, plug the power cord into the ac wall outlet, and turn the set on. All of the tube filaments will light except the 12AT6. This tube is dark. Remove the short between pin 4 and the center post of the 12AT6 socket.

You do not have to use test instruments when you find a condition of this type. Simply examine the schematic and consider what would happen if the cathode of any of the tubes shorted to its filament. The filament circuit beyond that point would be shorted out. In your 7YY receiver, if the short is in the 12AT6 tube, only that tube would not light, as you have just demonstrated. If you found that both the 12BE6 and the 12AT6 tubes were dark, you would suspect a cathode-to-heater short in the 12BE6 tube.

Step 4: To show the effects of a heater-cathode short in the audio output stage.

Take the two 120-ohm resistors and lay them side by side. Twist the adjacent leads together a turn or two to connect the two resistors in parallel. We will refer to the parallel 120-ohm resistors later as a 60 ohm resistor. Clip off one of the leads from each end of the resistor combination.

With the set unplugged, solder one end of the 60-ohm resistor to pin 1 of the 50C5. Solder the other lead to pin 4 of the same tube. Before you plug in the receiver, examine Fig. 63-1 and try to determine the results of your sabotage. Will all the filaments light? Will the set be dead? Plug the receiver in and observe its behavior. Check to see if all filaments light. Try to tune in a station. Turn off the receiver and remove the 60-ohm resistor from between pins 1 and 4.

Discussion: We have not attempted to show the effect of the third filament defect -- an intermittently open filament. The filament of a tube may become brittle with age and crack. When it is heated, the filament will expand, and the circuit will open. When the circuit opens, all of the tube filaments will go out. As the defective filament cools, it will contract, and the broken ends of the filaments will come back together, thus re-establishing current flow through the circuit. The time intervals between light and no light from the filaments are generally equal.

This defect cannot be located with an ohmmeter because when the tube filament is cold, there is continuity. Usually you cannot locate an intermittent open of this type with a tube tester. Very often the cathode will remain hot after the filament has opened, and will continue to emit electrons until the filaments have cooled sufficiently to come together again.

Trouble of this type, however, can be located with an ac voltmeter. You would use the same procedure given previously, by leaving the voltmeter connected in each test position long enough for the filament to open. If the voltage reading drops to zero, you know that the tube you are measuring across is not defective. However, if the voltage rises to the full line voltage, you have located the defective tube.

You can either make your measurements from one end of the filament string, or you can connect the meter directly across the filament of each tube, one at a time. Regardless of which method you use, the Range Selector switch of the meter should be set so that the full line voltage can be measured. Remember this test procedure. You will have occasion to use it in servicing TV sets as well as radios.

In each of the tests you have just conducted, the defect causing the receiver to be dead was indicated by the fact that some or all of the tubes failed to light. There are many other defects causing a set to be dead, which give no visible symptom. When you cannot see the underlying cause of a defect, you must use some servicing method that will quickly lead you to the defective section, stage, and part.

Instructions for Statement 63: In this experiment you have seen the effects of heater-cathode defects in some of the receiver circuits. For this statement you will observe the effects of a heater-cathode short in the i-f amplifier stage.

Solder one lead of the 60-ohm resistor to pin 4 of the 12BA6. Solder the other lead to pin 7 of the same tube. Turn on the receiver and observe the tube filament. Turn the volume control up and observe the results. Turn off the receiver, remove the 60-ohm resistor and answer the statement below and on your Report Sheet.

Statement No. 63: When I simulated a heater-cathode short in the i-f amplifier stage, I found

(1) all filaments
[✓ *(2) the 12 volt filaments*]
(3) no filaments

were dark and the 60 Hz hum

[✓ *(1) was louder*]
(2) was weaker
(3) did not change

as I advanced the volume control.

EXPERIMENT 64

Purpose: To show the effect of low emission in an amplifier tube and to show methods of quickly locating the defective tube.

Introductory Discussion: When we say that a tube has low emission, we mean that the cathode does not give off as many electrons as normal. We can demonstrate this by reducing the filament current to the point where the cathode is insufficiently heated to emit a normal quantity of electrons. We will do so in this experiment by partially shorting the filament of the 12AT6 with a resistor. This will lower the filament voltage of the 12AT6 from about 12 volts to approximately 4 volts ac. The extra voltage will be divided among the other tube filaments, but the increase of each will be too small to cause excessive filament current.

Shunting the tube filament also illustrates another defect frequently found in receivers. In some cases an internal short develops in a tube filament; and in an ac-dc filament string, the effect is exactly the same as that of an external resistor across a filament.

For this experiment you need your receiver, in first-class working condition, your tvom, and:

1 120-ohm resistor
1 60-ohm resistor

Step 1: To measure the plate voltage and the filament voltage of the 12AT6 tube.

Turn your set on, and when it warms up and is operating, measure the voltage between B- and the plate, pin 7 of the 12AT6 tube, and the filament voltage (B- to pin 4) of the same tube. Record your readings in Fig. 64-1.

CIRCUIT CONDITION	PLATE VOLTAGE	FILAMENT VOLTAGE
NORMAL	50VDC	12AC
FILAMENT PARTIALLY SHORTED	80VDC	3AC

Fig. 64-1. Record your readings for Exp. 64 here.

Next, feel the envelope of the 12AT6 tube so you can judge its temperature. Do not grasp the tube too tightly or you may burn your fingers. Now turn the set off and let it stand for five or ten minutes while the tubes cool.

Step 2: To measure the plate and filament voltages with the filament partially shorted.

Connect a 120-ohm resistor in parallel with the two already connected in parallel and connect the resulting 40-ohm resistor between pins 3 and 4 of the 12AT6 tube socket. Do not connect the third 120-ohm resistor permanently to the resistor combination since you will use it in a later experiment.

Turn the set on, and let it warm up for about five minutes. With the reduced filament voltage, it will take quite some time for sufficient heat to reach the cathode to produce any electron emission. Touch your finger to the grid of the 12AT6 from time to time so you can see how long it takes for the cathode of the tube to warm up.

When touching pin 1 of the 12AT6 tube causes a slight buzz in the speaker, try tuning in stations with the volume control all the way up. If you are near any stations and your line voltage is normal (115 volts or more), you will be able to pick up programs, but they will be quite weak.

Now repeat the plate and filament voltage measurements you made in Step 1. Record your readings in Fig. 64-1. Then, feel the tube envelope; notice how the heat produced compares to that when normal filament voltage is applied.

Discussion: You will frequently get sets for repair that take a long time to warm up. In some cases, the volume will be almost normal when the receiver does warm up. In others, the volume will remain quite weak.

In ac-dc receivers, you should suspect that one of the tubes has a partially shorted filament. A defective electrolytic capacitor will also cause the set to take a long time to warm up. Any tube can have a partially shorted filament, but it is more common in higher voltage tubes, such as rectifiers and power output tubes.

It is a good idea to be careful when you touch any of the tubes in a receiver. You may be badly burned if you grasp a tube firmly without first finding out how hot it is. Therefore, just barely touch the tube. If you find that it is not very hot, then you can grasp it more firmly.

Insufficient heat can be caused by a partially shorted filament, as in this case, or a lack of cathode emission. A partially shorted filament reduces the power dissipation in the filament, which is the greatest heat source in the tube.

You will seldom find this trouble in an ac-operated set. If a partial short does occur, the current through the rest of the filament will rise to the point where the filament will burn out, and the tube filament will be completely open. In ac-dc receivers, partial filament shorts are fairly common.

A partially shorted filament cannot be found with a tube tester, because in a tube tester, normal filament voltage is applied to the filament regardless of its condition. Thus, the tube will test good. However, you can test a tube suspected of having a partially shorted filament by measuring the ac filament voltage or by substituting another tube.

If you find that the filament voltage of a tube in a heater string is lower than normal, you can be pretty certain that the tube has a partially shorted filament, and you should install another tube.

The variations in the dc operating voltages that you recorded in Fig. 64-1 were due to the plate current variations of the tube. When the plate current is extremely low, there is little voltage drop across the plate load resistor. Therefore, the plate voltage has almost the same value as the B supply voltage. When the tube is drawing normal plate current, there is a large drop across the plate load resistor, and the plate voltage is lower. Remember that when there is a high value plate-load resistor in the circuit, excessively high plate voltage indicates lower-than-normal plate current.

Instructions for Statement 64: Remove the 40 ohm resistor from across the filament of the 12AT6 tube, and put it across the filament (pins 3 and 4) of the 12BE6 tube. You will not be able to pick up any stations when you try to tune them in. Check all operating voltages on the 12BE6 tube, and compare your results with those you recorded in Fig. 23. Think about the significance of the dc voltages you measure and complete the statement. Then, remove the resistors from pins 3 and 4 of the 12BE6 tube socket.

Statement No. 64: The receiver is dead when the 12BE6 tube has low emission because:

(1) the plate and screen voltages are too high.

[✓ *(2)*] *the oscillator is dead.*

(3) no rf signal voltage is being applied to the input of the stage.

EXPERIMENT 65

Purpose: To show the effect of leaky bypass capacitors in the B supply circuit;

and how to locate them with an ohmmeter and with a voltmeter.

Introductory Discussion: Leakage in a capacitor results when the dielectric resistance decreases to the point where dc can readily flow through the capacitor. To make a circuit act as though a bypass capacitor in it has become leaky, we can connect a resistor across the capacitor. We can simulate any degree of leakage merely by using resistors of various sizes.

To avoid damaging the rectifier tube, we will limit the leakage in each case to 3000 ohms. In an actually defective capacitor, the leakage could be higher or lower but 3000 ohms will show what can be expected and how the capacitor can be located with standard test procedures. We will simulate leakage in the plate bypass capacitor in the output stage, where leakage is frequently found, and in the rf bypass capacitor. The rf bypass capacitor in the plate and screen supply circuit of ac-dc sets does not become leaky as often as the one in the plate circuit of the output stage, but in TV receivers and in ac-operated radio sets where the B+ supply is higher, they often fail.

Experimental Procedure: For this experiment you will need the receiver in good operating condition, your tvom, and:

1 3k-ohm resistor

Step 1: To show the effect of leakage in the output tube plate bypass capacitor.

Solder one end of the 3k-ohm resistor to the plate, socket pin 7, of the 50C5 tube, and the other end of the resistor to terminal DB1.

CAUTION: With this resistor in the circuit, do not leave the receiver turned on too long, because abnormally high current will flow through the resistor and overheat it. For short periods of time, long enough to make the necessary measurements, it will be safe to have the set turned on. As soon as you have finished making a measurement or observation, turn the set off.

Turn the receiver on, allow it to heat up, and tune in a station. You may be able to note that the sensitivity is somewhat lower than normal. Turn the set off, and prepare your tvom for positive dc voltage measurements. Set the Range switch in the 120-volt position, and clip the ground lead of the tvom to a B− point. Turn on the receiver, allow it to heat up, and measure the dc voltage on screen pin 6 of the 50C5, and plate pin 7 of the 50C5. Record the values in Fig. 65-1, and turn off the receiver. Now compare these voltages to those you recorded in Fig. 23.

SCREEN GRID OF 50C5 (PIN 6)	53v	4.5K
PLATE OF 50C5 (PIN 7)	84	3.4K

Fig. 65-1. Record your voltage and resistance measurements here when the plate bypass capacitor is leaky.

Step 2: To show how leakage in the plate bypass capacitor of the output tube affects the dc resistance measurements.

Disconnect the set from the power line. Leave the ground lead of the tvom connected to B- Discharge the filter capacitors by shorting the cathode of the rectifier to B- with a screwdriver blade or a piece of hookup wire. Now measure the resistance from B- to the cathode of the 35W4, to the screen of the 50C5, and to the plate of 50C5. Record the values in Fig. 65-1. Compare your readings with the normal readings to B- in Fig. 24.

Disconnect the 3k-ohm resistor from the plate of the 50C5 (pin 7) and from B-.

Step 3: To show the effect on dc operating voltages if the rf bypass capacitor C9 is leaky.

Connect the 3k-ohm resistor from the screen (pin 6) of the 50C5 tube to B-. Turn the set on, let it warm up, and tune in a station. You may be able to notice that the sensitivity is again somewhat lower than normal. Next, perform the voltage measurements indicated in Fig. 65-2. Record the values.

Study these readings, comparing them with the ones for Step 1 and with the normal readings in Fig. 23. See if they will tell you anything about the probable location of the leaky part.

CATHODE OF 35W4 (PIN 7)		4,5K
SCREEN GRID OF 50C5 (PIN 6)	73VDC	3.5K
PLATE OF 50C5 PIN 7)	84VDC	4,6K

Fig. 65-2. Readings for Steps 3 and 4.

Step 4: To show the effect of leakage in the rf bypass capacitor on resistance measurements.

Unplug the receiver from the power line, and measure the resistance from the cathode of the 35W4 to B-. If the meter pointer reads off-scale, discharge the electrolytic filter capacitors by shorting the cathode of the 35W4 to B- with a piece of hookup wire.

Now measure the resistance from the screen of the 50C5 to B- and the resistance from the plate of the 50C5 to B-. Record your readings in Fig. 65-2. Study the values carefully, comparing them with those in Step 2, and also with the normal readings in Fig. 24. See if you can deduce from these measurements the probable location of the trouble.

Discussion: When either of the two shorts you introduced was in place, the receiver played with only slightly reduced sensitivity. If either of the capacitors had actually been leaky, the condition would have become progressively worse, and, eventually, the receiver would have gone dead. Perhaps the filament tap on the 35W4 would have opened. However, the method to use in localizing trouble of this kind through measurements is the same, regardless of the degree of leakage.

When looking for a defect of this kind, small variations from the normal voltage values are very important. In Step 1 all the readings should be lower than normal. The important thing to notice is that the reading at the screen of the 50C5 is considerably below normal and that the reading at the plate of the 50C5 changed even more. You will be able to see the variations more clearly if you will subtract the voltage values you recorded in

Fig. 65-1 from those recorded in Fig. 23. Enter them in the margin opposite the values in Fig. 65-1.

Even if it were only 1 or 2 volts, the fact that the plate voltage decreased more than the screen voltage is sufficient to indicate that the short is probably on the plate side of the output transformer primary rather than on the screen side. Then, if you studied the schematic diagram of the set carefully, you would see that leakage in the plate bypass capacitor of the tube would cause these particular readings, and you would disconnect the capacitor to check it. You could check the capacitor with an ohmmeter; or you could simply disconnect it and repeat the voltage measurements. If you measure normal voltages with the capacitor out of the circuit, you know that the capacitor is leaky.

In Step 2 the resistance between the plate of the 50C5 and B- should be the lowest. The resistance from the screen of the 50C5 to B- should be slightly higher, again showing that the leakage is on the plate side of the tube rather than on the screen side.

The fact that the resistance from the cathode of the 35W4 to B- is higher than from the plate of the 50C5 to B- indicates that the short is not on the cathode side of the output transformer but somewhere on the plate side or in a part connected to the plate side. The diagram shows that there is a plate bypass capacitor, so you would check it first.

In Step 3 again all of the voltages decreased, but this time the greatest decrease is in the screen voltage. Again subtract the values in Fig. 65-1 from the normal values in Fig. 23, and enter them in the page margin. The larger screen voltage variation indicates that the excess leakage is somewhere in the B+ line.

By examining the schematic diagram, you can see that the trouble could be due to leakage in C9 or C11B, or that there could be a partial short in one of the tubes or from any terminal in this circuit to B-. The voltage measurements show the approximate location of the trouble, but do not point to any particular part. You will have to check the parts you suspect are causing the trouble until you locate the defect.

When looking for a defect of this type, do not go through the receiver and check and replace parts indiscriminately. After you have located the defective stage or circuit, refer to the schematic diagram and determine what part would cause that type of defect. This is the procedure used by all successful radio-TV technicians.

In Step 4, the resistance measurements show that the lowest resistance is from the screen of the 50C5 to B-. This indicates that the trouble would not be in plate bypass C8 or in the input filter capacitor. It is somewhere in the regular B+ line.

Both the voltage and resistance measurements point to the defective circuit, but do not show which part in the circuit is defective.

Looking at the diagram, you would see that leakage in either C9 or C11B could cause the trouble, so you would disconnect the capacitors one at a time, and check them either by measuring the circuit voltage without the capacitor or by making resistance measurements on the capacitor itself. In most cases you would quickly find the defective part.

Instructions for Statement 65: In some receivers, you will find a small rf plate bypass capacitor between the plate and the cathode of the first audio amplifier stage. The capacitor is not needed in the plate circuit of the 12AT6 tube in this receiver because the circuit consisting of C5 and R5 acts as an i-f filter. These components prevent practically all the i-f signal from reaching the control grid of the 12AT6 tube.

For this statement, let us suppose that the 12AT6 uses such a capacitor, and that it has developed a leakage path with a resistance of 3000 ohms. To simulate this, connect your 3k-ohm resistor between pin 7 of the 12AT6 tube and terminal DB1.

For the statement of this experiment, you are to determine which of the three troubleshooting methods--voltage measurements, resistance measurements, or circuit disturbance tests -- is the quickest and easiest method to use in localizing the defect to a particular section of the receiver.

Turn the set on, allow it to warm up, and try to tune in a station. You will find that the receiver is dead. Measure the B- to cathode voltage of the rectifier, the B- to screen voltage of the output tube and the B- to plate voltage of the output tube. Then, measure the B- to plate voltage of the 12AT6 tube. Compare the values with those you recorded in Fig. 23.

Turn the set off, and measure the resistance from B- to cathode, of the 35W4, B- to screen to the 50C5, B- to plate of the 50C5, and B- to plate of the 12AT6 tube. Compare these measurements with the normal measurements in Fig. 24.

Finally, turn on the receiver, and momentarily short the grid and cathode pins 1 and 2 of the 50C5 tube with a screwdriver. Next, momentarily touch the plate of the 12AT6 tube with the screwdriver, and notice whether there is a buzz or click from the loudspeaker. Then, touch the grid, pin 1, of the 12AT6 and again listen for the buzz or click.

Consider the symptoms you would be called upon to repair, and decide which method is the quickest and easiest to use in localizing the defect. Then answer the statement. Remove the 3k-ohm resistor.

Statement No. 65: With a leaky plate bypass capacitor in the 12AT6 circuit, I found that the quickest way to localize the trouble to this stage was by:

(1) voltage measurements.
(2) resistance measurements.

EXPERIMENT 66

Purpose: To demonstrate typical causes of hum in a receiver; and to show how the hum can be localized to one section and to one stage of the receiver.

Introductory Discussion: When a technician finds hum in a set, he usually looks for its cause in the power supply, because the filter system in the power supply is supposed to remove hum (ripple) and deliver pure dc to the tube electrodes. The filter capacitors are the most frequently defective.

In this experiment you will learn about filter capacitor defects, and about other causes of hum. Some of these are not common, but finding them can be very time-consuming. You will learn how to localize hum to one section and to one stage.

Experimental Procedure: To carry out this experiment, you need your receiver, your tvom, and the following parts:

1 20-μf, 150-volt capacitor
1 3k-ohm resistor
1 220-ohm resistor
1 0.25 μf or 0.27 μf capacitor

Step 1: To demonstrate the effects of high power factor in the input filter capacitor.

Turn the volume control down to the no-sound level. Then, use your ac voltmeter to measure the ac ripple voltage between B– and each of the following points: the 35W4 cathode, the 50C5 screen grid, and the 50C5 plate. Record the readings in Fig. 66-1.

To simulate a high power factor in the input filter capacitor, unplug the receiver and unsolder the lead of the electrolytic capacitor going to terminal DB2. Connect the 3k-ohm resistor in series with this lead and terminal DB2.

Turn on the set, and allow it to warm up. Note that there is a hum coming from the loudspeaker.

Now, measure the ac ripple voltage at the cathode of the rectifier and at the plate and screen grid of the output tube, and record the readings in Fig. 66-1. Compare these with the normal readings.

Try tuning in various stations to judge the performance of the set. You will find the performance is somewhat different from normal. Now check the defective capacitor just as a technician would by shunting the 20 μf, 150-volt electrolytic from the 35W4 cathode to B–. When installing an electrolytic in a circuit, you must observe its polarity markings. If you connect the capacitor with the wrong polarity, it will be ruined. Use the same polarity as for the original capacitor.

Solder the negative lead of the test capacitor to B–. Now, with the set on and a station tuned in, touch the positive lead of the test capacitor to terminal DB2. The hum should drop to almost its normal level at the same time the volume comes up. You may not be able to detect the increase in volume since the hum effectively masks the change in volume, so you will use your tvom to measure it. Set the tvom to measure ac volts on the 120-volt range. Tune to a station that is broadcasting speech and measure the ac voltage from pin 7 of the 50C5 to B–. Adjust the volume so that the average speech level will produce a variation of about two divisions (4 volts) on the meter scale. With the tvom still connected to

AC RIPPLE FROM B– TO	NORMAL	HIGH POWER FACTOR IN C11A	HIGH POWER FACTOR IN C11B	SHORT BETWEEN + LEADS OF FILTER CAPACITORS
CATHODE OF 35W4	5	34	4.7	3.2
SCREEN GRID OF 50C5	.35	2.6	2.8	3.3
PLATE OF 50C5	3	25	7.4	6.7

the plate of the 50C5, touch the positive lead of the test capacitor to terminal DB2. Now note the average variations indicated on your tvom. Even though they are at a lower average level, the variations should be considerably larger than before, indicating an increase in volume.

Next, check the dc voltage at pin 7 of the 35W4 with and without the test capacitor in place. Note the radical drop in dc voltage caused by an input filter capacitor that is open or has developed a high power factor. (The two troubles are practically the same as far as a serviceman is concerned because they give similar results.) From this we can conclude that a high power factor in the input filter capacitor causes weak reception as well as hum. In a set using a filter choke rather than a filter resistor, less hum will be heard and at the same time there will be a smaller drop in dc supply voltage. Thus, the complaint would probably still be weak reception as well as hum.

Step 2: To show the effect of a high power factor in the output filter capacitor.

Remove the 3k-ohm resistor from the input filter capacitor circuit and resolder the positive lead of the input capacitor to terminal DB2. Next, unsolder the positive lead of the output filter capacitor from terminal DB3 and solder one free lead of the 3k-ohm resistor to the capacitor lead you just disconnected. Solder the other end of the 3k-ohm resistor to terminal DB3. The output filter will now act as if it has developed a high power factor or has become open. An open means that the capacitor lead is broken inside the case and does not make contact with the foil used as the plate.

Now turn on the set, and with the volume control adjusted for no sound, listen to the hum from the loudspeaker. You will find that there is a considerable hum present, indicating that an open or high power factor in the output filter capacitor produces considerable hum. If the loudspeaker were in its cabinet, the hum level would be even higher than it is.

Now, measure the ripple voltage at the rectifier cathode, at the screen, and at the plate of the 50C5. Record your readings in Fig. 66-1. Compare these to those you measured for a defective input filter capacitor.

Measure the dc voltage at the rectifier cathode and at the screen and the plate of the 50C5. Compare them with the values you recorded in Fig. 23. You will find that the high power factor in the output filter capacitor has little or no effect on the dc voltages. For this reason you would not expect any great change in volume.

Now with the receiver turned on and the volume turned all the way down, shunt the output filter capacitor with your 20 μf test capacitor. The negative lead of the test capacitor should still be connected to B-. Connect the positive lead to terminal DB3. This connects the test capacitor across the original output filter capacitor and the 3k-ohm resistor. The capacitor must shunt both of them because the 3k-ohm resistor represents the resistance inside the case of a defective capacitor.

Notice how the hum level drops as soon as you connect the test capacitor across the defective part. This is the method used by technicians to test a capacitor for high power factor or an open. Remember, however, that a capacitor must be disconnected from the circuit to test it for leakage.

Step 3: To show the effect of a short between the positive leads of filter capacitors in a common container.

Restore the receiver to its original condition by removing the 3k-ohm resistor from the circuit, and resoldering the positive lead of the output filter capacitor to terminal DB3. Try the set out to make sure it is working normally and that the hum is back to its normal level.

To show what happens when a direct short occurs between the positive leads of the filter capacitors, solder a piece of hookup wire from terminal DB2 to terminal DB3. Turn on the set, and notice the hum. Measure the ripple voltage at the rectifier cathode and at the plate and screen of the 50C5. Record the values in Fig. 66-1. Notice that the ripple voltage at the screen of the 50C5 is the same as that at the cathode of the 35W4. This indicates that there is no voltage drop across the filter resistor.

Now, try to reduce the hum by alternately shunting the input and output capacitors with your test capacitor. Be sure to observe the polarity of the test capacitor. You will find that shunting the test capacitor across either the input or the output capacitor has little effect on the hum level. This is a pretty good indication that there is a short or leakage between the positive leads of the filter capacitors. When you suspect this defect, there is only one thing to do. Completely unsolder the original capacitors from the circuit and install others. If this clears up the trouble, you know there is a short between the positive leads of the original capacitors.

The capacitor sections may not be completely shorted as they are here. To simulate a partial short, remove the piece of hookup wire, and solder one lead of a 220-ohm resistor to terminal DB3. Position the other lead so that it can be pushed into contact with terminal DB2. Turn on the set and move the free lead of the 220-ohm resistor into contact with terminal DB2 using a screwdriver or pencil. Notice the hum level increases with the partial "short" in place.

Remove the 220-ohm resistor. Then, check the receiver to be sure it is working properly before going on with the next step.

Step 4: To illustrate the effects of inter-element leakage, and to show how the stage at which the hum enters can be localized.

Leakage in a tube is not necessarily between the cathode and heater, although this is the most common type of leakage. There may be leakage between a diode plate and the filament. To see the effect of this, connect a 220-ohm resistor between pins 4 and 6 of the 12AT6 tube. This simulates a diode-plate-to-filament short.

Turn on the set, and allow it to warm up. Then advance the volume control. The hum level should increase as the control is advanced.

Since you can use the potentiometer to control the hum level, you know that the hum is originating on the input side of the volume control. With the control turned all the way down, the grid of the 12AT6 is essentially at B- potential as far as signals are concerned. As the control is gradually advanced, hum is fed to the grid of the tube and is amplified by the entire audio amplifier.

Advance the control to a point where you can hear the hum clearly. Then, take your 0.27 μf capacitor and touch one lead to B-, and touch the other to the control grid of the 12AT6. Note that the hum drops to zero, indicating that it was getting into the grid circuit of the tube. Now, touch the free lead of the 0.27 μf capacitor to plate pin 5 of the 12BA6 tube. There will be no change in hum, indicating that the hum is not originating in the 12BA6.

Now touch the free lead of the capacitor to the plate pin 7 of the 12AT6 tube. Again the hum will drop to a low level. These tests are pretty definite proof that the trouble originates in the 12AT6 tube or in its input circuit. You would try a new tube in such a case. Remove the 220-ohm resistor.

Step 5: To show the effect of hum modulation.

Hum modulation is hum that is heard only when an rf carrier is tuned in. To demonstrate this effect, disconnect the antenna lead at terminal C4 of the strip on the rear of the tuning capacitor. Hold the bare end of the free lead in your hand. Turn the receiver on, and allow it to warm up. Advance the volume control to a point where you can tune in stations. You will notice that as each station is tuned in, you will hear hum, and the sound may be distorted. In some cases, the sound may be clear, but it will still be accompanied by hum. If no hum is heard, reverse the power plug connected to the power outlet. This is sometimes due to cathode-to-heater leakage in an rf tube, and is sometimes due to signals picked up through the house wiring and modulated (because of a poor connection in the house wiring) by the 60 Hz current. If these signals get into the receiver, the 60 Hz modulation will be demodulated along with the radio signal, and will be heard in the loudspeaker. It is for this reason that the 0.01 μf bypass capacitor, C10, is included across the power line at the input to the receiver. Any signals attempting to enter by way of the power line are bypassed by this capacitor.

Now resolder the antenna connection to terminal C4 and make sure that the receiver is operating properly.

Discussion: Open loop antennas can cause trouble, and may block reception entirely, making the receiver dead. They may also cause chopped-up or intermittent reception, or may produce a form of hum. If you suspect an open in the loop antenna, check for continuity between the loop terminals. In receivers where the loop is attached to the cabinet, the defect is usually in the connecting leads.

Hum in either ac or ac-dc receivers is generally due to defective electrolytic capacitors, or to cathode-to-heater leakage in one of the tubes. In servicing, therefore, check these possibilities first -- shunt the capacitors one at a time with good ones, and check the tubes in a tube tester or by substitution.

You also demonstrated the effect of leakage between sections of the electrolytic capacitor. This frequently happens through the capacitor case, and very often occurs under the capacitor mounting strap. If you suspect this, push the capacitor so that the part under the strap is exposed. If there are green corroded spots, there is leakage to the strap and the capacitor should be replaced. Sometimes just moving the position of the strap will clear up the trouble, but there is usually enough leakage through the cardboard casing of the capacitor to prevent normal operation.

Instructions for Statement 66: In shunting the electrolytic capacitors with your test capacitor, you probably noticed a large arc between the capacitor lead and the 35W4 cathode as the uncharged capacitor charged. Ordinarily this does not cause trouble, but in some receivers sufficient current may be drawn from the rectifier to burn out the rectifier filament. This is particularly true in some of the older three-way portable receivers.

To avoid the surge of current into the uncharged capacitor, you can precharge the capacitor before connecting it across the input of the filter. To demonstrate this, turn the set on, and let it warm up. The 20 μf capacitor should still be connected to B-. Therefore, short the leads of your test capacitor, and then connect it to the cathode of the rectifier.

Now discharge the test capacitor, and connect it from B- to the screen of the output tube. You will see an arc as the capacitor charges, but the 1k filter resistor limits the charging current to a safe value. Now, without discharging the capacitor, shift its positive lead from the screen of the 50C5 to the cathode of the rectifier and note the arc. You now have sufficient information to answer the statement. Remove the capacitor from the circuit.

Statement No. 66: I found that if the capacitor connected across the input filter has previously been charged, the current flowing into the capacitor when contact is made to the rectifier cathode is:

(1) more than
[✓ *(2) less than*]
(3) about the same as

when an uncharged capacitor is used.

EXPERIMENT 67

Purpose: To show common causes of oscillation and how to locate them.

Introductory Discussion: Oscillation can be due to defective parts, to misplaced wiring, or to poorly soldered connections. If a part is defective, the trouble is usually easy to find.

Oscillation is the result of energy being fed back from the output of a stage to its input. This is called single-stage oscillation because only one stage in the receiver is involved. Overall oscillation occurs when the feedback path involves two or more stages. For example, from the plate of the 50C5 to the input of the 12AT6.

Oscillation can occur in either the af section or in the rf section. If turning the volume control down stops the oscillation, look for trouble in the af system. If tuning the receiver affects the oscillation, look for trouble in the rf section.

Oscillation does not always follow a fixed pattern. The defect that causes oscillation in one set may cause only regeneration or have no apparent effect in another. Regeneration is feedback in insufficient quantity to cause the receiver to squeal. Oscillation may result in a squeal, or it may cause motorboating. The position of the leads, the gain of the particular tubes used, and the Q of the tuned circuits determine the exact effects. These cannot always be predicted.

If your particular receiver is exceptionally stable, you may not get the results described. If not, go on to the next step, but remember the description of the effects so you will recognize them when you are doing servicing.

Experimental Procedure: To conduct the following steps, besides the receiver and your tvom, you will need:

- 1 0.25 μf or 0.27 μf capacitor
- 1 20 μf, 150-volt capacitor
- 1 120-ohm resistor
- 1 100k-ohm resistor
- 1 3k-ohm resistor

Step 1: To show that an open plate bypass capacitor for the power output tube and misplaced wiring may result in overall oscillation.

First, check your receiver to be sure it is operating normally. Now disconnect C8 from terminal DB1. Tune to a station, and turn the volume control up. If you hear a rushing, high-pitched squeal, the 50C5 has gone into oscillation. However, there may be no effect, especially if the grid and plate leads are well separated and are kept close to the chassis.

To give the effect of misplaced wiring, cut a piece of hookup wire about 9 inches long, and remove some of the insulation from one end of the wire only. Solder this lead to plate socket terminal 7 of the 50C5 tube. Bend the wire around until the insulation is against the grid lead of the 12AT6.

Now turn on the set again, and advance the volume control setting. You should hear a very loud squeal at a certain volume level. This indicates that energy is being fed back from the plate circuit of the 50C5 to the grid circuit of the 12AT6, resulting in overall oscillation. While the receiver is squealing, push the case of C8 so that the lead you disconnected is in good electrical contact with terminal DB1. This should stop or, at least, reduce the oscillation.

When replacing output transformers, be sure to keep the leads short and down close to the chassis. This will prevent radiation from the plate lead which might induce signal voltages in the input of the output tube or in the input of the first audio tube.

Turn the set off, unsolder the piece of hookup wire from the plate of the 50C5, and solder C8 firmly in place. Now try out the receiver to make sure that it is still operating normally.

Step 2: To show that the screen grid shields the plate from the control grid.

In this step you will install an unbypassed resistor in the screen supply of the i-f tube. In most ac-dc receivers the screen connects directly to B+, but in TV sets and in ac-operated receivers there is usually a resistor used to reduce the screen voltage, and a bypass capacitor between the screen and the chassis. If the bypass capacitor opens, oscillation will occur.

To demonstrate this, unsolder the three leads going to pin 6 of the 12BA6. Twist the three bare leads together and connect a 3k-ohm resistor between pin 6 of the 12BA6 tube socket and the junction of the three leads. Position these parts so nothing shorts out. Now turn on the receiver, and try tuning in stations. You will hear squeals as stations are tuned in. A signal voltage is developed across the screen supply resistor, and because of the capacity between the screen grid and the control grid, feedback takes place within the tube.

While the receiver is oscillating, touch one lead of a 0.27 μf capacitor to a B- point, and the other lead directly to the screen of the 12BA6 tube. Note that the oscillation stops. This is the method used by technicians to check suspected capacitors.

Now permit the receiver to oscillate, and bring your hand near the oscillator coil. Note that, as your hand approaches this coil, the pitch of the oscillation changes because you are changing the oscillator frequency by changing the capacity in the oscillator circuit. Exactly the same effect is produced by adjusting the tuning capacitor knob of the set. Many technicians are fooled by this effect; they assume that there is a defect in the oscillator circuit, when the trouble is really elsewhere in the receiver.

Step 3: To show that under some conditions a high power factor in the output filter capacitor results in overall oscillation.

Turn the set off, and remove the 3k-ohm resistor. Solder the three leads back to pin 6 of the 12BA6. Possibly you may be unable to get the three wires back through the hole in pin 6. In that case simply "tack" solder the three leads to pin 6. If the solder is allowed to flow smoothly over the joint, a good mechanical connection will result. Now try out the receiver to be sure that it is operating normally.

In the preceding experiment, you demonstrated that high power factor in the output filter capacitor produced hum. However, a small increase in power factor will not have any appreciable effect on the hum level. To demonstrate this, disconnect the positive lead of the output filter capacitor, C11B, from terminal DB3 and connect a 120-ohm resistor in series with this lead.

Turn the set on. If you notice any increase in hum, it will be very slight. However, there is another effect that would be noticeable if it were not for the 0.1 μf rf bypass capacitor. To demonstrate this, turn the set off, and disconnect this capacitor from the screen grid, pin 6, of the 50C5. Turn the set back on, turn up the volume, and tune over the dial. You will probably hear squeals and howls wherever a station should be received, because the electrolytic capacitor will not bypass rf signals, and signal voltage is built up in the B supply and is fed from one stage to another, resulting in oscillation.

To prove that the trouble is in the electrolytic, shunt your test electrolytic, the 20 μf capacitor, from DB3 to B- with the proper polarity. If you have trouble holding the leads in contact with the proper points in the circuit, turn the set off, solder the capacitor in place, and then turn the set back on to recheck it. You should get normal operation.

Now disconnect the test electrolytic, and let the receiver oscillate. Move the lead of the 0.1 μf rf plate bypass capacitor so that it is again in contact with the screen of the 50C5. As soon as you make contact, the oscillation will stop.

As an electrolytic capacitor ages, its ability to serve as an rf bypass decreases, and oscillation takes place. A paper bypass capacitor, even one as small as 0.01 μf, is used in parallel with the electrolytic output filter capacitor in well designed receivers to prevent this trouble. The set may play for months or years before the power factor in the electrolytic increases to the point where hum becomes a problem.

Remove the 120-ohm resistor from the circuit, and resolder the positive lead of the output filter capacitor to terminal DB3, and the 0.1 μf bypass to the screen of the 50C5 tube. Try out the set to be sure it is working normally.

Step 4: To show that single-stage rf oscillation can be due to misplaced wiring.

Solder a short length of wire to the control grid, pin 1 of the 12BA6. Gently push the wire down near the blue i-f transformer lead connecting to the plate of the 12BA6. Turn the set on, and after it warms up, try tuning in stations. You will find violent oscillation. If you do not get this oscillation, try moving the lead around and bring it even closer to the plate lead of the 12BA6. Do not, however, permit the end of the wire to come in contact with any parts or with the chassis.

The squeal may not be as loud as some of those you have formerly noticed, because the tremendous avc voltage being developed practically blocks all signals from the mixer. Check on this avc voltage by connecting the ground clip of the tvom to Pl of the volume control and touching the probe to the hot side of the volume control P3. The Function switch should be set to measure a negative dc voltage. You will measure from 3 to 15 volts across the volume control. Notice that this voltage does not vary as you tune the receiver throughout the tuning range. This avc voltage is being applied to the control grid of the mixer and also to the 12BA6 tube.

In a receiver, of course, you would not look for a piece of stray hookup wire hanging on the control grid of an i-f amplifier. However, the same effect would be produced if either of the i-f transformers had been replaced and the leads had not been cut to the proper lengths and kept close to the chassis. Therefore, when replacing i-f transformers, remember to keep the wiring neat and as much like the original as possible.

When you are satisfied that you have made the necessary observations in this experiment, turn the set off, and leave the lead connected to the control grid of the 12BA6. You will use it in the statement at the end of this experiment.

Discussion: In ac-dc receivers, oscillation can be caused by open bypass capacitors, defective output filter capacitors, and misplaced wiring.

In some cases, misalignment results in oscillation. Frequently, if a receiver is dead because of a defective oscillator, an inexperienced person may start adjusting the i-f transformers. He may turn them out far enough so that the i-f amplifier is actually tuned to a station at the low-frequency end of the broadcast band. Then the tuned circuit in the plate circuit of the mixer may be sufficiently near the tuned circuit in the grid circuit to permit feedback at the same frequency, resulting in oscillation. Therefore, in servicing a receiver, do not adjust the i-f transformers unless you have a good reason to.

In some receivers, oscillation will not occur when an i-f amplifier is peaked exactly. A slight detuning, however, may cause oscillation, because when one winding of an i-f transformer is detuned, the secondary winding absorbs less power from the primary, and the primary impedance rises. The voltage across the primary also rises, and stray coupling in the circuit may permit enough feedback into the grid circuit to cause oscillation.

Single-stage rf-if oscillation can often be controlled by increasing the bias. In your receiver, the cathode bias resistor for the i-f tube is 150 ohms. If there were uncontrollable oscillation, which could not otherwise be stopped, you could install a larger value resistor. Sometimes a resistor value will have to be as high as 300 or 400 ohms.

In your receiver, you have grounded the center shield on the rf-if tube sockets. If the ground (B-) connection were left off, feedback could occur between the plate and control grid, resulting in oscillation. This is a point you should watch in servicing receivers. The center shields in these stages should be grounded.

In servicing a set for oscillation, you should carefully examine the top of the chassis to see if all the tube shields are in place. Leaving off a tube shield frequently results in oscillation. The tubes requiring shields can be easily identified; their bases will have metal rings into which the shields should go.

Octal-base tubes were used in older ac-dc sets, and in many ac sets. These tubes may be either glass or metal. If oscillation is the complaint, try metal tubes in the rf-if stages. If you do this, ground pin 1, unless it is used as a tie point for other purposes. The No. 1 pins connect to the metal shell, which acts as a shield around the tube.

In older receivers using a three-gang tuning capacitor, check the wiper contacts used to ground the rotors to the capacitor frame. A dirty contact or a high resistance at this point will result in feedback between the sections, and oscillation in the rf stage. You will rarely find this difficulty in ac-dc sets, because practically no ac-dc receivers use a tuned rf stage.

Instructions for Statement 67: For this statement you will learn another method frequently used to eliminate oscillation. Turn your set on, and with your finger, move the short lead connected to the 12BA6 control grid away from the plate to the point where oscillation starts. In other words, if you move the lead farther, there will be no oscillation. With the receiver oscillating, turn off the set.

We will now proceed to lower the Q of the resonant circuit feeding the control grid of the 12BA6 and note the effect on the oscillation. Solder one end of your 100k-ohm resistor to the the control grid of the tube, and the other end to the avc line at terminal KB3. Do this without disturbing the position of the free lead connected to the control grid of the 12BA6. Now turn on the set, and try tuning in stations over the dial. You should now be able to answer the statement. Remove the 100k-ohm resistor and the short piece of wire from the circuit.

Statement No. 67: With the first i-f transformer secondary loaded by a 100k-ohm resistor, I found that the oscillation:

(1) increased.
[✓ *(2) decreased.*]
(3) remained the same.

EXPERIMENT 68

Purpose: To show that distortion can be caused by a leaky coupling capacitor in an RC coupled amplifier stage, and if so, there will be a dc voltage drop across the grid resistor of the following stage.

Introductory Discussion: Up to the final audio stage, we are primarily interested in obtaining as high a voltage gain as possible without undesirable feedback, oscillation, or distortion. In the final stage, however, we must develop sufficient power to drive the loudspeaker. This is done by using power pentodes or beam power output tubes. Typical examples are the 3V4, 3S4, and 3Q5 tubes used in older battery sets, the 6BQ5, 6BK5, 6V6, and 6AQ5 tubes used in ac-operated sets using a power transformer, and the type 50C5, 35C5, and 50L6 tubes used in ac-dc sets.

All type 50C5 beam power amplifier tubes have rather high harmonic distortion when operated in single-ended (one tube) output stages at high audio output levels. To keep the distortion to a minimum, it is common to operate these tubes as class A amplifiers. This means that the bias for such a tube must be sufficient to keep it operating on the straight part of its Eg-Ip characteristic curve, and the input signal must be limited so that it will never drive the grid positive, and thus produce a grid current flow.

RC coupling is generally used between the plate of the voltage amplifier stage and the grid of the power output stage. The coupling capacitor is likely to have high voltage peaks applied to it. Thus, in some receivers, the capacitor is likely to become quite hot. It is not uncommon, therefore, for it to become leaky, or to break down completely after being in service for some time. When this happens, the plate voltage, which is positive with respect to ground, is applied to the control grid of the following stage, causing a large grid current to flow. If the grid current flow is allowed to continue for any great length of time, it will permanently damage the tube. The effect of such a breakdown on the operation will be severe distortion, because the stage is no longer operating as a class A amplifier. In this experiment you will demonstrate the effects of leakage in the coupling capacitor.

Experimental Procedure: Here you need the receiver and your tvom, plus:

1 1 meg resistor

Step 1: To simulate leakage in the coupling capacitor.

Solder one lead of the 1 meg resistor to the control grid, pin 2, of the 50C5 tube socket, and arrange the other lead so that it can be pushed into contact with plate pin 7 of the 12AT6 socket.

Step 2: To demonstrate the effects of a leaky coupling capacitor.

Turn on the set, tune in a station (preferably one presenting a musical program), set the volume at a fairly high level, and then push the 1 meg resistor into contact with plate pin 7 of the 12AT6 socket. Use the eraser end of a pencil, or a small wooden stick for this. The reproduction should be weak and distorted.

Tune to other stations, and repeat the foregoing procedure. Distortion should be produced in all instances.

To avoid damaging the 50C5 power output tube, release the 1 meg resistor from contact with plate pin 7 as soon as you have noted the effect of the simulated leakage.

Step 3: Measure the dc voltage across the 470k-ohm grid resistor R8, first with coupling capacitor C7 normal, then with leakage simulated.

Prepare your tvom for dc voltage measurements, and turn on the set. Tune in any local station, and adjust the volume to a comfortable level. Now see if you can measure a dc voltage across the 470k-ohm grid resistor. Enter the value for each test in Fig. 68-1. If you get no reading, write 0 in the space.

Without turning off the set or changing the position of the Function switch, set the Range switch at 12V, and push the free lead of the 1 meg resistor into contact with plate pin 7 of the 12AT6 tube socket. There should now be an appreciable dc voltage indicated by your meter. Enter the value you get in Fig. 68-1. Turn off the set, and disconnect the tvom. Also unsolder the 1 meg resistor from pin 2 of the 50C5 socket.

CONDITION OF C7	READING
NORMAL	0
LEAKY	12V

Fig. 68-1. Record your readings for Exp. 68 here.

Discussion: Since the 50C5 power output stage of your receiver is supposed to operate as a class A amplifier, you should get no voltage for either of the measurements when no leakage is simulated in the coupling capacitor C7. A -dc voltage reading could occur only if the tube were drawing grid current, which would happen only if there were no bias. However, you may get a small positive reading because there may be a slight amount of gas in the 50C5. If this is true, the voltage will remain when you disconnect C7.

When you simulate leakage by connecting the 1 meg resistor across C7, you should get an appreciable voltage. The leakage resistance you are using, together with grid resistor R8, constitutes a voltage divider for which the plate voltage of the first audio stage acts as a source. This voltage divides across the leakage resistance of the coupling capacitor and the grid resistor according to their values, and with such polarity that the grid of the output tube is now positive. This causes a flow of grid current and a tremendous increase in the plate current, and severe distortion takes place in the output.

Whenever you have a case of severe distortion in general service work, check for a positive dc voltage across the grid resistor of the power output tube. If there is voltage, and the set uses a power transformer for the filament supply, pull out the power output tube and again check for voltage across the grid resistor. If there is none now, the output tube is gassy and should be replaced. However, if the voltage does not disappear when the output tube is removed, the coupling capacitor is leaky, and should be replaced.

In ac-dc sets, the tube filaments are in series, so you cannot pull out the output tube. Here, you must disconnect the coupling capacitor and repeat your measurement. If the voltage disappears with the capacitor disconnected, you know the capacitor is leaky; otherwise, the tube is gassy.

Another defect you will find in your work as a technician is an open grid resistor in the first audio stage. You will simulate this defect in order to answer the statement for this experiment.

Instructions for Statement 68: It is not uncommon to find the grid resistor of the 12AT6 tube either open or increased greatly in value. You will determine the behavior of the receiver with an open grid resistor in the first audio stage.

Tune in a station and adjust the volume to a comfortable level. Unplug the receiver and unsolder the lead of the 10 meg resistor connected to pin 1 of the 12AT6. Leave the set turned off for about five minutes to allow the tubes to cool off. Then turn the set on and observe the sound as you turn the volume control up and down. Continue listening to the sound for about five minutes then answer the statement below and on your Report Sheet.

Statement No. 68: I found that, with an open resistor in the grid of the 12AT6, the audio output at first distorted:

(1) at low volume
[✓ *(2) at high volume*]
(3) at all volume

control settings and, after a short time, the sound

[✓ *(1) improved.*]
(2) disappeared.
(3) faded to a very low level.

Reconnect the lead of the 10 meg resistor to pin 1 of the 12AT6 and check to make sure the receiver is operating properly.

EXPERIMENT 69

Purpose: To show that noise can be localized by a stage-blocking technique, even though blocking is so incomplete that some noise can still be heard.

Introductory Discussion: The circuit disturbance test that you demonstrated in a previous experiment is based on the fact that any sudden irregular current change will produce a noise in the loudspeaker. In a circuit disturbance test, these current changes are deliberately produced for the purpose of localizing the source of trouble when a receiver is dead.

There are many things that will create the sudden current changes that produce noise in the output of a receiver. These may be within the set itself, such as poor contact in a volume control or a partial or intermittent open in an rf or af transformer, or external to the set, such as arcing electric motor brushes and defective neon signs. In this experiment, you will deal only with noise that originates within the set itself.

After creating a source of noise, you will demonstrate the stage-blocking technique in which you will make each stage in turn inoperative, and note if the noise is still present in the output. In an ac-operated set, this can be done by pulling out the tubes one by one. Since you cannot pull out the tubes in ac-dc receivers, technicians generally short-circuit the input and output of each stage in turn. This is the method you will follow in this experiment.

Experimental Procedure: For this experiment you will need:

1 20 μf electrolytic capacitor

Step 1: To create an intermittent open in the plate circuit of the 12BE6 converter stage.

Unsolder the blue i-f transformer lead from pin 5 of the 12BE6 tube socket. Remove all solder from the hole in this pin, and any excess solder that may be on the end of the blue wire.

Now, push the blue lead back into the hole, and if possible, place it so that striking the chassis or table forcibly with your hand will produce an intermittent contact between the plate lead and the pin. Turn on the set and try this effect. If you find it difficult to get the correct adjustment of this lead, the noise pulses can be produced by striking the loose lead with the eraser end of a pencil.

Step 2: To block the input to the mixer-oscillator stage.

Solder the negative lead of the 20 μf capacitor to the ground terminal in the center of the 12BA6 socket. Turn on the receiver, set the volume control for a high output, create noise pulses by striking the chassis or by moving the loose plate lead, and note that noise is plainly audible in the loudspeaker. Touch the positive lead of your blocking capacitor to pin 7 of the 12BE6 tube to block the input to the mixer oscillator stage. Continue creating noise pulses and note they are still plainly audible in the output. It is not necessary for the receiver to be tuned to a station for these tests.

Step 3: To block the input of the 12BA6 i-f amplifier stage.

Move the positive lead of your blocking capacitor to pin 1 of the 12BA6 and create the noise pulses. Note that although the noise is still audible, it is not nearly so loud.

Step 4: To block the output of the i-f amplifier stage.

Move the positive lead of the blocking capacitor to pin 5 of the 12BA6. Create the noise, and again note that although it is still audible, it is not nearly as loud.

Remove the stage block long enough to tune in a station. Then restore the block at pin 5, and again create the noise pulses. Although the incoming program is blocked, the noise pulses should still be audible in the speaker. This proves that the noise pulses are not getting into the output along the usual signal paths.

Now restore the receiver to normal operation. Securely solder the loose plate lead to pin 5 of the 12BE6 tube socket.

Discussion: As you found in Step 2, a stage block between the input of the set and the source of the noise will have no effect on the strength of the noise pulses in the output, because the normal signal path from the noise source to the loudspeaker is unobstructed.

However, the reason that the noise is still audible when the signal path is blocked anywhere between the noise source and the output is not so apparent. To understand this, you must remember that the noise is caused by a sudden current change. In this experiment, it is the plate current of the 12BE6 mixer-oscillator stage that is changing and producing the noise in the output. Since this changes the loading on the power supply unit, small changes occur in the plate and screen currents of other stages. This again produces noise; but since these changes are very small compared to the change that produces them, these noise pulses are comparatively weak.

You must also consider the fact that every time the contact at the plate pin of the tube socket is made and broken, a small electric arc is formed. This arc produces a pulse of rf energy, which can be picked up by unblocked rf stages by direct radiation from the arc, or the rf energy may travel along the intercircuit wiring to unblocked stages.

You may begin your stage-blocking procedure at either the input or the output of the set. In either case, the defective stage is indicated by a change in the noise level as you move the block along. Thus, in the experiment, you started at the input and worked toward the output. Noise was heard at the original loudness level until the defective stage was passed, then the noise level was much weaker. If you had started at the output stage and worked toward the input, the noise pulses would have been weak until you passed over the defect, then the noise pulses would have become much stronger.

Instructions for Statement 69: For your report on this experiment, you will simulate noise originating in the audio section of the set, block the following stage, and determine whether or not the results are the same as those observed in carrying out the experiment. Proceed as follows:

Solder a short piece of hookup wire to pin 7 of the 12AT6. Position the wire so you may easily touch it to terminal DB3. Turn on the set and make and break the contact between DB3 and the hookup wire. This should produce noise in the output.

Try a block ahead of the trouble by touching the positive lead of the blocking capacitor to pin 1 of the 12AT6. Again make and break the contact between pin 7 and terminal DB3 and note the effect on the noise.

Now block the output of the 50C5 by touching the positive lead of the blocking capacitor to pin 7 of the 50C5. If the capacitor leads do not reach this far conveniently, resolder the negative lead to a more convenient ground connection such as terminal DB1. Turn on the set and again create noise pulses. Note the effects, then answer the statement below and on the Report Sheet.

Restore the receiver to normal operation by removing the short wire and the blocking capacitor.

Statement No. 69: When I blocked the output stage, noise pulses, which were created by opening and closing the plate circuit of the first audio stage:

(1) could still be heard
[✓ *(2) could not be heard*]

from the loudspeaker.

EXPERIMENT 70

Purpose: To show alignment problems; and to show how alignment can affect tracking.

Introductory Discussion: The i-f, rf, and mixer stages of the superheterodyne receiver are aligned to produce maximum signal strength at the second detector output for each station tuned in, so that the dial pointer indicates the frequencies of the various stations accurately.

Misalignment can have several effects. The local oscillator frequency may not be separated from the frequency of the rf tuned circuit by the i-f frequency over the entire tuning range, although stations will come in at about the right dial settings. In this case we say that the oscillator and preselector do not track. Another effect of misalignment might be that the oscillator and preselector track, but the dial readings are not correct at the lower frequencies.

To carry out this experiment successfully, you must be able to receive strong stations at both ends of the dial. You should have a station you can easily identify that operates between 1400 kHz and 1600 kHz, and one that operates between 550 kHz and 900 kHz. Preferably the station frequency should fall on a marked division of the dial, especially at the high-frequency end. At NRI we used stations at 1500 kHz and 630 kHz.

If you do not receive such stations in your locality, do only the first part of Step 1 and the Statement. Do not detune the i-f's.

Your results will depend on the ease with which you can spot stations on the dial, the condition of your receiver to start with, and the care with which you follow the instructions.

You will find it much easier to tune in the stations accurately if you use the rim of the tuning knob rather than the smaller center knob. In this way, you can tune in stations more easily.

A properly aligned i-f amplifier is the heart of the superheterodyne receiver. If the i-f amplifier is properly aligned, the oscillator and preselector trimmers can easily be adjusted using known broadcast station signals.

Experimental Procedure: You need only your receiver and the tvom.

To guarantee consistent results, it is important to set the antenna winding on the ferrite rod exactly in the center of the rod. Later, you may find you can peak up the low end of the band by slightly repositioning the winding.

Step 1: To check the tracking of the oscillator, preselector, and dial.

You have already made preliminary adjustments of the oscillator and preselector trimmers. You will now check the alignment of your receiver at the high end of the band.

Tune to a station at the high end of the band and make sure the dial setting is correct for this station. If the receiver has been jarred or banged while performing the experiments, the oscillator adjustment may be slightly off and the high frequency station may be at the wrong dial setting. If it is, turn the dial to the correct setting and adjust the oscillator trimmer CT2 to bring in the station. CT2 is the trimmer farthest from the front panel. Now adjust the preselector trimmer, CT1, for maximum volume.

With the receiver still tuned to the high frequency station, carefully adjust the i-f slugs for maximum volume beginning with T2. Make these adjustments very carefully since the slugs will need only very slight adjustment. Do the same thing with the adjustments on T1.

You will adjust your i-f transformers with the alignment tool provided. So that you can easily observe how far you have turned the tool, attach a piece of tape to the center of the alignment tool as shown in Fig. 70-1. The end nearest the tape "flag" is the end to use for all transformer adjustments. It is possible to adjust both the top and bottom slugs of the transformer from either the top or bottom hole. However, to avoid confusion, you should make all of your adjustments from the end closest to the

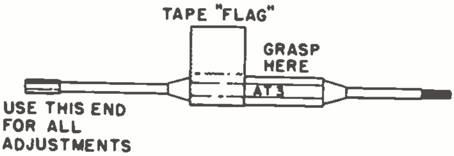

Fig. 70-1. Attaching a tape "flag" to the alignment tool.

slug that you are adjusting. Make sure that you insert the tip of the alignment tool into the transformer only far enough to reach the first slug.

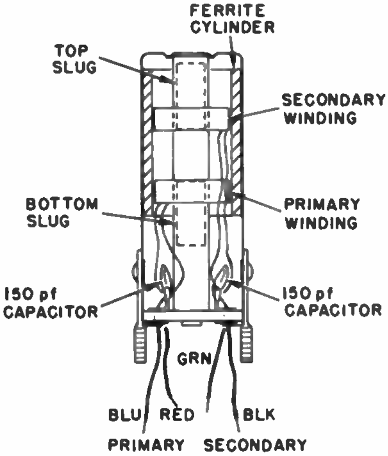

Fig. 70-2. Internal construction of the i-f transformers.

As you can see from Fig. 70-2, there is one powdered iron slug associated with each of the transformer coils. When you look at the transformer from the top, turning the top slug counterclockwise will move it toward the top of the transformer, and since the slug is moving away from the coil, the inductance of the coil will be decreased, so the resonant frequency will increase. Looking at the transformer from the bottom, turning the bottom slug counterclockwise will move it toward the bottom of the transformer, which will reduce the inductance of the bottom coil, and therefore raise the resonant frequency of that part of the transformer.

Next, detune the i-f's approximately 10 kHz by turning each of the i-f slugs one-eighth of a turn in a counterclockwise direction. This will raise the i-f about 10 kHz.

Instead of relying on your ear to indicate maximum volume while aligning the receiver, you will use your tvom to measure the avc voltage developed in the receiver. Clip the ground lead of your tvom to P1 of the volume control and the probe to P3. Set the meter to read -dc volts on the 3V range.

With the receiver still tuned to the highest frequency station and while watching the meter, adjust the rf trimmer CT1 on the front section of the tuning capacitor gang for maximum avc. Tune the receiver over the dial, noting how the avc reading increases as you tune to each moderately strong station. Weak stations will produce little avc.

Tune to the low-frequency end of the dial, and check the preselector and oscillator tracking by turning the dial knob to bring in a station for greatest avc. Do not touch the oscillator trimmer. Try adjusting the rf trimmer CT1 to see if the avc can be increased. If the receiver is tracking properly, no change, or less than half a turn of the trimmer should be necessary to pass through a maximum on the meter.

You will find that you have to tighten the rf trimmer almost all the way to get maximum avc and maximum volume. Leave the rf trimmer set for maximum volume, and tune back to the high-frequency station. Note how little avc is now produced. Readjust the rf trimmer for maximum avc. Naturally, something must be done, because the customer cannot readjust the rf trimmer each time he tunes in a new station.

Step 2: To show that poor tracking of the oscillator, preselector, and dial can be

due to incorrect alignment of the i-f amplifier.

You should have noticed that although the high-frequency station comes in at the correct dial setting, the low-frequency station comes in at a somewhat higher dial setting than called for by its operating frequency. The condition is not serious and would probably go unnoticed unless your attention were called to it. The receiver is not tracking its dial as well as it might, because the i-f amplifier is tuned to approximately 456 kHz, but the i-f frequency that should be used with the oscillator coil and dial is about 446 kHz.

Normally a serviceman would read the i-f value on the manufacturer's diagram and would realign the i-f amplifier to the specified frequency using a signal generator. If you have a signal generator, you can use it to check the i-f alignment after completing Experiment 70.

Now tune to the low-frequency station, and set the dial slightly below the point where maximum avc is received, but where the station can still be heard. Adjust the first i-f transformer, T1, and then the second i-f transformer, T2, for maximum avc. The slugs will have to be turned only a very small amount so make the adjustment carefully.

Again set the dial pointer toward the low-frequency end at a point where you can still hear the station. Readjust the first and second i-f transformer slugs for maximum avc. Repeat this procedure once more (three adjustments in all), remembering to reset the dial to a lower frequency and to adjust the first i-f transformer and then the second i-f transformer.

This procedure should lower the frequency of the i-f amplifier about 10 kHz, and the low-frequency station should be coming in at very nearly its right dial setting, or perhaps a little lower.

Now tune to the correct dial setting for the high-frequency station, and adjust the oscillator and rf trimmers, CT2 and CT1, for maximum avc. You may find that the trimmers do not need to be readjusted. Tune to the low-frequency station, and check the tracking by adjusting the rf trimmer. If it is already peaked and no further (not more than half a turn) adjustment is needed, the oscillator and preselector are tracking each other and the dial. If you still have to screw the trimmer rather tight, the i-f is still too high, and the procedure of lowering the i-f should be done once more. Don't go too far or the i-f will be too low. If you experience any difficulty in making these adjustments or if you do not get the proper tracking as described, return the i-f trimmers to the settings used in the beginning of this experiment.

Discussion: You probably wonder why readjustment of the i-f amplifier frequency three times changes the i-f by 10 kHz. The receiver has a band width of slightly less than 10 kHz; you can tune away from a desired station about 3-1/3 kHz, and still receive its signal. If you shift the frequency 3-1/3 kHz three times, and readjust the i-f each time, there will be an overall change of approximately 10 kHz in the i-f amplifier frequency.

Exact tracking between the rf and oscillator is possible, but is seldom achieved in commercial receivers. Usually some slight readjustment of the rf trimmer can be made to improve the tracking at a given frequency. If the necessary readjustment is small, the change in volume cannot be noticed by the ear.

Some manufacturers compromise on the adjustment by setting the oscillator at the highest dial marking, for example 1600 kHz, and adjusting the rf trimmer at 1400 kHz so that the tracking is equally good at the high and low ends of the dial.

Remember that in a well designed receiver using specially cut plates in the oscillator section of the tuning capacitor, poor tracking is an almost sure sign of incorrect i-f alignment. If you have to screw the rf trimmer in at the low-frequency end, the i-f is too high; if you have to loosen the rf trimmer at the low-frequency end, the i-f is too low. To lower the i-f, tune below a station, and readjust the i-f slugs. To raise the i-f, tune the receiver above a station, and readjust the i-f slugs. In both cases the job is easier if you use a station at the low-frequency end of the dial. A signal generator set to the particular value recommended by the manufacturer can be used to adjust the i-f, or you can use the methods outlined in this experiment.

Many different i-f values have been used in commercial receivers. Frequencies of 130 kHz, 175 kHz, 262 kHz, 455 kHz, 456 kHz, and 470 kHz have been commonly used in broadcast receivers. Other values can, of course, be used; for example, we used 446 kHz for this receiver.

Instructions for Statement 70: Strip 1/4" of insulation from both leads at one end of a 3" length of twisted wire. Make sure the insulated ends are not touching one another by slightly separating the two leads. You will use this length of twisted wire as a small capacitor of about 5 pf to slightly detune the rf input and the two i-f transformers.

Turn on the receiver and tune in a station at the low end of the band (550 kHz to 700 kHz). Clip the ground lead of your tvom to terminal P1 on the volume control and the probe to P3. Set the tvom to read -dc volts and note the avc voltage.

Turn off the receiver and solder one lead of the twisted pair to the center post of the 12BE6 tube. Solder the other lead to pin 7 of the same tube. Turn on the receiver and adjust the tuning knob for maximum avc voltage. Note the value of voltage. 6 → 8

Turn off the receiver and disconnect the leads from pin 7 and the center post of the 12BE6. Reconnect the leads to pins 5 and 6 of the 12BE6. Now the capacitor is across the primary of the input i-f transformer. Turn on the receiver and adjust the tuning knob for maximum avc voltage. Note the value of voltage. 6 → 7

Turn off the receiver and disconnect the leads from pins 5 and 6. Reconnect the leads to pin 6 and the center post of the 12AT6 tube. The capacitor is now across the secondary of the output i-f transformer. Turn on the receiver and adjust the tuning knob for maximum avc voltage. Note the voltage. You now have enough information to answer the statement. Turn off the receiver and disconnect the two leads from the 12AT6 tube. ~~6 →~~ 3 → 5

Answer the statement below and on your Report Sheet.

Statement No. 70: I found the sensitivity of the receiver, as indicated by the avc voltage, was decreased most by detuning of the

[✓ *(1) first i-f transformer.*]
(2) second i-f transformer.
(3) preselector.

ALIGNING THE I-F WITH A SIGNAL GENERATOR

Here are some instructions on aligning the i-f amplifier section of the receiver, using a signal generator. If the rf signal from the generator is modulated by an audio signal, you can make your alignment adjustments by ear, adjusting the various slugs for maximum sound output. You can also use your tvom, connected across the volume control, to indicate when the transformers are peaked for maximum voltage output. Using a tvom will usually give better results; but if the input level is kept to a low value, your ear is quite sensitive to changes in volume.

The signal generator can be coupled to the receiver by connecting it between terminals C2 and C3 of the loop antenna. This will cause energy to flow through the second winding of the loop, and will induce the signal in the loop antenna. For i-f alignment, the receiver should be tuned to the low-frequency end of the dial, at a point where a squeal or a station is not received. If you cannot find such a point, you can stop the local oscillator by holding a screwdriver blade between the tuning capacitor plates to short it out. Adjust the i-f slugs to give maximum output at the setting of the signal generator. The signal generator should, of course, be tuned to the recommended i-f value (in this case, 446 kHz).

If a receiver has been badly misaligned, it is sometimes impossible to feed enough energy into the loop to get a reading on the output meter or to hear the signal. In this case, align the i-f transformers one at a time. Clip the ground lead of the signal generator to B- (clipping it to the chassis may result in hum modulation), and touch the hot lead of the signal generator to the control grid of the i-f tube. Adjust the second i-f transformer for maximum output.

You can then move the hot probe of the signal generator to the mixer grid of the detector-oscillator tube, and adjust the first i-f slugs. The exact order in which the slugs are adjusted is of no particular importance.

Clip the antenna and ground leads of the signal generator to the antenna and ground leads of the loop. The signal generator and the receiver should both be tuned to some setting at the high-frequency end of the dial such as 1600 kHz. If you do not receive a signal, adjust the oscillator trimmer for maximum signal. Next, tune the signal generator and receiver to a lower frequency, such as 1400 kHz, and adjust the rf trimmer for maximum output. Now tune to a station at the low-frequency end of the dial and see if adjustment of the rf trimmer improves the volume. If there is no noticeable improvement, the receiver is tracking properly.

CONCLUSION

This concludes the experiments in this kit. Check over your Report Sheet to see that you have answered all the Statements, and that your answers are just as you want them. Then send it to us for grading.

INSTALLING THE RECEIVER IN THE CHASSIS

Remove the power cord from both the receiver and the ac outlet. Slip one of the power cord clamps on the interlock connector as shown in Fig. 25. . . . . ( )

Fig. 25. Placement of first cord clamp on interlock.

Run the ac plug from the inside of the cabinet through the rectangular cutout marked "interlock." . . . . ( )

Draw the interlock portion of the cord into the cutout and push the second power cord clamp between the body of the interlock connector and the outside of the cabinet, as shown at "1" in Fig. 26. . . . . ( )

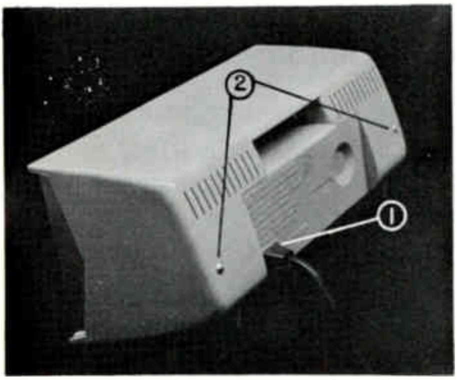

Fig. 26. Mounting the receiver in its cabinet.

With the cabinet right side up, position the chassis and panel so the chassis rests on the guide strips on either side of the cabinet. . . . . ( )

Slowly slide the chassis into the cabinet. Position the interlock connector so the interlock plug on the chassis will go into the female connector in the back of the cabinet. . . . . ( )

To make certain the interlock is correctly seated, plug in the receiver and turn it on. The receiver should operate. ( )

If it does not operate, pull the chassis forward and reseat the interlock connector. . . . . ( )

Place the two 4-1/4" screws through the two holes in the rear of the cabinet, as shown at "2" in Fig. 26. Tighten securely. . . . . ( )

The handsome 5-tube ac-dc superheterodyne receiver that you assembled in this kit is well worth keeping. You can use it on your servicing bench as a test set or use it in your home.

HELP YOUR MEMORY

Experience is a great teacher, providing you have a good memory! An unusual defect may take hours to locate the first time you meet it – but the next time, you should be able to spot the difficulty quickly. However, that "next time" may not occur for several months; by then you may have forgotten what you did.

You can aid your memory by keeping notes. Every time you meet an unusual trouble, write up a careful and complete description of its symptoms and your isolation procedure.

Also, draw schematics of any changes you may make in wiring. Even simple changes will make the circuit different from its original diagram and may give you puzzling test results at some later date, unless you are aware of the change.

After collecting this information, you'll never use it unless it is placed conveniently near your workbench. It is best to arrange your notes and sketches by make and model number in a file. In time, you will have a valuable assortment of service information – such as only YOU can collect!

DC CIRCUIT CALCULATIONS

One of the very first things that is explained to anyone learning electronics is Ohm's Law. You will remember that this is the basic law covering the relations of voltage, current, and resistance in electrical circuits. In addition to being one of the most basic of the fundamentals of electronics, it is also one of the most important rules or laws. You will find that no matter how far you go in the study of industrial electronics, radio communications, or electronics engineering, this law which states that "the current flowing in a circuit is equal to the applied voltage divided by the resistance" will be used and applied over and over again.

At the same time that you learned about Ohm's Law, you also learned that it could be expressed much more simply by using the symbols for current, voltage, and resistance in the formula: I = E ÷ R. This is the mathematical expression of the law using symbols instead of words and is called a formula. Most of the rules or laws of electronics, or of any other science for that matter, are expressed with formulas for two reasons. One reason is that these simple mathematical expressions of the laws are much easier to memorize. The other reason is that they automatically provide a workable relationship of the laws for use in calculations. Thus, once you have learned the formulas, you not only have learned the rules, but you also have them expressed properly for use in circuit calculations.

One of the best things about formulas is that they can be arranged to find a particular quantity that we want to know. For example, the formula for Ohm's Law, I = E ÷ R, is used when we know the voltage and resistance and want to find the current in a circuit. We also learned that another way of saying the same thing is to state that E = I × R. We usually simplify this expression still further by dropping the × sign and writing the formula simply $E = IR$. This way of expressing the basic formula is used when we know the current and resistance and want to find the voltage.

By still another arrangement, we can state the formula so we can easily find the resistance by saying $R = E \div I$. We use the formula in this form when we know the voltage and current in the circuit and want to find the resistance. All three of these statements of Ohm's Law say exactly the same thing. They are simply arranged in different ways for convenience in making circuit calculations.

If you do not already know the three forms of Ohm's Law, stop right now and memorize them. You will save yourself a great deal of time in the long run, and in addition, knowing these formulas and understanding the way in which voltage, current, and resistance in a circuit are related will help you to understand electronic circuits. The three forms of Ohm's Law are:

$$I = E \div R$$
$$E = IR$$
$$R = E \div I$$

Actually the three forms of Ohm's Law are really only one formula with the letters manipulated around the equals sign. We are able to change these formulas around to suit our purposes by applying some very basic rules of mathematics. In electronics, we must learn quite a few formulas to perform certain calculations so that we can understand how the circuits work and what may be wrong with them. Of course, the formulas can be arranged depending on what we want to find out and what we already know. Obviously, if we have to learn not only all the formulas but all the different forms of the formulas as well, we would have to do a lot of memorizing.

This would be impractical because we can easily learn a few of the basic laws of mathematics and then change the formulas to suit our own purposes. By doing this, we need to learn only one form of each formula, plus the rules for changes. In this way, mathematics becomes a useful tool, both in studying, and working in the electronics field. You will learn how to rearrange formulas later, so that then all you will have to do is remember one form of Ohm's Law and you will be able to get the other two. Right now, however, to save time, be sure that you know all three forms.

These lessons in mathematics may be just review for you. However, don't skip over them lightly. They are just as important as any other lessons in your course. You must study them carefully and send in answers to the questions in the back of the book. The only difference between these mathematic lessons and your regular study lessons is the order in which you will do them. The math lessons should be studied immediately after the regular lesson text with the same number. For example, the first lesson should be studied after you finish lesson five.

We will break up our study of mathematics in this way for two reasons. The first and most important reason is that these math lessons are different from any you have ever seen. Most math textbooks teach general mathematics so that the learning can be applied to any subject. Here, we are primarily interested in mathematics from the standpoint of usefulness in electronics. In other words, we are interested in its application to a specific purpose. Therefore, we will take up the subjects in the order that you will need them and will use practical examples from the text that you have already studied. In this way you will be sure to learn the mathematics that you need, and you will also learn how to use it in practical examples.

The other reason that we break it up into several books spaced among the technical lessons is that we don't want to take you away from your technical progress long enough to study the math lessons all at once. By spacing the math lessons, you will be able to keep up with your technical lessons too. In this first lesson, we will do a number of problems in electronics which involve only addition, subtraction, multiplication and division. We will then start a detailed review of arithmetic starting with fractions and decimals. Examples and problems include circuit applications to help you learn how to make calculations in dc circuits. It may seem rather simple, however, you should read it all to be sure you remember it. Also, we have put in a few short cuts which you probably did learn in school and presented some of the material in a special way to help you later in your more advanced studies.

If mathematics has always bothered you before, don't be discouraged by the fact that you have to study it now. We present it very simply, and having a practical use for it makes it easier to understand.

Simple Arithmetic Review

Before going ahead with fractions and decimals, we want to point out here that the basic arithmetic operations of addition, subtraction, multiplication and division are important in electronics as they are in every other science. We assume that you are able to perform these basic operations; if you cannot, stop and get a book on basic arithmetic from your library. If you know how to add, subtract, multiply and divide, but have become rusty because you have not had occasion to perform these basic arithmetic operations, take some time now to do a little practicing. You will be surprised how quickly you will be able to pick up speed again after a little practice.

ADDITION

You might think that you will not have much occasion to use such a basic arithmetic operation as addition. However, this is not the case. As an example, in a series circuit, where two resistances are connected in series, the total resistance is equal to the sum of the two resistors. This means that if you have two 100-ohm resistors in series, to get the total resistance you add the resistance of the two resistors, 100 + 100 = 200. If you have a 100-ohm resistor in series with a 25-ohm resistor, to find the total resistance you add 100 + 25 = 125. If you have a number of resistors connected in

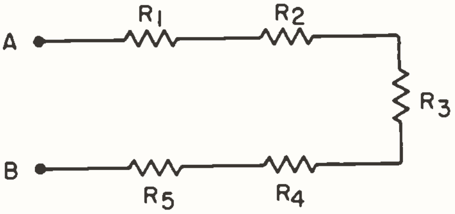

Fig. 1. A simple series circuit.

series, such as shown in the series circuit in Fig. 1, to get the total resistance between terminals A and B you add the resistance of the individual resistors. Suppose in this circuit that R1 = 100 ohms, R2 = 250 ohms, R3 = 150 ohms, R4 = 175 ohms, and R5 = 250 ohms. To find the total resistance between terminals A and B you write down the value of the individual resistors as shown and add.

$$\begin{array}{r}100\\250\\150\\175\\250\\\hline 925\end{array}$$

The preceding example is a simple example of addition in electronics to find the total resistance in a series circuit. Sometimes you have to be somewhat careful because the value of the resistors may vary quite widely and then it is important to get the digits arranged in the proper columns. In other words, you simply have to make sure that you arrange your work neatly so that the addition can be performed easily. As a second example, suppose the resistors have the following values: R = 5 ohms, R2 = 75 ohms, R3 = 6 ohms, R4 = 125, R5 = 32 ohms. To add the resistance of these resistors to get the total resistance between terminals A and B you write the resistors down as shown below and add.

$$\begin{array}{r}5\\75\\6\\125\\32\\\hline 243\end{array}$$

SUBTRACTION

There are occasions when you will have to subtract. In Fig. 2 we have shown a series circuit where the total resistance of the circuit is 197 ohms. The value of four of the resistors is known, but the value of the fifth resistance is unknown.

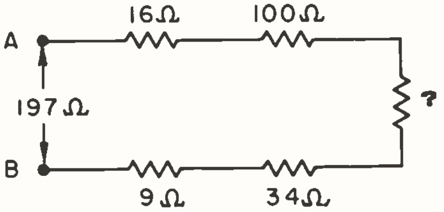

Fig. 2. A series circuit where one resistance is unknown.

You will remember that in a series circuit the total resistance is equal to the sum of the individual resistances. Therefore, the sum of the resistances must be 197 ohms. Since we know the value of four of the resistances we can find what their resistance is and then subtract this one value from 197 ohms to get the value of the unknown resistance.

To solve this problem we first write down the value of the known

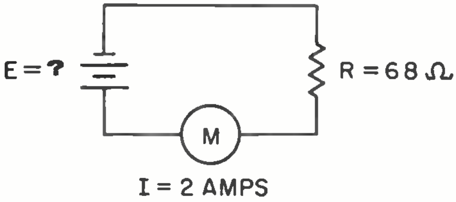

Fig. 3. An example where the formula E=IR is used to find the voltage.

resistors and add as shown:

$$\begin{array}{r}16\\100\\34\\9\\\hline 159\end{array}$$

Thus the total resistance of the four known resistors is 159 ohms. Since the total resistance is 197 ohms we can find the resistance of the unknown resistor by subtracting 159 from 197. We set the problem down as shown below and subtract:

$$\begin{array}{r}197\\-159\\\hline 38\end{array}$$

MULTIPLICATION AND DIVISION

Simple multiplication and division are also important in electronics. The various forms of Ohm's Law that you memorized demonstrate the importance of being able to multiply and divide.

An example of the use of the formula E = IR is shown in Fig. 3. In this circuit we know that the resistance is 68 ohms and the current flowing in the circuit is 2 amps and we want to find the value of the applied voltage. Using the formula E = IR in substituting 2 amps for I and 68 ohms for R we get:

$$\begin{aligned}E &= IR\\E &= 2 \times 68\\E &= 136 \text{ volts}\end{aligned}$$

In case you wonder why we used this particular form of Ohm's Law, the answer is that this is the form which is used to find the voltage, which is the unknown, when we know the value of the current and resistance, which are the known values. We have the unknown on one side of the equals sign and the two known values on the other side of the equals sign.

In the circuit shown in Fig. 4 we know the value of the voltage and resistance and want to find the current. Therefore, we will use a form of Ohm's Law which places the unknown on one side of the equals sign and the known values on the other side. This means that I must be on one side of the equals sign, and E and R on the other side. Thus, we use the formula I = E ÷ R. Substituting 32 volts for E and 16 ohms for R, we can get the value of the current:

$$\begin{aligned}I &= E \div R\\I &= 32 \div 16\\I &= 2 \text{ amps}\end{aligned}$$

Fig. 5 is an example in which we use the remaining form of Ohm's Law, R = E ÷ I. Again, in this case we have R, which is the unknown

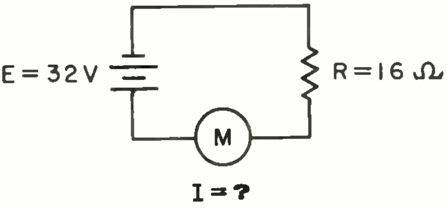

Fig. 4. An example of the formula I=E÷R used to find the current.

value, on one side of the equals sign, and the two known values E and I on the other side. Substituting 26 volts for E, and 2 amps for I we get:

$$R = E \div I$$
$$R = 26 \div 2$$
$$R = 13 \text{ ohms}$$

Notice that in each of the three preceding examples, not only did we carry out the mathematical operations to get a numerical answer, but we also gave the answer in its correct units. For example, in the first case, in the circuit shown in Fig. 3, where we wanted to find the value of the applied voltage, we gave the answer in volts. In the second case, where we had to find the current we gave the answer in amps. In the third case, where we had to find the resistance, we gave the answer in ohms. Remember this, it is important. You should always indicate the units of your answer. If you simply give a numerical answer, it has no meaning. If you are looking for the voltage in the circuit, the answer should be given in volts or some fraction or multiple of a volt. If you are looking for the current in a circuit then the answer should be given in amps or again in some fraction or a multiple of an ampere. Similarly, if you are looking for the resistance in a circuit, then the answer should be given in ohms or some fraction or multiple of an ohm.

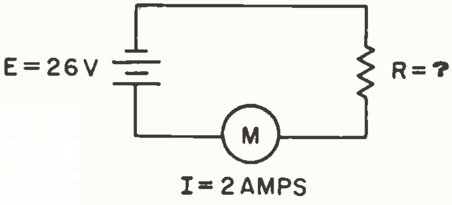

Fig. 5. An example of where the formula R = E ÷ I is used to find the resistance.

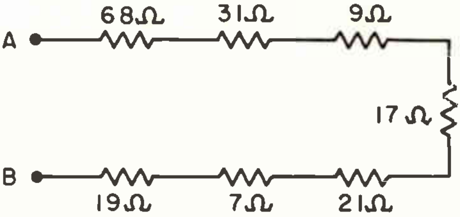

Fig. 6. Circuit for problem no. 1.

So far we have shown simple applications of addition, subtraction, multiplication and division in electronics. The examples were very simple, and in all probability you can handle problems of this type without any trouble. However, just to be sure, we have included ten practice problems which we have called, "Self-Test Questions." Even though you may think the problems are extremely simple, we urge you to do all ten to get practice finding the resistance in a circuit and in using Ohm's Law. A little practice now will help you become so familiar with these basic operations that when you have more complicated calculations to perform later, you will see that in many cases you're simply performing these simple operations several times.

You will find the answers to these questions at the back of the lesson along with a brief solution of each problem. Try to do each problem before you look at the answer so you will be working on your own. Be sure to check your answer and if you have made a mistake be sure to find out where the mistake is before going on.

SELF-TEST QUESTIONS

1. Find the total resistances between terminals A and B in the circuit shown in Fig. 6.

2. In the circuit shown in Fig. 7 the total resistance is 81 ohms. Find the resistance of the unknown resistor R.

RULES OF ORDER

So far we have done problems involving addition, subtraction, multiplication and division. These are all very basic mathematical operations which we will use over and over again in our study of electronics. In the preceding problems, we have been concerned with just one operation at a time. In actual practice we will find a need to do several, or perhaps all these operations in order to find an answer to these problems.

While it may not seem at first glance that there is anything special about this, most of the time there will be a definite order in which we should do them. For example, take a simple problem like "find the value of 10 × 5 + 2." Let us look at this problem closely.

If we do the multiplication first and then the addition, we get 10 × 5 = 50, then we add the 2 and find the answer 52. However, if we look at the problem and say 5 + 2 = 7 and then 7 × 10 we come up with an answer of 70. As you can see, there is quite a difference between our first answer of 52 and our second answer of 70. Thus, the order in which we do a problem is important.

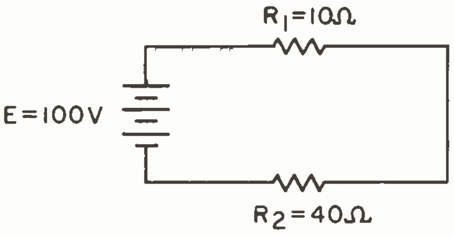

Fig. 16. Practical circuit where rules of order are important.

Let us take another more practical operation that we might find in our work in electronics. In the circuit shown in Fig. 16, we have a voltage supply of 100 volts and two resistors. One resistor is 10 ohms and the other is 40 ohms. Now the current in the circuit will be equal to this voltage divided by the resistance ($I = E \div R$). Let us take the problem mathematically and then substitute the values in the formula:

$$\begin{aligned} I &= E \div R \\ I &= 100 \div 10 + 40 \end{aligned}$$

Which operation do we do first? We know from our lessons on Ohm's Law that we are dealing with a total voltage of 100 volts. Therefore, we will be finding the total current, and to do this we will want to divide the total voltage by the total resistance. For this reason, we must add the two resistances first to get 10 + 40 = 50 ohms and then divide 100 by 50 to get a current of 2 amperes.

We did the problem this way because we know something about electronics; Ohm's Law states that total current equals total voltage divided by total resistance. We also know that the total resistance is equal to the sum of the resistances in the circuit. Therefore, in our problem, though we might not be aware of it, we actually thought this way:

$$\begin{aligned} I_T &= E_T \div R_T \\ R_T &= R_1 + R_2 \end{aligned}$$

so we kept the two resistances together.

If a person who did not know anything about electronics tried to work this problem he might not know the importance of keeping the two resistances together. Yet, one of the big advantages of using formulas in electronics is to express things simply so that problems can be easily worked out. Therefore, so that there will be no misunderstanding about the fact that R_1 and R_2 should be kept together, we enclose them in parentheses and write them as $(R_1 + R_2)$. Now the formula becomes:

$$I_T = E_T \div (R_1 + R_2)$$

Then we substituted to get:

$$\begin{aligned} & I_T = 100 \div (10 + 40) \\ \text{thus,}\ & I_T = 100 \div 50 \\ & \quad = 2 \text{ amps} \end{aligned}$$

If someone saw this problem without the parentheses, and he knew nothing about electronics, or math, other than addition and subtraction, multiplication and division, he might come up with a different answer. For example:

$$\begin{aligned} I &= E \div R \\ I &= 100 \div 10 + 40 \end{aligned}$$

Then, they might first divide 10 into 100 and get 10 so that for the current they would get

$$\begin{aligned} I &= 100 \div 10 + 40 = 10 + 40 \\ &= 50 \text{ amperes} \end{aligned}$$

From the preceding you can see the value of using parentheses, and also the need for establishing some rules in which the various arithmetic operations should be performed. These rules are called the rules of order and they insure that everyone everywhere will always know in what order to tackle a problem. The rules of order are very easy to learn and must always be followed. Always start at the left of a problem and work towards the right and do all the operations inside the parentheses first. Next, start at the left again and work towards the right and do all the multiplication and division in the order in which they occur. Then go back to the left of the problem again and once again work to the right doing the addition and subtraction.

By following these rules there is no possibility of coming up with the wrong answer or doing the wrong operations at the wrong time. A problem such as:

$$(6 + 3) \times 3 - 81 \div 9 + 4$$

can have only one answer. We start at the left and do the operations enclosed in the parentheses first. Since there is only one parenthesis, the first time, working from left to right, there is only one operation to perform: we add 6 + 3. Thus our problem becomes:

$$(6 + 3) \times 3 - 81 \div 9 + 4 =$$
$$9 \times 3 - 81 \div 9 + 4$$

Now we start at the left and go through from the left to the right again doing the multiplication and division in the order in which they occur. The first multiplication we hit is 9×3 and this is 27. The next operation we must perform is the division of 81 by 9; 9 goes into 81, 9 times. Since there are no other multiplications or divisions indicated these are the only operations we perform through this time. Thus we have:

$$9 \times 3 - 81 \div 9 + 4 = 27 - 9 + 4$$

Now we go through the problem again, working from the left to the right, doing the addition and subtraction.

$$27 - 9 = 18 \text{ and adding } 4$$

to this would give us 22. Thus we have

$$27 - 9 + 4 = 22$$

Sometimes all of the operations covered in the preceding example are not found in a problem. For example in the problem

$$8 \times 7 + 2 \times 4 - 16 \times 3$$

there are no parentheses and therefore we start right in going from left to right to do any multiplication or division that might be indicated. You will notice that in this problem there is no division so you simply go through doing the indicated multiplication. $8 \times 7 = 56$, $2 \times 4 = 8$ and $16 \times 3 = 48$; therefore, our problem becomes:

$$8 \times 7 + 2 \times 4 - 16 \times 3 =$$
$$56 + 8 - 48 = 16$$

The problem might have parentheses in it, but no multiplication or division. As long as the parentheses are there, you must perform the operations inside the parentheses. As an example, in the problem,

$$29 - (17 + 4) + 11$$

we must perform the operation 17 + 4 which is inside the parentheses first. Since $17 + 4 = 21$ our problem becomes:

$$29 - (17 + 4) + 11 = 29 - 21 + 11 = 19$$

Sometimes we need to do two or

more things in a special order. For this reason we also use brackets [ ] which are really a different kind of parentheses to indicate which comes first. Thus, we might have a problem:

$$5 \times 300 \div [2 \times (15+35)] + 20 - 5$$

Here we do the operations within the parenthesis, $(15 + 35) = 50$ first, and rewrite the bracket operation, replacing the $(15 + 35)$ with 50 to get

$$5 \times 300 \div [2 \times 50] + 20 - 5$$

then we do the operation inside the bracket to get:

$$2 \times 50 = 100$$

Now we rewrite the whole problem, placing everything inside the brackets with 100 and leaving the brackets out, thus, our problem becomes:

$$5 \times 300 \div 100 + 20 - 5$$

By following our rules of order, we start at the left and multiply 5×300 to get 1500, and then we divide this by 100 to get 15. Now we do our addition and subtraction: $15 + 20 - 5 = 35 - 5 = 30$ to find our final answer.

Since these rules of order are so important, let us state them again. First we do all the operations within the parentheses. Second, if we have one parenthesis within another, we do the operations inside the inner parenthesis first, and then do the operations within the outer parenthesis. When all the parenthetical operations are out of the way, we remove the parentheses, replacing the data within them with the answer we got. Then we rewrite our problem, starting at the left and working towards the right, doing all the multiplication and division in the order in which they occur. Then we return to the left and work to the right, doing the addition and subtraction in the order in which they occurred to get our answer.

You are going to run into problems in which you will have to perform the various operations in the correct order to get the correct answer. You will run into problems of this type in this lesson. Therefore, to get some practice doing the various operations in the right order, do the following five Self-Test Questions. You will find the answers in the back of the book.

SELF-TEST QUESTIONS

11. $25 + 16 \times 3 - 28 \div 7$
12. $5 \times (11 - 8) + 3 \times (7 - 5) \div 2$

Fractions

In the simple circuit shown in Fig. 17, we have 100 volts applied to a circuit containing a total resistance of 100 ohms. This means that we will have a current flowing through the circuit of 1 ampere and a voltage drop across the resistances equal to the applied voltage of 100 volts. However, in this circuit we do not have a single 100-ohm resistor. Instead, we have two 50-ohm resistors in series, which makes up the total resistance of 100 ohms. Therefore, our voltage drop of 100 volts does not occur as one voltage, it occurs as two voltage drops of 50 volts across each resistor. In a case like this, where we have two equal voltage drops of 50 volts that add up to a total voltage of 100 volts, we often say that each drop of 50 volts is equal to one half of the total voltage. Just what do we mean when we say that we have one half of something? First, we mean that the "something," in this case 100 volts, is split up into parts. Further, since we have only two parts and they are equal we mean that the whole 100 volts is split into two equal parts. Thus, when we say one half of one hundred, it is like saying one of two equal parts of one hundred, or, more simply we mean 100 ÷ 2

Likewise, in a circuit such as the one shown in Fig. 18, the total voltage drop of 90 volts is split up into three equal parts of 30 volts each. This is just the same as saying that the voltage is split into thirds and one drop of 30 volts is equal to one-third of the total or 90 ÷ 3.

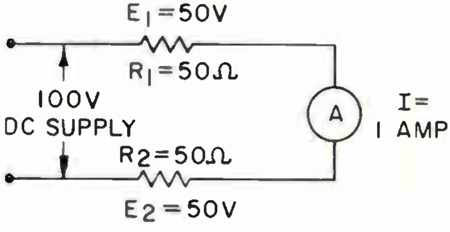

Fig. 17. One hundred volts divided into two equal parts or halves.

This can be written as $\frac{90}{3}$

100 ÷ 2 can be written as $\frac{100}{2}$

Whenever we split anything into parts we call the parts fractions. Thus, $\frac{100}{2}$ is a fraction and $\frac{90}{3}$ is also a fraction. Now these particular fractions can easily be worked out by performing the actual division so that $\frac{100}{2}$ is 100 ÷ 2, or 50; and $\frac{90}{3}$ is 90 ÷ 3, or 30. When they are worked out like this, 50 and 30 actually become whole numbers in themselves because they each represent an individual voltage drop. However, when we consider them as part of the total

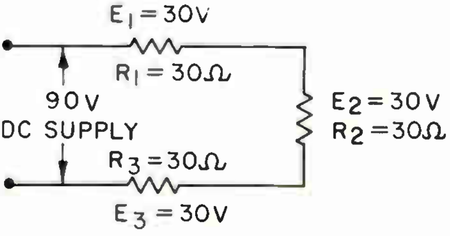

Fig. 18. Ninety volts divided equally into three parts or thirds.

voltage drop, they are both fractional parts of something and therefore they are also fractions.

When we want to represent 50 volts as some fraction of 100 volts, or 30 volts as a fraction of 90 volts, we would write them as $\frac{50}{100}$ or $\frac{30}{90}$, respectively. The fraction $\frac{50}{100}$ can be written more simply by dividing both the top of the fraction 50 and the bottom of the fraction 100 by the same number. For example, if we divide 100 by 50 we get 2 for an answer, and if we divide 50 by 50 we get an answer of 1. But placing the 1 in place of the 50 and the 2 in the place of the 100, our fraction becomes $\frac{1}{2}$, or one-half. Thus $\frac{50}{100}$ can be changed to $\frac{1}{2}$, or as we say, one-half, by dividing both the top and the bottom of the original fraction by 50. In the same way we can write $\frac{30}{90}$ or can simply divide both 30 and 90 by 30. This gives us $30 \div 30 = 1$ and $90 \div 30 = 3$. Then by replacing 30 with 1 and 90 with 3 we have the fraction $\frac{1}{3}$, which we pronounce "one-third." This fraction $\frac{1}{3}$ and the fraction $\frac{1}{2}$ which we found previously, are the simplest forms of the original fraction. We call this process of changing a fraction to its simplest form reducing the fraction.

Thus, in the circuit in Fig. 17 either one of the voltage drops can be considered several ways. They can be considered as one-half of a hundred which we write mathematically as $\frac{1}{2}$ of 100. They can be considered as $\frac{50}{100}$ which we can reduce to one-half or $\frac{1}{2}$ or they can be considered $\frac{100}{2}$ which is equal to 50. Now, these are all just different ways of saying the same thing. Likewise, any one of the voltage drops in the circuit in Fig. 18 can be expressed $\frac{1}{3}$ of 90, $\frac{30}{90}$ which equals $\frac{1}{3}$, or $\frac{90}{3}$ which equals 30.

We also have many other fractions. In fact, just as there is no limit to the largest number we can write by using combinations of digits from 0 to 9, there is no limit to the smallest part of something we can write by using the same digits. Just as $\frac{1}{2}$ means a whole something divided into two parts and $\frac{1}{3}$ means something divided into three parts, we can write $\frac{1}{6}$, which means the whole something is divided into six equal parts. We can continue in this way indefinitely. For example, $\frac{1}{64}$ means one of sixty four parts; $\frac{1}{128}$ means one of one hundred and twenty-eight equal parts and $\frac{1}{2465}$ means one of two thousand four hundred and sixty-five equal parts of something.

Notice, however, that a fraction by itself does not mean anything specific. For example, one half, one third, $\frac{1}{128}$, or $\frac{1}{2465}$ are fractions, but until we say what they are fractions of, we do not have any idea to what they are equal. One half of 50 volts is 25 volts, but as we have already seen one half of 100 volts is 50 volts. So a fraction to indicate anything definite must be accompanied by the whole something that we are talking about. Thus, we always say one-half of a gallon, or one-third of a quart, $\frac{1}{128}$ (pronounced one, one hundred twenty-eighth) of an ounce, one-fifth of the voltage, etc.

There are two parts to every fraction: there is the top part written above the line which is called the numerator, and there is the bottom part below the line called the denominator. The number in the numerator always tells us how many parts we have, and the number in the denominator tells us the size of the parts. Just as we can have one third of a gallon, it is also possible to have two $\frac{1}{3}$'s of a gallon which we would write $\frac{2}{3}$ of a gallon. The two indicates that we have two parts of a gallon and the three indicates that each part equals $\frac{1}{3}$ of a gallon.

There are also two kinds of fractions. One kind is called a proper fraction and always has a numerator that is smaller than the denominator, thus, $\frac{1}{3}$, $\frac{1}{2}$, $\frac{4}{7}$, and $\frac{5}{128}$ are all proper fractions because their numerator is smaller than the denominator. The other kind of fraction is called an improper fraction. An improper fraction is one in which the numerator is larger than the denominator, such as $\frac{100}{50}$, $\frac{100}{2}$, $\frac{755}{4}$, etc.

Improper fractions can always be converted into whole numbers or whole numbers and proper fractions. For example, the improper fraction $\frac{100}{50}$ becomes 2 if we perform the division and divide 50 into 100. The improper fraction $\frac{100}{2}$ becomes 50 if we divide 2 into 100. In the improper fraction $\frac{755}{4}$, when we divide 4 into 755, it will not go an even number of times. It will go one hundred and eighty-eight times with a remainder of 3. This means that in the improper fraction $\frac{755}{4}$ there are one hundred and eighty-eight whole parts and three $\frac{1}{4}$ parts. Thus we can write the improper fraction $\frac{755}{4}$

as $188\frac{3}{4}$

Both proper and improper fractions can be added, subtracted, multiplied and divided just like any whole numbers. After all, it is possible to have several halves of something, or several fifths of something which we might want to add or subtract from each other. The basic operations with fractions are much the same as with whole numbers, but there are certain rules that we must follow. In this section of the lesson we will learn the rules and see how to apply them.

ADDITION OF FRACTIONS

In adding fractions, we must remember one of the basic rules of any addition problem. Only like things can be added together. For example, we can add six oranges and four oranges and say we had ten oranges. Similarly, we can add twenty apples and nine apples and say we had twenty-nine apples. However, we could not add six apples and eight oranges and say we had fourteen oranges or fourteen apples. If we want to call the oranges and apples pieces of fruit then we could add the six and eight and say we had fourteen pieces of fruit because here we equated them to a common name. Similarly, we can add any number of volts to any other number of volts and get a total number of volts. We can add ohms to ohms and amperes to amperes, but we cannot add ohms to amperes or volts. The same rule applies to fractions except that we have an additional item of similarity to consider.

The denominators of fractions must be alike if we are going to add them. For example, one half a gallon can be added to another one half of a gallon to get a whole gallon. One third of a gallon can be added to another one third of a gallon to get two thirds of a gallon. Thus, fractions of like things with like denominators can be added together very simply by adding their numerators. Thus:

$$\frac{1}{2} + \frac{1}{2} = \frac{1 + 1}{2} = \frac{2}{2} = 1$$

$$\frac{2}{3} + \frac{1}{3} = \frac{2 + 1}{3} = \frac{3}{3} = 1$$

$$\frac{1}{3} + \frac{1}{3} = \frac{1 + 1}{3} = \frac{2}{3}$$

$$\frac{1}{5} + \frac{3}{5} = \frac{4}{5}$$

$$\frac{12}{64} + \frac{13}{64} = \frac{12 + 13}{64} = \frac{25}{64}$$

$$\frac{55}{137} + \frac{67}{137} = \frac{55 + 67}{137} = \frac{122}{137}$$

Now we have just seen that all fractions with like denominators can be added together simply by adding their numerators. However, fractions with unlike denominators cannot be added so simply. Before we can add fractions with unlike denominators, we must arrange them in a way that their denominators are all alike. This is called finding the lowest common denominator.

The Common Denominator.

When we first started our discussion of fractions, we discovered that we could "reduce" a fraction such as $\frac{50}{100}$ to a fraction $\frac{1}{2}$ by dividing both the numerator and the denominator by the same number. In this case, the number was 50 because with both the numerator and denominator of $\frac{50}{100}$ divided by 50, we get $\frac{1}{2}$. When we did this, we realized that either $\frac{50}{100}$ or $\frac{1}{2}$ meant exactly the same thing. Since either of these two ways of writing the fraction is correct, the two fractions must be equal. Thus, by dividing the numerator and the denominator by the same number, we have not changed the value of the number.

If this is true, we must also be able to multiply the numerator and denominator of a fraction by the same number without changing its value. 50 times both the numerator and denominator of $\frac{1}{2}$ is $50 \times 1 = 50$ and $50 \times 2 = 100$, or $\frac{50}{100}$. From this we can see that we can either multiply or divide the numerator and the denominator of a fraction by the same number without changing the value of the fraction. Accordingly, a fraction such as $\frac{1}{2}$ might be written in any one of several ways as follows:

$$\frac{1}{2} \times \frac{2}{2} = \frac{2}{4}, \frac{2}{4} \times \frac{2}{2} = \frac{4}{8}$$

$$\frac{1}{2} \times \frac{3}{3} = \frac{3}{6}, \frac{4}{8} \times \frac{4}{4} = \frac{16}{32}$$

$$\frac{16}{32} \times \frac{100}{100} = \frac{1600}{3200}$$

All these fractions are exactly equal to $\frac{1}{2}$ because they can all be reduced to $\frac{1}{2}$.

Likewise, we can change a fraction such as $\frac{1}{3}$ to any of the following fractions:

$$\frac{1}{3} \times \frac{3}{3} = \frac{3}{9}, \frac{1}{3} \times \frac{2}{2} = \frac{2}{6},$$

$$\frac{2}{6} \times \frac{5}{5} = \frac{10}{30}, \text{ etc.}$$

Let's see how this will help us in adding fractions. Suppose we want to add $\frac{1}{2} + \frac{1}{3}$. Since their denominators are not alike, we know that we can't add them as they are. However, suppose we change $\frac{1}{2}$ to $\frac{3}{6}$ which we can do by multiplying both the numerator and denominator by 3. Then, if we also change $\frac{1}{3}$ to $\frac{2}{6}$ which we can do by multiplying both numerator and denominator by 2, we now have two fractions which have the same denominator. They are $\frac{3}{6}$ and $\frac{2}{6}$ and they can be added together in the usual way to get $\frac{3+2}{6}$ or $\frac{5}{6}$. We have changed $\frac{1}{2}$ and $\frac{1}{3}$ to fractions with the same denominator so that they can be added without changing the values of the fractions themselves. $\frac{3}{6}$ is exactly the same as $\frac{1}{2}$ and $\frac{2}{6}$ is exactly the same as $\frac{1}{3}$. Added together they make $\frac{5}{6}$ or five-sixths.

When two fractions have the same denominator, we say they have a common denominator. When we change two or more fractions to equal fractions having the same common denominator so that we can add them, we call it finding the common denominator. Let's try a few more examples. For example:

$$\frac{1}{5} + \frac{1}{3} + \frac{4}{5} =$$

This is a very simple problem and we can readily see that both 5 and 3 will go into 15. As a matter of fact, 15 is the lowest common denominator of 5 and 3. 5 goes into 15 three times and therefore we change $\frac{1}{5}$ to a fraction and with 15 as the denominator we must multiply both the top and bottom by 3. Thus $\frac{1}{5}$ becomes $\frac{3}{15}$.

Similarly, 3 goes into 15 five times and therefore to change $\frac{1}{3}$ into a fraction with 15 as the denominator, we must multiply both the top of the fraction by 5 and the problem becomes $\frac{5}{15}$. To change $\frac{4}{5}$ into a fraction with 15 as the denominator, we again multiply the numerator and the denominator by 3 and therefore $\frac{4}{5}$ will become $\frac{12}{15}$. Thus our problem becomes:

$$\frac{1}{5} + \frac{1}{3} + \frac{4}{5} =$$

$$\frac{3 + 5 + 12}{15} =$$

$$\frac{20}{15}$$

While $\frac{20}{15}$ is the correct sum of the three fractions, it is not the usual custom to leave a fraction in the form of an improper fraction. We normally simplify the fraction. 15 goes into 20 once with a remainder of 5. Therefore,

$$\frac{20}{15} = 1\frac{5}{15}$$

Thus, we can say our answer is $1\frac{5}{15}$ However, $\frac{5}{15}$ can be simplified by dividing both the numerator and denominator by 5 and this would give us $\frac{1}{3}$. Therefore our sum is $1\frac{1}{3}$

If we look back at the original problem we can see that this is the answer we should expect. Notice that the first fraction we have is $\frac{1}{5}$ and the third one is $\frac{4}{5}$

$\frac{4}{5} + \frac{1}{5} = \frac{5}{5}$ which is equal to 1. Now we add $\frac{1}{3}$ to 1 and the answer is $1\frac{1}{3}$

In this problem it is quite obvious that the lowest common denominator of 5 and 3 is 15. However, suppose that instead of using 15 as the common denominator we had used 30. Both 5 and 3 will go into 30. This will not cause any difficulty; we will get exactly the same answer, but we will be working with bigger numbers because we did not use the lowest possible common denominator. Using 30 as the common denominator the problem becomes:

$$\frac{1}{5} + \frac{1}{3} + \frac{4}{5} =$$

$$\frac{6 + 10 + 24}{30} =$$

$$\frac{40}{30} =$$

$$1\frac{10}{30} =$$

$$1\frac{1}{3}$$

Similarly, if we had used 45 as a common denominator, once again we would get the same answer, but we would have to work with larger numbers. In this case the problem is,

$$\frac{1}{5} + \frac{1}{3} + \frac{4}{5} =$$

$$\frac{9 + 15 + 36}{45} =$$

$$\frac{60}{45} = 1\frac{15}{45} = 1\frac{1}{3}$$

In the preceding example it was easy to find the lowest common denominator. We were dealing with fifths and thirds and we got the lowest common denominator simply by multiplying 5 and 3 together. However, we cannot always do this and get the lowest common denominator. Suppose, for example, that you had the problem:

$$\frac{1}{6} + \frac{2}{9}$$

If we simply multiply the two denominators together we will get 6 × 9 = 54. Therefore, 54 is a common denominator. Now our problem is:

$$\frac{1}{6} + \frac{2}{9} =$$

$$\frac{9 + 12}{54} =$$

$$\frac{21}{54} = \frac{7}{18}$$

When we get the answer $\frac{21}{54}$ we immediately could see that 3 could be divided into both the numerator and the denominator and therefore we could reduce the fraction to $\frac{7}{18}$. Often when you get a fraction that can be reduced it is a sign that you did not use the lowest common denominator. However, as long as you reduce the fraction and perform your addition correctly, you will come out with the same answer as you would have if you had used the lowest common denominator. When you can find the lowest common denominator, it is best to use it, because you will be working with smaller numbers and there will be less chance of making a mistake.

There is an easy way to find the lowest common denominator. To do this take the denominators of the various fractions and factor them. Now you might wonder what a factor is. A factor is a number that when multiplied by another number gives you the original number. For example, 1 × 6 = 6. Therefore, 1 and 6 are factors of 6. Also 3 × 2 = 6 and therefore 3 and 2 are factors of 6. We call 3 and 2 prime factors because they themselves cannot be broken down into factors other than the number and one. In other words, you could say that 2 was equal to 2 × 1, but there is no other way you could factor it. The factor 2 still appears in 2 × 1; therefore, 3 and 2 are prime factors. When we factored 6 into 6 × 1 we did not factor it into prime factors because the 6 could be broken down into 3 and 2. Therefore, we break our denominators down into prime factors. The prime factors of 6 are 3 × 2 and the prime factors of 9 are 3 × 3. Now to find the lowest common denominator we look for common factors in the two denominators. We see immediately that we have a 3 in each denominator and therefore we write down 3 as one of the factors in our lowest common denominator and then place a stroke through the 3 in 3 ×2 and one 3 in 3 × 3. This leaves us two unused prime factors: the 2 from the factoring of 6 and one of the 3's from factoring 9. Since these are not common, but are different numbers, we must write both of these down beside the first three we set up in determining our lowest common denominator. Therefore, our lowest common denominator will be 3 × 2 × 3 = 18. Now if we add $\frac{1}{6} + \frac{2}{9}$ using 18 as the common denominator we have:

$$\frac{1}{6} + \frac{2}{9} =$$

$$\frac{3 + 4}{18} =$$

$$\frac{7}{18}$$

Now let's try another example. Let us do the problem,

$$\frac{3}{7} + \frac{5}{14} + \frac{8}{21}$$

We can find a common denominator in this problem by multiplying 7 × 14 × 21. However, you can see immediately if we do this we are going to have a rather large number as our common denominator. There is no point in getting involved in such big numbers because we see at a glance that 7, 14 and 21 are all divisible by 7. Therefore, it is worthwhile to factor the three denominators into prime factors to see if we can find the lowest common denominator. When we factor them we get:

$$\begin{aligned} 7 &= 7 \times 1 \\ 14 &= 7 \times 2 \\ 21 &= 7 \times 3 \end{aligned}$$

Now to get our lowest common denominator we first look for prime factors that are common to all three denominators. We notice first that 7 is a prime factor of all three so the first digit in our common denominator will be 7. Now we mark out the three 7's to be sure that we see they have been used. This leaves us with 1 in the first number, 2 in the next and 3 in the third. Therefore our complete lowest common denominator will be 7 × 1 × 2 × 3. This is equal to 42 and therefore 42 is the lowest common denominator. Now the problem becomes:

$$\frac{3}{7} + \frac{5}{14} + \frac{8}{21} =$$

$$\frac{18 + 15 + 16}{42} =$$

$$\frac{49}{42} = 1\frac{7}{42} = 1\frac{1}{6}$$

Let us do one more example. Add the following:

$$\frac{5}{18} + \frac{7}{27} + \frac{8}{45}$$

Again, we see immediately that if we find a common denominator by multiplying the three denominators together we will have a very large denominator. Therefore it is worthwhile to factor the denominator to see if we can find a smaller common denominator. 18 is equal to 9 × 2, but 9 is not a prime factor because it in turn can be factored into 3 × 3. Therefore, the prime factors of 18 are 3 × 3 × 2. Similarly, 27 and 45 can be factored into prime factors so that we will get:

$$\begin{aligned} 18 &= 3 \times 3 \times 2 \\ 27 &= 3 \times 3 \times 3 \\ 45 &= 3 \times 3 \times 5 \end{aligned}$$

Now to get our lowest common denominator we first look for factors that are common to the three numbers. We see that the first digit in each factor, which is 3, is common to all three so we put down the 3 as the first factor in our common denominator and then mark out the first 3 in each of the factors to indicate that this 3 has been used. The second digit is also a 3 so we use a second 3 in our lowest common denominator to give us 3 × 3 and we mark out the second 3 in each of the three numbers. Now this leaves us 2, 3, 5 and since these are not common in any of the three numbers we must include them in our lowest common denominator. Thus the lowest common denominator becomes 3 × 3 × 2 × 3 × 5. Multiplying these together we get 270 as the lowest common denominator. 18 goes into 270, 15 times. 27 goes into 270, 10 times and 45 goes into it 6 times. Therefore, our problem becomes:

$$\frac{5}{18} + \frac{7}{27} + \frac{8}{45} =$$

$$\frac{75 + 70 + 48}{270} =$$

$$\frac{193}{270}$$

So far, in finding common factors in the denominators in order to find the lowest common denominator, we have had a common factor in each of the denominators. However, this will not always be the case. Sometimes the common factor may appear in only two of the denominators. For example, in the problem,

$$\frac{1}{3} + \frac{1}{14} + \frac{1}{21}$$

we will have two different common factors which appear in only two of the denominators. Factoring the denominators we get:

$$\begin{aligned} 3 &= 3 \times 1 \\ 14 &= 2 \times 7 \\ 21 &= 3 \times 7 \end{aligned}$$

Now we start looking for common factors. Looking at the first number factored, we see that 3 is one of the factors so we place a stroke through it to indicate that we have used it. Looking at the second number we see that there is no 3 in its factors, but we see a 3 in the factors of the third number so we place a stroke through it indicating that it has been used and then put down 3 as the first number in the product which will eventually give us our lowest common denominator. Now looking at the first number again we see that the only factor left is 1, so we skip it and go on to the second number. Here we see that the factors are 2 and 7 and we take the first number which is a 2 and place a stroke through it. Now we write a × sign next to the 3 we have in the common denominator and place the 2 to the right of the × sign. This gives us 3 × 2 as the first two numbers in the common denominator. Since there is no 2 in the third group of factors we start over again. Looking at the second number we see that we still have a 7 left so we place a ×7 as the next factor in our common denominator and place a stroke through the 7 to indicate it has been used. Moving on to the third group of factors we see that we also have a 7 so we place a stroke through it to indicate that it has been used. Now the factors we have for our lowest common denominator are 3 × 2 × 7 and if we multiply these out we get 42 which is the lowest common denominator.

From the preceding we can see that some of the factors that go to make up our lowest common denominator might not appear in all of the numbers factored. However, when a common factor appears in two or three of the denominators that have been factored there is no point in placing it in the product that is going to make up our lowest common denominator more than once unless it appears in one of the factors more than once.

Another situation that you should be on the lookout for is a problem in which one of the denominators is a factor of the denominator in one of the other factors. When you run into this situation you can completely forget about the smaller denominator. For example, in the problem,

$$\frac{1}{3} + \frac{1}{7} + \frac{1}{14}$$

we see that 7 is a factor of 14. Therefore any number that 14 will divide into, 7 will divide into also. Therefore, we can simply forget about the 7 and find the lowest common denominator for 3 and 14.

You should also be on the lookout for a fraction which may not be reduced to its simplest form. For example, in the addition,

$$\frac{1}{5} + \frac{1}{4} + \frac{6}{8}$$

we could go ahead and find a common denominator. The lowest common denominator in this case is 40. However, $\frac{6}{8}$ can be reduced to $\frac{3}{4}$ by dividing the top and bottom of the fraction by 2. If we do this our problem becomes:

$$\frac{1}{5} + \frac{1}{4} + \frac{3}{4}$$

Now we see that our lowest common denominator is 20. In this problem it would not make a great deal of difference if we used 20 or 40 as a common denominator in performing the addition so long as we reduced the fraction to the simplest form after the addition; in some problems the lower figure could make the addition a great deal simpler.

Now to get practice adding fractions do the following problems. Be sure to work each problem carefully before looking at the answers at the back of the book. If by any chance you find that you have made a mistake in one of the additions, be sure to check your work over carefully comparing it with our solution to see where you made your mistake.

SUBTRACTION OF FRACTIONS

Subtracting fractions is just the reverse of adding fractions. All the rules that apply to the addition of fractions apply to subtraction. First, the fractions must be parts of like things and they must have the same denominator in order to subtract them. If they do not have a common denominator, we must find the lowest common denominator for them. We do this in exactly the same way as we did for addition.

When we are subtracting one fraction from another, we subtract only the numerators and when we have finished our subtraction, we always reduce the answer as much as possible. For example:

$$\frac{5}{6} - \frac{1}{6} = \frac{5 - 1}{6} = \frac{4}{6} = \frac{2}{3}$$

To subtract $\frac{1}{3}$ from $\frac{1}{2}$, we must find the lowest common denominator which is 6. Thus the subtraction becomes:

$$\frac{1}{2} - \frac{1}{3} = \frac{3 - 2}{6} = \frac{1}{6}$$

As you can see, the procedure is essentially the same as adding fractions, however, in this case we subtract the numerators instead of adding them.

Just as in problems involving addition of fractions where we had more than two fractions to add, sometimes we have several subtractions to perform. You proceed in essentially the same way. For example, in the problem,

$$\frac{11}{12} - \frac{1}{4} - \frac{1}{3}$$

we first find the lowest common denominator, which in this case is 12. Then we perform first one subtraction and then the other. If we wanted to do so we could add the numerators of the two fractions to be subtracted and then perform a single subtraction. The problem will be worked out as follows:

$$\frac{11}{12} - \frac{1}{4} - \frac{1}{3} =$$

$$\frac{11 - 3 - 4}{12}$$

Now we can subtract 3 from 11 which would give us 8 and 4 from 8 which gives a remainder of 4 and an answer of $\frac{4}{12}$ which we reduce to $\frac{1}{3}$. The other method would be to first add the 3 and 4 together to get 7 and then subtract the 7 from 11 which again gives us $\frac{4}{12}$. We get the same answer in either case so you can do the problem whichever way you want. The usual procedure is to start at the left and go from left to right and perform one subtraction after the other.

There is no way to really learn how to subtract fractions other than by doing problems involving subtraction of fractions. Therefore, you should do the following problems. Do each problem carefully before looking at the answers in the back of the book. Once again, if you should fail to get the same answers we got, be sure to check your work to find out where the mistake is.

MIXED NUMBERS

Often you will have to add and subtract mixed numbers. You will remember that a mixed number is a number made up of a whole number and a fraction. For example, add,

$$1\frac{2}{3} + 2\frac{1}{6}$$

There are two ways you can do this problem. One method is to add the whole numbers first and then add the fractions and then add the sum of the fractions and the sum of the whole numbers together. The other method is to convert each mixed number to an improper fraction and then go ahead and perform the addition and then convert the answer back to a mixed number. Usually the easiest way to do this type of problem is to add the whole numbers and the fractions separately. However, we will go through both methods here. Using the first method first, that is of adding the whole numbers and fractions separately we get:

$$1\frac{2}{3} + 2\frac{1}{6} =$$

$$1 + 2 + \frac{2}{3} + \frac{1}{6} =$$

$$3 + \frac{4 + 1}{6} =$$

$$3 + \frac{5}{6} = 3\frac{5}{6}$$

As you can see, in using this method we simply add the whole numbers and then add the fractions, following the same procedure as we used before, that of finding the lowest common denominator and then adding.

When we convert the numbers to improper fractions we sometimes have to deal with slightly larger numbers, but this method works out equally as well. For example,

$1\frac{2}{3}$ can be converted to $\frac{5}{3}$

1 is $\frac{3}{3}$ and $\frac{3}{3} + \frac{2}{3} = \frac{5}{3}$

$2\frac{1}{6}$ can be converted to $\frac{13}{6}$

Now our problem becomes

$$\frac{5}{3} + \frac{13}{6}$$

And using the lowest common denominator of 6 we get:

$$\frac{10 + 13}{6} = \frac{23}{6}$$

$$\frac{23}{6} =$$

$$3\frac{5}{6}$$

As you see, we got $3\frac{5}{6}$ as the answer both ways. One method is as good as the other; use whichever method you prefer.

Subtraction of mixed numbers can be performed in essentially the same way as addition. However, sometimes we come up with a small complication in subtraction. Let us look at the problem:

$$3\frac{3}{4} - 2\frac{1}{8}$$

We can perform this subtraction by subtracting the whole numbers first and then by subtracting the fractions, using the same method as we used previously. Following this procedure the problem becomes:

$$3\frac{3}{4} - 2\frac{1}{8} =$$

$$3 - 2 + \frac{3}{4} - \frac{1}{8} =$$

$$1 + \frac{6 - 1}{8} =$$

$$1 + \frac{5}{8} =$$

$$1\frac{5}{8}$$

We can also perform this subtraction by converting both numbers to improper fractions and then subtracting. To convert $3\frac{3}{4}$ to a mixed number we multiply 3×4 which gives us 12; there are twelve quarters in 3 plus 3 which gives us $\frac{15}{4}$

$2\frac{1}{8}$ becomes $2 \times 8 + 1 = \frac{17}{8}$

Now our problem is

$$\frac{15}{4} - \frac{17}{8}$$

As in previous subtraction problems we must convert to the lowest common denominator which in this case is 8 so we get:

$$\frac{30}{8} - \frac{17}{8} =$$

$$\frac{13}{8} =$$

$$1\frac{5}{8}$$

Once again, you see that we get the

same answer so it does not matter which method you use. The first method is simple enough in most cases, but sometimes when using this method you have to borrow in order to perform one of the subtractions. We can best see what this involves by looking at the example:

$$4\frac{1}{8} - 2\frac{3}{4}$$

If we proceed with the subtraction by subtracting the whole numbers first, we get 4 - 2 which is 2. Now when we try to subtract the fractions we have

$$\frac{1}{8} - \frac{3}{4}$$

and when we convert this to the lowest common denominator which is 8 we have

$$\frac{1 - 6}{8}$$

If we subtract 6 from 1 we end up with a minus answer. Therefore, to perform this subtraction we must borrow from the whole number. In the original problem the whole number was 4 - 2 which gave us 2. We can change 2 to $1 + \frac{8}{8}$ and then add the $\frac{8}{8}$ to $\frac{1}{8}$ and get $\frac{9}{8}$

Now we can subtract

$\frac{6}{8}$ from $\frac{9}{8}$ and get $\frac{3}{8}$

and our answer is $1\frac{3}{8}$

If you do this problem by converting to improper fractions, you do not run into this problem.

$4\frac{1}{8}$ becomes $4 \times 8 + 1 = \frac{33}{8}$

$2\frac{3}{4}$ becomes $2 \times 4 + 3 = \frac{11}{4}$

Now our problem is

$$\frac{33}{8} - \frac{11}{4} =$$

$$\frac{33 - 22}{8} = \frac{11}{8} = 1\frac{3}{8}$$

Some problems will involve addition and subtraction of mixed numbers. When you encounter this type of problem you can do the addition and subtraction of the whole numbers first and then the addition and subtraction of the fractions or you can convert all the numbers to improper fractions and work the problem this way. As an example, consider the problem:

$$7\frac{1}{4} - 2\frac{3}{8} + 4\frac{7}{8} - 3\frac{9}{16}$$

Adding and subtracting the whole numbers we get 7 - 2 + 4 - 3 = 6. Now we must handle the fractions and to do this we must convert to the lowest common denominator which in this problem is 16. Thus, we have:

$$\frac{4 - 6 + 14 - 9}{16}$$

Now adding together the numbers to be added and at the same time adding the numbers that are to be subtracted we get:

$$\frac{4 + 14 - 6 - 9}{16} =$$

$$\frac{18 - 15}{16} = \frac{3}{16}$$

Therefore, our complete answer is

$$6\frac{3}{16}$$

Now if we decide to do the problem by converting the fractions to improper fractions

$7\frac{1}{4}$ becomes $7 \times 4 + 1 = \frac{29}{4}$

$2\frac{3}{8}$ becomes $2 \times 8 + 3 = \frac{19}{8}$

$4\frac{7}{8}$ becomes $4 \times 8 + 7 = \frac{39}{8}$

and $3\frac{9}{16}$ becomes $3 \times 16 + 9 = \frac{57}{16}$

Thus our problem becomes:

$$\frac{29}{4} - \frac{19}{8} + \frac{39}{8} - \frac{57}{16}$$

and changing these fractions to a common denominator of 16 we get:

$$\frac{116 - 38 + 78 - 57}{16} =$$

$$\frac{99}{16} = 6\frac{3}{16}$$

Once again we have the same answer so the choice of which way you do the problem is yours. Decide on which way you think is the easier and then do all of them the same way. Usually it is best to stick to one method rather than jump back and forth between the two because this often results in confusion. Now to get practice handling mixed numbers do the following problems. Again, be careful of your work to be sure that you get the right answer. Be sure you check each problem carefully before comparing your answers with ours which are at the back of the book.

MULTIPLYING FRACTIONS

There is a very simple rule that we follow in multiplying fractions. We simply multiply the numerators of the fractions together to get the numerator of the product and multiply the denominators together to get the denominator of the product. For example, $\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$. We have multiplied the two numerators, 1 × 1 and got 1 as the product and then multiplied the two denominators, 2 × 2 and got 4 as the new denominator. Actually, we can take the problem $\frac{1}{2} \times \frac{1}{2}$ and write it as $\frac{1 \times 1}{2 \times 2}$ and then it becomes quite obvious that our product will become $\frac{1}{4}$. It might at first disturb you that when you multiply two fractions together the product is smaller than either fraction. However, if you consider the multiplication as $\frac{1}{2}$ of $\frac{1}{2}$, you will see that the resultant should be $\frac{1}{4}$ In other words, you have $\frac{1}{2}$ of something and you are taking $\frac{1}{2}$ of that so that the resultant will be $\frac{1}{4}$

Often after you have multiplied two fractions together you can reduce the fraction to its simplest form. For example:

$$\frac{2}{3} \times \frac{1}{2} =$$

$$\frac{2 \times 1}{3 \times 2} =$$

$$\frac{2}{6} = \frac{1}{3}$$

We can also multiply several fractions together at once. For example, $\frac{2}{9} \times \frac{3}{4} \times \frac{5}{7}$ would be set up for the multiplication like this:

$$\frac{2 \times 3 \times 5}{9 \times 4 \times 7} = \frac{6 \times 5}{36 \times 7} =$$

$$\frac{30}{252} = \frac{15}{126} = \frac{5}{42}$$

In this example the resultant fraction is reducible: this usually means that it is possible to reduce some of the fractions before we perform the multiplication by what we call division or cancellation, before we multiply. Thus, in the problem,

$$\frac{2 \times 3 \times 5}{9 \times 4 \times 7}$$

the first number in the numerator is 2 which can be divided into the second number in the denominator which is 4. This would leave us:

$$\frac{\overset{1}{\cancel{2}} \times 3 \times 5}{9 \times \underset{2}{\cancel{4}} \times 7}$$

We can also divide the 3 in the numerator into 9 in the denominator which leaves us:

$$\frac{\overset{1}{\cancel{2}} \times \overset{1}{\cancel{3}} \times 5}{\underset{3}{\cancel{9}} \times \underset{2}{\cancel{4}} \times 7}$$

Now when we multiply we have 1 × 1 × 5 or 5 in the numerator, and 3 × 2 × 7 or 42 in the denominator and we get our answer $\frac{5}{42}$ directly. Thus, by cancellation before we multiply we simplify the problem.

You can perform your multiplication of fractions either way: you can multiply them out and then cancel later or you can do the cancellation first. Usually the best method is to do the cancellation first because you will then be multiplying smaller numbers together and there will be less chance of your making an error.

For practice do the following multiplication problems. As before, be sure to do each problem carefully before checking your answer with those given in the back of the book and if you do make a mistake be sure to find out where your mistake lies before leaving the problem.

DIVIDING FRACTIONS

Division of whole numbers is just the opposite of multiplication of whole numbers. For example, if we are multiplying 3 × 4 we get 12. If we divide 4 into 12 we get 3. Likewise, division of fractions is just the reverse of multiplication of fractions. In division we have a fraction for our dividend and a fraction for our divisor and we are asked what number or fraction, when multiplied by the divisor, will give us the product that equals the dividend.

If $\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$

$\frac{1}{4} \div \frac{1}{2}$ must equal $\frac{1}{2}$

Likewise,

if $\frac{2}{3} \times \frac{1}{2} = \frac{2}{6}$ or $\frac{1}{3}$

then $\frac{1}{3} \div \frac{1}{2}$ must equal $\frac{2}{3}$

To divide one fraction into another, all we do is invert the divisor, in other words, we turn it upside down, and then multiply the two fractions together. Thus, in the problem,

$$\frac{1}{6} \div \frac{2}{3}$$

$\frac{2}{3}$ is the divisor so to perform the division we invert it and multiply so that our problem becomes:

$$\frac{1}{6} \div \frac{2}{3} =$$

$$\frac{1}{6} \times \frac{3}{2} = \frac{1}{4}$$

Likewise,

$\frac{3}{7} \div \frac{5}{6}$ becomes $\frac{3}{7} \times \frac{6}{5} = \frac{18}{35}$

When performing the multiplication it is usually worthwhile to see if it is possible to do any cancelling. This will simplify the problem and usually you will be working with smaller numbers so there is less chance of your making a mistake. For example, in the problem,

$$\frac{3}{4} \div \frac{9}{16}$$

we invert the $\frac{9}{16}$ and multiply so we have

$$\frac{3}{4} \times \frac{16}{9}$$

We immediately see that the 4 in the denominator of $\frac{3}{4}$ will go into 16 in the numerator of $\frac{16}{9}$ four times. At the same time we see that the 3 in the numerator of the fraction $\frac{3}{4}$ will go into the 9 in the denominator of $\frac{16}{9}$ three times. Thus, dividing by 4 and 3 we get:

$$\frac{\overset{1}{\cancel{3}}}{\underset{1}{\cancel{4}}} \times \frac{\overset{4}{\cancel{16}}}{\underset{3}{\cancel{9}}} =$$

$$\frac{4}{3} = 1\frac{1}{3}$$

In some problems we will have more than one division to perform. In this case you can set the problem up as one problem by inverting all the divisors. For example, in the problem,

$$\frac{3}{8} \div \frac{7}{16} \div \frac{3}{7}$$

we have two divisors. The first divisor is $\frac{7}{16}$ which when inverted becomes $\frac{16}{7}$ and the second divisor which is $\frac{3}{7}$ becomes $\frac{7}{3}$ when it is inverted. Thus, if we invert both divisors our problem becomes:

$$\frac{3}{8} \times \frac{16}{7} \times \frac{7}{3}$$

Again, we can multiply all the numbers in the numerator to get the numerator product and then multiply all the numbers in the denominator to get the denominator product, but it is easier if we cancel first. Notice that in the first fraction, which is $\frac{3}{8}$, the 3 in the numerator will cancel the 3 in the denominator of the last fraction, $\frac{7}{3}$. Similarly, the 8 in the denominator of the first fraction will go into the 16 of the numerator of the second fraction twice. The 7 in the denominator of the second fraction will go into the 7 in the numerator of the third fraction. Thus when we perform the divisions our problem becomes:

$$\frac{\cancel{3}}{\underset{1}{\cancel{8}}} \times \frac{\overset{2}{\cancel{16}}}{\cancel{7}} \times \frac{\cancel{7}}{\cancel{3}} =$$

$$\frac{2}{1} = 2$$

Now you need to get practice dividing fractions so do the following problems carefully and compare your answers with those at the back of the book to be sure that you have the correct answer for each problem.

MIXED NUMBERS AND IMPROPER FRACTIONS

To multiply and divide mixed numbers, you should convert the mixed number to an improper fraction and then proceed as you do with simple fractions. For example, in the problem,

$$1\frac{3}{4} \times 2\frac{2}{7}$$

we convert the $1\frac{3}{4}$ to fourths; to do this we multiply 1 × 4 which gives us 4 plus 3 or the total of $\frac{7}{4}$. We convert the $2\frac{2}{7}$ to sevenths by multiplying 2 × 7 to get 14 plus 2 equals $\frac{16}{7}$. Our problem then becomes:

$$\frac{7}{4} \times \frac{16}{7}$$

and rather than perform the indicated multiplications we cancel the 7 in the numerator of $\frac{7}{4}$ and the 7 in the denominator of $\frac{16}{7}$. Similarly, we divide 4 into the denominator of $\frac{7}{4}$ and 4 into the numerator in the fraction $\frac{16}{4}$. Thus, our problem becomes:

$$\frac{\cancel{7}}{\underset{1}{\cancel{4}}} \times \frac{\overset{4}{\cancel{16}}}{\cancel{7}} =$$

$$\frac{4}{1} = 4$$

We do our division the same way: we convert both mixed numbers to improper fractions. For example:

$$2\frac{5}{7} \div 1\frac{3}{7} =$$

$$\frac{19}{7} \div \frac{10}{7} =$$

$$\frac{19}{\cancel{7}} \times \frac{\cancel{7}}{10} = 1\frac{9}{10}$$

Sometimes you will run into problems with both multiplication and division involving mixed numbers. To do these problems you convert the mixed numbers to improper fractions and then go ahead and proceed as you would in a multiplication and division of simple fractions. Remember that to divide you simply invert the divisor and multiply. For example:

$$3\frac{1}{4} \div 1\frac{1}{8} \times 3\frac{6}{13} =$$

$$\frac{13}{4} \div \frac{9}{8} \times \frac{45}{13} =$$

$$\frac{\cancel{13}}{\cancel{4}} \times \frac{\overset{2}{\cancel{8}}}{\cancel{9}} \times \frac{\overset{5}{\cancel{45}}}{\cancel{13}} =$$

$$\frac{10}{1} = 10$$

If you worked all these preceding multiplication and division problems you should have no difficulty doing the following problems involving mixed numbers. Be sure to check your work carefully as you go along and if you should get the wrong answer be sure to find out where you made your mistake before leaving the question.

RULES OF ORDER

In some problems you will have addition, subtraction, multiplication and division all in the same problem. In problems of this type you follow the rules of order that we established for addition, subtraction, multiplication and division of whole numbers. You will remember that you do any operations enclosed inside of brackets or parentheses first. Then going through the problem, working from the left to the right, you do the multiplication and division in the order in which they occur and then you go back to the left and work through to the right doing the addition and subtraction this time all the way through.

Where there is a multiplication and division side by side, rather than perform either operation separately, you can set the problem up so you can cancel as you did in earlier examples and, in this way, sometimes save yourself some work.

We are not going to give you any detailed examples on how to do problems of this type because you have done all the operations involved many times and you should be able to work out this type of problem. However, we have included five problems at the end of this section for you to do. Try working these problems and then after you have worked them out check with the answers at the back of the book to see how you made out. If you have made any errors be sure to check the sample solution carefully to be sure where your error lies.

SUMMARY

We have now gone through all the rules for operating with fractions and we can summarize our results for easy reference as follows:

(1) The product of two or more fractions is a new fraction whose numerator is a product of the numerators of all these fractions, and whose denominator is the product of the denominators of all the factors. Any whole number may be considered as a fraction with a denominator of 1. For instance, 127 means $\frac{127}{1}$

(2) The quotient of two fractions is the product of the dividend times the divisor inverted (turned upside down).
Notice that neither multiplication nor division of fractions require the use of a common denominator.

(3) To add fractions, they must be reduced to equivalent fractions with a common denominator; then their sum is the sum of the numerators divided by the common denominator.

(4) Similarly, to subtract one fraction from another, we must use a common denominator and the difference is the difference of the numerators, divided by the common denominator.

(5) All results should be reduced to their simplest form by dividing both numerator and denominator by the largest common divisor.

Decimals

A decimal is simply a fraction whose denominator is 10 or some multiple of 10, for example, 100, 1000 etc. For example, the fraction $\frac{6}{10}$ can be written as .6 and .6 is called a decimal or a decimal fraction. We omit the denominator because it is understood. The decimal fraction $\frac{65}{100}$ can be written as .65 and the fraction $\frac{655}{1000}$ can be written as .655

At first you might think decimals are something new or something difficult to deal with, but this is not the case. You deal with decimals everyday when you handle money. You are acquainted with these coins: a cent, a nickel, a dime, a quarter dollar, and a half dollar.

$\frac{1}{100}$, $\frac{1}{20}$, $\frac{1}{10}$, $\frac{1}{4}$, $\frac{1}{2}$ of a dollar

or $\frac{1}{100}$, $\frac{5}{100}$, $\frac{10}{100}$, $\frac{25}{100}$ and $\frac{50}{100}$ of a dollar.

It is just second nature to write these as \$.01, \$.05, \$.10, \$.25 and \$.50. That is, \$1.25 means one dollar and twenty-five cents or $1\frac{25}{100}$ dollars. On this basis you can easily add up such amounts as:

$$\begin{array}{r} \$\ 3.25 \\ 7.12 \\ 2.84 \\ 6.33 \\ \hline \$19.54 \end{array}$$

Just as we separate the dollars and cents (the cents are hundreths of a dollar), we can separate our whole numbers and fractions with a point. This is called a decimal point, and we can write all our fractions with denominators of 10, 100, 1000, etc. as whole numbers by learning to use this decimal point. To do this, we use the first place to the right of the point for tenths, the next for hundredths, the third for thousandths etc.

In this fashion $1\frac{1}{10}$ becomes 1.1

$1\frac{2}{10}$ becomes 1.2

$1\frac{1}{100}$ becomes 1.01

and $1\frac{1}{1000}$ can be written as 1.001

CONVERTING FRACTIONS TO DECIMALS

With a little practice many fractions can be converted to decimals simply by inspection. This is true of fractions whose denominators are multiples of 10. However, there is a standard rule that we can follow for converting other fractions to decimals so that the procedure becomes almost automatic. Let us take as an example the fraction $\frac{1}{8}$.

To convert $\frac{1}{8}$ into a decimal we simply divide 8 into 1. We do this by setting up the problem for division and then placing a decimal point to the right of the 1 and then adding as many zeros as we may need to the right of the 1. Now we start by dividing 8 into 1 and since it cannot go, we place a decimal point above

$$\begin{array}{r@{}l} & .125 \\ 8 & \overline{)1.00000} \\ & \underline{8} \\ & 20 \\ & \underline{16} \\ & 40 \\ & \underline{40} \end{array}$$

Fig. 19. Converting 1/8 to a decimal.

the line immediately above the decimal point to the right of the 1 and now divide 8 into 10 as shown in Fig. 19. 8 will go into 10 once so we place a 1 to the right of the decimal point and place an 8 beneath the 10. Subtracting 8 from 10 we get 2, so we bring down the next 0 and now divide 8 into 20. It will go twice so we place the 2 in our answer to the right of the 1 and multiplying 8 by 2 we get 16 which we place beneath the 20. Now subtracting 16 from 20 gives us 4 and we bring down the next 0. 8 will go into 40 five times so we place a 5 to the right of the 2 in our answer and since 5 times 8 is 40 we place this 40 beneath the other 40 and subtracting, our remainder is 0 so the decimal equivalent of $\frac{1}{8}$ is .125.

To convert $\frac{5}{8}$ to a decimal we proceed in exactly the same manner. We set down the division as shown in Fig. 20 and divide 8 into 5 and get as our answer .625.

$$\begin{array}{r@{}l} & .625 \\ 8 & \overline{)5.000} \\ & \underline{4\,8} \\ & 20 \\ & \underline{16} \\ & 40 \\ & \underline{40} \end{array}$$

Fig. 20. Converting 5/8 to a decimal.

Any fraction can be converted to a decimal by following this simple procedure. However, not all fractions will work out to an even value. Sometimes you will get a number in the answer or a combination of numbers that will repeat indefinitely. In this case you simply carry out the division as far as necessary. How far you will actually have to carry it out depends upon what accuracy you want in your answer. If you are dealing with money, there would not be much point in carrying the division past two decimal places because the third decimal is less than a cent and a cent is the smallest denomination of money we have.

$$\begin{array}{r@{}l} & .3333 \\ 3 & \overline{)1.00000} \\ & \underline{9} \\ & 10 \\ & \underline{9} \\ & 10 \\ & \underline{9} \\ & 10 \\ & \underline{9} \\ & 1 \end{array}$$

Fig. 21. Converting 1/3 to a decimal produces a repeating 3. No matter how far we carry the division we will always have the remainder of 1 in this problem.

An example of a common fraction that cannot be converted to an exact decimal value is $\frac{1}{3}$. Fig. 21 shows the conversion of $\frac{1}{3}$ to a decimal. We have shown four decimal places and you will notice that no matter how far we carry the division we will always have a remainder of 1 and the next figure to the right will always be a 3. If we wanted to express the fraction $\frac{1}{3}$ as a decimal to 3

places we would write it as .333

When we try to convert $\frac{2}{3}$ to a decimal we run up against a repeating 6 as shown in Fig. 22. Here again we have to decide how many figures we want and then round off our answer. If we wanted to express $\frac{2}{3}$ as a decimal to three decimal places we would write it as .667. Notice that we changed the digit in the third decimal place from a 6 to a 7. The rule for rounding off decimals in this way is that if the next number to the right is more than 5 we add 1. If it is less than 5 we leave the decimal figure as it is. If the next digit to the right should happen to be a 5 then we add 1 if it will make the last number an even number. If the last digit is already an even number we do not add 1. For example, to express the decimal .7635 to three decimal places, since the 3 is an odd number, adding 1 will make it an even number so we would round that off as .764. On the other hand, to express the decimal .8665 to three decimal places, since the third digit is a 6 which is already an even number, we simply drop the 5 and write the decimal as .866

```

          80
          80
          --
```

Fig. 23. Converting 1/16 to a decimal.

Another example of converting a fraction to a decimal is shown in Fig. 23. Here we have converted $\frac{1}{16}$ to a decimal. Notice that in the first division when we try to divide 16 into 10 it will not go so we place a 0 to the right of the decimal point. Then we try to divide 16 into 100 and it will go 6 times. 6 sixes are 96 which we subtract from 100 to give us a 4. Now we bring down another 0 and 16 into 40 goes twice. 2 × 16 are 32 and subtracting we get 8. Bringing down another 0 we get 80, and 16 goes into 80, 5 times. Thus the decimal equivalent of $\frac{1}{16}$ is .0625. You will run into this situation quite frequently in converting small fractions to decimals, however, do not forget, if the denominator of the fraction will not go into 10, we must place a 0 to the right of the decimal point. If the denominator of the fraction is so large it will not go into 100 then you have to put two zeros to the right of the decimal point and try to divide it into a thousand etc.

Now to get practice converting fractions to decimals, convert the following fractions to decimals. If a fraction does not convert evenly to a decimal, round your answer off correctly to four decimal places. You will find the answers in the back of the book so you can check your results.

ADDITION AND SUBTRACTION OF DECIMALS

The operations of addition and subtraction of numbers involving decimals are precisely the same as those involving whole numbers. In setting up the problems, the decimal points must be all placed in a vertical line and the decimal point in the sum or difference will be in that same line. Here are several examples:

$$\begin{array}{lr}

MULTIPLYING DECIMALS

Multiplication of decimal numbers is exactly the same as multiplication of whole numbers except that we need a rule for determining the position of the decimal point in the product. The rule is that we count the number of decimal places in each factor. Then, starting at the right of the product we count off the same number of decimal places to the left as the sum of the number of places in the two factors. For example, in the multiplication

$$232.7 \times 4.89$$

there is one decimal place in the number 232.7 and two decimal places in the number 4.89 and therefore in our answer we will count off three decimal places to the left starting at the right of the product. The multiplication is shown in Fig. 24 and notice that we have a total of 3 decimal places in our answer.

$$\begin{array}{r}
232.7 \\
4.89 \\
\hline
20943 \\
18616 \\
9308 \\
\hline
1137.903
\end{array}$$

Fig. 24. There are three decimal places in the factors and therefore there must be three places in the product.

We follow this rule for placing the decimal point at all times even if it means adding several zeros in our answer. For example, if we find the product of

$$.1273 \times .0032$$

we will get as our product 40736 as shown in Fig. 25. However, there are four decimal places in the number .1273 and four decimal places in the number .0032. Therefore, there must be eight decimal places in our answer. Starting at the right of the product and counting to the left, we find that there are only five digits in our answer and therefore we must add three zeros to the left of the 4 before placing the decimal point so that our answer becomes .00040736.

.1273	4 decimal places
.0032	4 decimal places
2546	8 decimal places
3819	
40736	5 digits
.00040736	8 decimal places

Fig. 25. We must add three zeros to get the required eight decimal places.

DIVIDING DECIMALS

It is no more difficult to divide numbers involving decimals than it is to divide whole numbers, if we remember a few simple facts. You will remember that a division problem is really a fraction. In other words, 1000 ÷ 18 can be written as $\frac{1000}{18}$

You will also remember that in a fraction you can multiply the numerator and the denominator by the same number without changing the value of the fraction.

In division involving decimals, if the divisor has a decimal in it we get rid of the decimal by moving the decimal point to the right. If we move the decimal point one place to the right. This is the equivalent of multiplying the divisor by 10 so we must multiply the dividend by 10 also. We do this by moving the decimal point one place to the right also. For example, in the problem 42.97 ÷ 4.8, we can get rid of the decimal in the divisor by moving it one place to the right and at the same time moving the decimal point in the dividend one place to the right so that our problem then becomes 429.7 ÷ 48.

Sometimes in order to move the decimal point to the right in the dividend we have to add a 0. For example, in the problem 634 ÷ 82.7, to get rid of the decimal point in the divisor we move the decimal point one place to the right and the divisor becomes 827. We must move the decimal point one place to the right in the dividend also and to do this we add a 0 so that the dividend becomes 6340.

When performing a division involving decimals we must keep track of the decimal point. This is done by placing the decimal point in the quotient immediately above the decimal point in the dividend. For example, in the problem 207.09 ÷ 3.9, the first thing we do is move the decimal point one place to the right to get rid of the decimal in the divisor. Then we proceed with the divisor as follows:

$$\begin{array}{r} 53.1 \\ 39\overline{)2070.9} \\ \underline{195} \\ 120 \\ \underline{117} \\ 39 \\ \underline{39} \end{array}$$

Notice that the decimal point in the quotient is placed immediately above the decimal point in the dividend and the first two digits in the quotient were obtained before we used the decimal in the quotient. This means that the 5 and the 3 to the left of the decimal point and the 1 which was obtained using the .9 from the dividend obtained from the right of the decimal point.

Now to get practice adding, multiplying, dividing and subtracting with decimals do the following problems. Be sure that you do your arithmetic carefully and watch the decimal point to be sure you have it in the right place. Check your answers with the answers given in the back of the book.

MULTIPLYING AND DIVIDING BY TEN

One of the greatest advantages of the decimal system is that multiplication or division by 10,100, or 1000, or any power of ten can be accomplished by simply moving the decimal point as many places to the right (in multiplication) or left (in division) as there are zeros in the particular power of ten. Thus, to multiply a number like 2.35 by 1000, all we have to do is move the decimal point three places to the right, filling in the vacant spaces with zeros to get 2350.

Similarly, to divide by any power of ten requires only that we move the point to the left. Thus, 3500 ÷ 1000 = 3.5.

You will remember that the basic electric units - ampere, volt, farad, cycle, henry, watt, etc. -- are sometimes too large for convenient handling in electronics. In other cases they are much too small. So a set of five prefixes for measurement are used to remedy these situations. These are:

		Units
M	MEGA	1,000,000
k	KILO	1000
m	MILLI	.001
µ	MICRO	.000,001
p	PICO	.000,000,000,001

Pico = µµ or micro-micro.

These units help us by making it possible to express electrical terms in more convenient figures. For example, a radio station in the standard broadcast band might operate on a frequency of 1,470,000 cycles. By moving the decimal point three places to the left, we can convert this frequency in cycles to a frequency in kilocycles. The frequency in kilocycles would be 1,470 kilocycles. If we wanted to go a step further, we could move the decimal point six places to the left instead of 3 places and convert from cycles to megacycles. In this case the frequency would be 1.470 megacycles. Since a kilocycle equals a thousand cycles and a megacycle equals a million cycles it follows that a megacycle equals a thousand kilocycles. Therefore, we can convert from kilocycles to megacycles by moving the decimal point three places to the left. The terms milli, micro and pico are used to express values smaller than one. Thus, to change a current of 1 amp to milliamps, we would move the decimal point three places to the right so that 1 amp = 1000 milliamps. If we had a current .047 amperes, we would convert this to milliamperes by moving the decimal point three places to the right and the current would then be 47 milliamperes. If the current was .000047 amperes, we could convert this to milliamperes again by moving the decimal point three places to the right and the current would be .047 milliamperes. If instead of converting to milliamperes we converted to micro-amperes, we would move the decimal point six places to the right, in which case the current would be 47 micro-amperes. To convert from units such as farads to picofarads, we move the decimal point twelve places to the right. This term has recently come into use and previously was referred to as micro-micro. You will probably see both terms used; you should remember that they mean the same thing. To summarize, to convert from a unit to a larger value we move the decimal place to the left. To convert from units to kilo you move three places to the left and to convert from units to megaunits move it six places to the left. To convert from kilo units to mega units move it three places to the left. It follows that if you are given a value in megohms and you want to convert to ohms, you would move the decimal point six places to the right and if you were given the value in kilohms and you wanted to convert to ohms, you would move the decimal point three places to the right. Thus, in a resistor that had a value of 4.7 megohms, to convert to ohms, you move the decimal point six places to the right and get 4,700,000 ohms. If you had a resistance of 4700 ohms and wanted to convert this to kilohms, you would move the decimal point three places to the left and get 4.7K (kilohms).

PERCENTAGE

It is very expensive to make any electronic part to an exact value. Fortunately, considerable tolerance is permissible in most electronic circuits so that the components used in it do not have to be made to an exact value. Parts usually have a certain tolerance and this tolerance is expressed as a percentage of the rated or required value.

Percentage is a fractional part expressed in hundredths. In other words, 1% is $\frac{1}{100}$, 2% is $\frac{2}{100}$ and 10% is $\frac{10}{100}$. We normally use the symbol % to stand for the word percent. Thus 5 percent is written 5%. This means $\frac{5}{100}$.

If we say that a resistor has a tolerance of 10%, what we mean is that its actual measured resistance will be within 10% of the value it is supposed to be. In other words, if a resistor is supposed to be a 1,000 ohm resistor and it has a tolerance of 10%, 10% of 1000 is

$$\frac{10}{100} \times 1000 = 100 \text{ ohms}$$

This means that the resistor is within 100 ohms of 1000 ohms. The resistor might have a value as low as 900 ohms or as high as 1100 ohms. In other words, the resistance of the resistor will fall somewhere between 900 ohms and 1100 ohms - it is rare that the value would fall on the exact value of 1000 ohms.

Most resistors used in communications and electronics equipment have tolerances of 5% or 10%. If you want to find an exact range of resistance that a resistor might have, you find how much it might vary from its value by determining the percentage variation from its rated value. If the resistor is a 5% resistor multiply the value of the resistor by 5 over 100 to get the amount it could vary from its rated value and if it is a 10% resistor, multiply the value by 10 over 100. For example, a 470 ohm 5% resistor may have a tolerance of $\frac{5}{100} \times 470 = 23.5$ ohms. This means its value will lie somewhere between 470 - 23.5 ohms and 470 + 23.5 ohms.

The same value resistor that has a 10% tolerance could vary by as much as

$$\frac{10}{100} \times 470 = 47 \text{ ohms}$$

Therefore, it might have a value anywhere between 470 - 47 and 470 + 47 ohms.

In accurate measuring equipment, resistors having a tolerance of 1% or $\frac{1}{2}$ of 1 % are frequently encountered. If you want to find how much a 1% resistor can vary from its rated value, you multiply 1 over 100 times the value of the resistor. If you want to find how much a one half percent resistor varies, then multiply $\frac{1}{2}$ over 100 times its rated value or $\frac{1}{200}$ times its rated value to find how much the one half percent resistor could vary. Then to get the limits of the resistor, you subtract the variation to find how low the resistance can actually be and then you add the variation to find out how high the resistance can actually be.

Sometimes you know the value by which a part varies from its rated value and you want to find what percentage this is of the rated value. To find the percent that one number is to the second number, divide the first number by the second and multiply the quotient by 100. In other words, if you had a 600 ohm resistor and found that it actually measured 650 ohms and you wanted to find what percentage the resistor was of its rated value you would subtract 600 from 650. In other words, the resistor was 50 ohms over its rated value. To convert this to percentage you set the problem up as

$$\frac{50}{600} \times 100 = 8.33\%$$

Since percentage is a fraction of 100 we can easily convert percentage to its decimal number. For example, 40% means $\frac{40}{100}$

To divide 40 by 100 we move the decimal point two places to the left.

$$\text{Thus } 40\% = \frac{40}{100} = .40$$

$$\text{Similarly, } 12\% = \frac{12}{100} = .12$$

$$6\% = \frac{6}{100} = .06$$

You will find it useful to be able to find the given percent of a number. For example, what number is 40% of 350? To find this number we convert 40% to a decimal and then multiply 350 by the decimal.

$$40\% \text{ of } 350 = 350 \times \frac{40}{100} =$$
$$350 \times .40 = 140$$

To get practice doing percent problems you should do the following ten problems. If you find that you are unable to do one particular type, be sure to refer to the model solution in the back of the book to see how the problem is worked and then go back and work the other problems of the same type. Percentage is useful not only in electronics, but in many other activities of every day life.

Solving Circuit Problems

Now that we have reviewed the operations of basic arithmetic let us use these operations to solve some simple dc circuit problems. This will help you in two ways. First, you will get a chance to review some of the facts you learned in this lesson and secondly, you will get a chance to practice applying your arithmetic to actual electronic circuits. This will help you to better understand how these circuits work.

Earlier in this lesson you did a number of problems involving Ohm's Law. We won't do any more examples involving simple applications of Ohm's Law at this time. If you have forgotten the three forms of Ohm's Law, be sure to memorize them again. Remember the three forms are:

$$I = E \div R$$
$$R = E \div I$$
$$E = I \times R$$

You can use Ohm's Law to solve many circuit problems. If you know the voltage and the resistance in the circuit, you can use the formula $I = E \div R$ to find the current. If you know the voltage and the current in a circuit, you can use the formula $R = E \div I$ to find the resistance and if you know the current and the resistance in the circuit, you can use the formula $E = I \times R$ to find the voltage. Remember, if you know any two of the quantities - resistance, current or voltage - you can use the appropriate form of Ohm's Law to find the other quantity.

Remember to give your answer in the proper units. If you are finding the voltage in the circuit, give your answer in volts; if you are finding the current in the circuit, give the answer in amps, and if you are finding the resistance in the circuit, give the answer in ohms. Simply giving a numerical answer without the correct units after it is unsatisfactory.

Remember also that to use Ohm's Law you must have the voltage in volts, the current in amps, and the resistance in ohms. If you are given the current in milliamperes, you must change it to amperes to use Ohm's Law. Similarly, if the voltage is given in millivolts or kilovolts, change it to volts and if the resistance is given in megohms or kilohms, change it to ohms.

In your regular lesson text you learned the power formulas that let you find the power consumed in watts. These formulas are:

$$P = E \times I$$
$$I = P \div E$$
$$E = P \div I$$

Using these formulas, if you know any two of the quantities, power, voltage or current, you can find the other.

For example, find the power in a

circuit if the voltage is 150 volts and the current is 3 amps. Using the formula $P = E \times I$ and substituting for E and I we get:

$$\begin{aligned} P &= E \times I \\ &= 150 \times 3 \\ &= 450 \text{ watts} \end{aligned}$$

If in another problem you are given that the power in a circuit is 660 watts and the voltage is 110 volts, you can find the current in the circuit using the formula $I = P \div E$. For example:

$$\begin{aligned} I &= P \div E \\ &= 660 \div 110 = 6 \text{ amps} \end{aligned}$$

If you are given that the power in the circuit is 800 watts and the current is 2.5 amps, you can find the voltage using the formula $E = P \div I$. You proceed as follows:

$$\begin{aligned} E &= P \div I \\ &= 800 \div 2.5 \\ &= 320 \text{ volts} \end{aligned}$$

There is another formula for power when we know the value of current and resistance, $P = I^2R$. I^2 is equal to $I \times I$. We would use this formula in examples where current and resistance are given and we want to find power. For example, if the current in the circuit is 3 amperes and the resistance in the circuit is 15 ohms, we can find the power dissipated in the circuit.

$$\begin{aligned} P &= I^2R \\ &= 3 \times 3 \times 15 \\ &= 135 \text{ watts} \end{aligned}$$

We can also rearrange this formula to get $I^2 = P \div R$ or $R = P \div I^2$ These two forms are also useful in solving certain problems. For example, if the power in a circuit is 400 watts and the resistance in the circuit is 100 ohms, we can find the current flowing in the circuit using the formula:

$$\begin{aligned} I^2 &= P \div R \\ &= 400 \div 100 \\ &= 4 \end{aligned}$$

This gives us the value of I^2 or $I \times I$. To get the value of I we need a number that when multiplied by itself will give us four. Obviously the answer is 2 and therefore the current is 2 amps. 2 is called the square root of 4. In a later lesson you will learn how to find the square root of a number, but for the present the only problems we will have you do involving square roots will be simple numbers which you will be able to recognize readily. For example, the square root of 4 is 2, the square root of 9 is 3, the square root of 16 is 4, the square root of 25 is 5 etc.

Another version of the power formula that is useful is $P = E^2 \div R$. We use this formula when we know the voltage and the resistance in the circuit. To find the power in the circuit, we divide the voltage squared, which is equal to $E \times E$, by the resistance and this will give us the power in watts. We can also rearrange this formula into the form $E^2 = P \times R$ and $R = E^2 \div P$ and use it to find the voltage in the first case when the power and resistance are known and the resistance in the second case when the voltage and power are known. We will not give any examples in the use of these formulas because they are exactly the same as the other power formulas.

You already learned how to find the resistance of resistors in series, but sometimes you have to find the value of resistors in parallel. The total resistance of two resistors in parallel can be found using the formula:

$$R_t = \frac{R_1 \times R_2}{R_1 + R_2}$$

We would use this formula to find the resistance of two resistors in parallel if we have been given the resistance of the individual resistors. For example, if a 20 ohm resistor and a 30 ohm resistor are connected in parallel, find the resistance of the two resistors in parallel. Substituting these values in the formula:

$$R_t = \frac{R_1 \times R_2}{R_1 + R_2}$$

$$= \frac{20 \times 30}{20 + 30}$$

$$= \frac{600}{50}$$

$$= 12 \text{ ohms}$$

Sometimes you will have a circuit where there are more than two resistors connected in parallel. You can use the same formula for finding the resistance of the parallel combination by finding the resistance in groups. For example, if there are three resistors, find the resistance of two of the resistors in parallel while ignoring the third resistor. When you have found the resistance of two of the resistors in parallel, treat this parallel resistance as a single resistance and find the resistance of it in parallel with the third resistor. If there should happen to be four resistors in parallel, group them into two groups of two each. Find the parallel resistance of each group and then treat each group as a single resistor and then find the parallel resistance of the two groups of resistors.

Now to get practice applying the power formulas, Ohm's Law and the various resistance formulas, do the following problems. You will find many of the problems are very similar to many of the problems you have worked in this lesson, but the time you will spend on these additional problems will be spent in a very worthwhile way. It will not only help you with the mathematics, but it will also help you remember the various formulas and how to use them - and give you a better understanding of electronics. Also, if you will work these problems, you should have no difficulty doing the lesson questions because they are very similar to the problems in this group.

SELF-TEST QUESTIONS

106. What is the total resistance of a circuit that has a 35-ohm resistor in parallel with a 75-ohm resistor? Round off your answer to the nearest ohm.
107. If we have a voltage of 120 volts applied to a lamp with a resistance of 100Ω, how many watts of power will be consumed?
108. In the circuit shown in Fig. 27, the total resistance of the circuit is 335 ohms. What is the resistance of R_2?
109. If the current flowing through the circuit in Fig. 27 is 6 amps, what is the power in watts?
110. What is the maximum rated current-carrying capacity of a 500-ohm resistor marked: 500 ohms, 2000 watts?
111. If a vacuum tube that has a filament rating of .25 amps at 5 volts is to be operated from a 6-volt battery, what value of series-dropping resistor would we need?

117. Three resistors in series have voltage drops of 36 volts, 24 volts, and 40 volts. What percentage of the total voltage is the 24-volt drop?

118. In the circuit shown in Fig. 29, 450 watts of power are consumed. What is the voltage drop across R_1?

119. How many amperes of current flow through R_4 in the circuit described in Problem 118?

120. A current of 400 milliamps flows through a resistance of 2.2K. What is the voltage drop across the resistor?

Now, as soon as you feel sure that you are ready, work out the answers to the ten questions at the end of the lesson and submit your answers for grading.

Answers To Self-Test Questions

The following solutions to the various problems are to be used after you have tried to work the problems out yourself. Don't look at the answer or the solution until you have made an attempt to do the problem yourself. However, if you do not get the same answer as we do, be sure to go through the solution very carefully to be sure that you find out where you made your mistake. If you work each problem and then check your answer with ours, and if you make any mistakes find out where the mistake is, you should have no difficulty doing the questions at the end of the lesson.

1. The problem here is simply to find the resistance of a number of resistors in series. To do this you simply add the value of the individual resistors. Setting down the values as below we add and get 172 ohms.

$$\begin{array}{r} 68 \\ 31 \\ 9 \\ 17 \\ 21 \\ 7 \\ \underline{19} \\ 172 \end{array}$$

2. In this problem you know the total resistance in the circuit, and you know the resistance of four of the resistors. To find the resistance of the unknown resistor you add the resistance of the four known resistors. We know that this value plus the resistance of the unknown resistor must be equal to 81 ohms. Therefore, to get the correct resistance of the unknown resistor you subtract the resistance of the four resistors in series from the 81 ohms. Putting down the values of the four known resistors to get their total resistance we have:

$$\begin{array}{r} 14 \\ 8 \\ 17 \\ \underline{23} \\ 62 \end{array}$$

Since the total resistance of the four known resistors is 62 ohms, we now subtract 62 from 81 and get 19 ohms; this is the value of the unknown resistor.

$$\begin{array}{r} 81 \\ \underline{-62} \\ 19 \end{array}$$

3. This is simply a series circuit with five resistors connected in series. To find the total resistance we simply add the resistance of the resistors as shown below and get as our answer 511 ohms.

$$\begin{array}{r}127\\97\\9\\219\\\underline{59}\\511\end{array}$$

4. The first step in solving this problem is to determine the resistance of the four known resistors. To do this we put down the values and add as below:

$$\begin{array}{r}216\\318\\91\\\underline{56}\\681\end{array}$$

Thus, the total resistance of the four known resistors is 681 ohms. Since the total resistance in the circuit is 823 ohms, the value of the unknown resistor must be equal to 823 - 681. Thus, we set down the problem subtracting as shown below and get as our answer 142 ohms.

$$\begin{array}{r}823\\\underline{-681}\\142\end{array}$$

5. Here we have a simple application of Ohm's Law. The unknown value is I so we want this on one side of the equation. The known values are $E = 57$ volts and $R = 19$ ohms, so we want these values on the other side of the equation. Thus we use the formula:

$$\begin{aligned}I &= E \div R\\ &= 57 \div 19\\ &= 3 \text{ amps}\end{aligned}$$

6. To solve this problem we want to use Ohm's Law in the form $E = IR$. Here we have the unknown E on one side of the equals sign and the known values $I = 3$ amps and $R = 21$ ohms on the other side of the equals sign. Thus we have:

$$\begin{aligned}E &= IR\\ &= 3 \times 21\\ &= 63 \text{ volts}\end{aligned}$$

7. To do this simple Ohm's Law problem we use, $I = E \div R$ $E = 84$ volts and $R = 28$ ohms so we have:

$$\begin{aligned}I &= E \div R\\ &= 84 \div 28\\ &= 3 \text{ amps}\end{aligned}$$

8. In this problem the known values are E and I, $E = 96$ volts and $I = 4$ amps. We have to find R so we use the formula:

$$\begin{aligned}R &= E \div I\\ &= 96 \div 4\\ &= 24 \text{ ohms}\end{aligned}$$

9. We are given that $I = 5$ amps and $R = 17$ ohms. To find the voltage we use Ohm's Law in the form:

$$\begin{aligned}E &= IR\\ &= 5 \times 17\\ &= 85 \text{ volts}\end{aligned}$$

10. In a problem such as this, where we have the total voltage equal to 32 volts and the total current equal to 2 amps, we can find the total resistance using the formula:

$$\begin{aligned}R &= E \div I\\ &= 32 \div 2\\ &= 16 \text{ ohms}\end{aligned}$$

Since $R_1 = R_2$ and since the two

are in series, $R_1 + R_2 = 16$ ohms and each resistor must be equal to 8 ohms.

11. Using the rules of order, we go through the problem doing the multiplication and division first as we go from left to right. Thus we have:

$25 + 16 \times 3 - 28 \div 7 =$
$25 + 48 - 4 =$
69

12. In this problem we have to do the operations inside the parentheses first and then we go from left to right doing the multiplications and divisions in the order in which they occur. Thus we have:

$5 \times (11 - 8) + 3 \times (7 - 5) \div 2 =$
$5 \times 3 + 3 \times 2 \div 2 =$
$15 + 3 =$
18

13. $4 + (5+2) \times 20 - (10-6) \div (7-5) =$
$4 + 7 \times 20 - 4 \div 2 =$
$4 + 140 - 2 = 142$

14. In this problem you must perform the operation inside the parentheses first, and then we do the operation inside the bracket. Then we go through the problem from left to right doing the multiplication and division in the order in which they occur and then finally go through the problem again from left to right doing the addition and subtraction.

$3 \times 500 \div [2 \times (28 + 22)] + 25 - 6 =$
$3 \times 500 \div [2 \times 50] + 25 - 6 =$

100. 10% of 680 =

$\frac{10}{100} \times 680 = 68$ ohms

∴ Lowest value = 680 - 68 = 612 ohms.

101. 5% of 2200 =

$\frac{5}{100} \times 2200 = 110$ ohms.

2200 + 110 = 2310 ohms.

∴ 2300 ohms is within its rated tolerance.

102. 10% of 4.7 K =

$\frac{10}{100} \times 4700 = 470$ ohms

4700 + 470 = 5170 ohms.

5200 is greater than 5170

∴ resistor is above its rated tolerance

103. $\frac{1}{4} \times 100 = 25\%$

104. $\frac{1}{8} \times 100 = 12.5\%$

105. 75% of 200 volts =

$$\frac{75}{100} \times 200 = 150 \text{ volts}$$

106. $R_t = \frac{R_1 \times R_2}{R_1 + R_2}$

$$= \frac{35 \times 75}{35 + 75}$$

$$= \frac{2625}{110}$$

$$= 23.8 \text{ ohms}$$

$$= 24 \text{ ohms}$$

107. $P = E^2 \div R = \frac{12\cancel{0} \times 120}{10\cancel{0}}$

$$= \frac{12 \times 12\cancel{0}}{1\cancel{0}} = \frac{12 \times 12}{1}$$

$$= \frac{144}{1} = 144 \text{ watts}$$

108. $R_1 + R_2 = 75 + 150 = 225\,\Omega$
$R_t = 335\,\Omega$
$\therefore R_2 = 335 - 225 = 110\,\Omega$

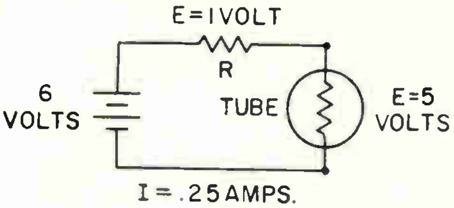
109. $P = 1^2 \times R$
$= 6 \times 6 \times 335$
$= 12{,}060$ watts

110. $P = 2000$ watts $R = 500\,\Omega$
$I^2 = P \div R$

$$= \frac{2000}{500} = 4$$

If $I \times I = 4$, then $I = 2$ amps.

111. In this problem you have 2 resistors in series. One resistor is the tube filament which has a voltage drop of 5 volts across it. The other resistor must use up or drop the extra voltage which is the difference between the battery voltage and the tube filament voltage in this case. 6-5 = 1 volt. Therefore we have the circuit:



We have E across R = 1 volt, I = .25 amps

$$\therefore R = \frac{E}{I} = \frac{1}{.25} = 4 \text{ ohms}$$

112. The current through the tube filament = 200 milliamps

200 milliamps = .2 amps.

resistance of filament = 500 ohms.

$\therefore$ voltage across filament

$E = I \times R$
$= .2 \times 500$
$= 100$ volts

$\therefore$ series resistor must drop 110-100 = 10 volts

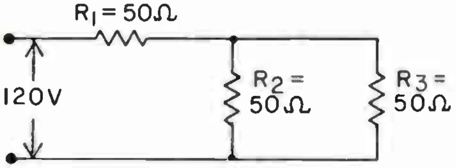
$$\therefore R = \frac{10}{.2} = 50 \text{ ohms.}$$

113. $R_t = \frac{R_1 \times R_2}{R_1 + R_2}$

$$= \frac{5 \times 15}{5 + 15}$$

$$= \frac{75}{20} = 3.75 \text{ ohms}$$

114. The circuit we have in this problem is:



First we find the value of R^2 and R^3 in parallel:

$$R_t = \frac{R_2 \times R_3}{R_2 + R_3}$$

$$= \frac{50 \times 50}{50 + 50} = \frac{2500}{100} = 25$$

∴ total series resistance is R_1 in series with 25 Ω

$50 + 25 = 75\Omega$

Now we know $E = 120V$ and $R = 75\Omega$ so we can find I:

$$I = \frac{E}{R}$$

$$= \frac{120}{75} = 1.6 \text{ amps}$$

115. At first glance, this problem might look difficult, but it is just a matter of solving it a step at a time.

First we find the value of $R_6 \times R_7$ in parallel:

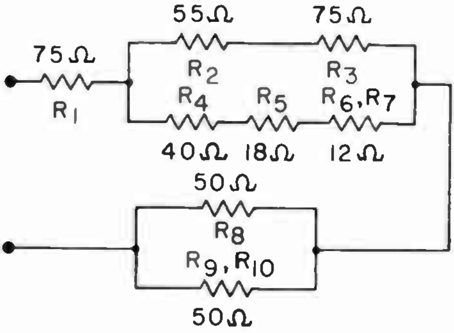
$$R_t = \frac{R_6 \times R_7}{R_6 + R_7}$$

$$= \frac{30 \times 20}{30 + 20} = \frac{600}{50} = 12\Omega$$

Next we find the value of R_9 and R_{10} in series:

$R_9 + R_{10} = 35 + 15 = 50$

Now we can redraw the circuit and substitute for R_6 and R_7 and for R_9 and R_{10}:



Now we find R_2 and R_3 in series:

$R_2 + R_3 = 55 + 75 = 130\Omega$

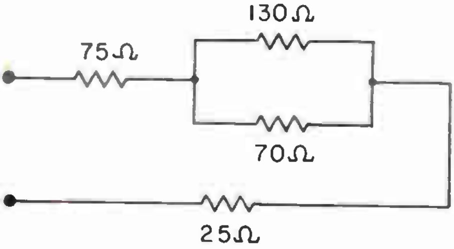
and R_4, R_5 and $R_6 - R_7$ in series:

$40 + 18 + 12 = 70\Omega$

Also we find R_8 in parallel with $R_9 - R_{10}$:

$$R_t = \frac{50 \times 50}{50 + 50} = \frac{2500}{100} = 25\Omega$$

Now we can redraw our circuit and substitute this value:



Now we find the value of 130Ω in parallel with 70Ω:

$$R_t = \frac{130 \times 70}{130 + 70} = \frac{9100}{200} = 45.5\Omega$$

Now we have 75 + 45.5 + 25 = 145.5

116. 10% of 450Ω =

$$\frac{10}{100} \times 450 = 45\Omega$$

$\therefore$ 450-45 = 405Ω is the lowest value in tolerance

$\therefore$ 410Ω is in tolerance

117. Total voltage = 36 + 24 + 40 = 100 volts.

$\therefore$ 24 volts $= \frac{24}{100} \times 100 = 24\%$

118. The first step in solving this problem is to find the total R.

$R_3 + R_4 = 25 + 15 = 40\Omega$

$\therefore$ $R_3 + R_4$ in parallel with R_2 =

$$\frac{40 \times 40}{40 + 40} = \frac{1600}{80} = 20\Omega$$

$\therefore$ R_1 + parallel combination = 30 + 20 = 50Ω

power = 450 watts

$$\therefore \quad I^2 = \frac{450}{50} = 9$$

$\therefore$ I × I = 9 and I = 3 amps.

$\therefore$ Voltage drop across R_1

E = I × R = 3 × 30 = 90 volts

119. Total current = 3 amps. Part flows through R_2 and part through R_3 and R_4.

Since $R_2 = 40\Omega$ and $R_3 + R_4 = 40\Omega$

current flowing in each branch will be equal

$$\therefore \quad I_{R4} = \frac{3}{2} = 1.5 \text{ amps}$$

120. I = 400 milliamps = .4 amps
R = 2.2K = 2200 ohms.
$\therefore$ E = I × R = .4 × 2200 = 880 volts.

Lesson Questions

Be sure to number your Answer Sheet X105.

Place your Student Number on *every* Answer Sheet.

Most students want to know their grades as soon as possible, so they mail their answers immediately. Others, knowing they will finish the next lesson within a few days, send in two sets of answers at a time. Either practice is acceptable. However, don't hold your answers too long; you may lose them. Don't hold answers to more than two sets of lessons at any time, or you may run out of lessons before new ones can reach you.

1. A supply voltage of 120 volts is applied to three resistors in series. One resistor has a drop of 55 volts, another a drop of 30 volts. What is the voltage drop across the third resistor?

2. A 750-ohm resistor has a rated tolerance of ±5%. When it is measured with an accurate ohmmeter, we find that the meter reads 697 ohms. Is the resistor (a) above, (b) below, (c) within its rated tolerance?

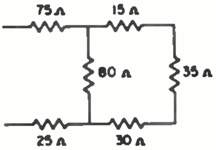
3. If 640 watts are consumed in a circuit with a total resistance of 160 ohms, how much current will flow in the circuit?

4. A current of 200 milliamps flows through a resistance of 1.6K. What is the voltage drop across the resistor?

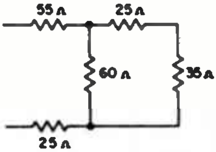
5. Find the answer to the problem 5 + 60 X 3 ÷ 4 – 6.

6. If 1/16th of the voltage applied to a circuit is dropped across a certain resistor, exactly what percentage of the total voltage does this represent?

7. What is the total resistance of the circuit shown at the right?



8. If 440 volts is applied to the circuit at the right, how much voltage will be dropped across the 35Ω resistor?



9. If a vacuum tube filament has a resistance of 20 ohms, and is rated at 250 milliamps, how much voltage should we apply so that it will draw its rated current?

10. The power consumed in a circuit is 160 watts. The voltage applied is 80 volts. What is the resistance of the circuit?

LEARNING NEVER ENDS

More and more it becomes evident that learning is a continuous process--that it is impossible to break the habit of studying without slipping backward. Look around you at all the marvelous developments of the last twenty years. You have the advantage of having "grown up" with them--yet there are probably many things you wish you knew more about. Then, consider what can happen in the years ahead if you do not keep abreast of the stream of new things that are bound to come!

Your NRI Course is preparing you for the problems of today and tomorrow, but what about the day after tomorrow? In five or ten years, will you still be up-to-date? Yes, if you plan your future. Resolve now--that you WILL keep up. You have the fundamentals; keep them fresh in your mind by constantly reviewing. Read and study technical literature and textbooks; join in discussion groups and listen to lectures; take advantage of every possible educational opportunity. Then, and only then, can you face the future unafraid, no matter what technical developments the future may hold.

AC CIRCUIT CALCULATIONS

In your reference lesson on dc circuit calculations, you reviewed and studied many of the operations of basic arithmetic. You learned how simple addition, subtraction, multiplication, and division can be used in your work with electronics and electronic circuits. In this reference lesson you will take another step in your study of electronics by learning how to apply these same fundamental operations when solving ac circuit problems. However, as you learned when you studied coils and capacitors, alternating current reacts much differently from direct current in certain circuits. For this reason, you will have to expand your knowledge of basic mathematics in order to handle some of these conditions.

One of the first things you learned in dealing with alternating current is that the reactance of coils and capacitors causes the voltage and current to be out-of-phase with each other, while any resistance tries to keep them in phase. Consequently, you cannot add or subtract these ac circuit quantities without taking these phase differences into consideration. Although this might have seemed pretty difficult at first, you quickly learned that it could be done quite easily by using vectors to represent the phase relationships as well as the values. Then, by adding and subtracting the vectors, you were able to account for both the phase and the size of the circuit quantities.

While there is really no limit to the circuit solutions you can obtain by using simple vector measurement methods, they are very awkward and clumsy for the more complex circuits. For this reason, a number of simpler methods have been worked out to use in practical circuit solutions. Some of them involve square roots, others trigonometry, and one very common system uses a principle known as the j-operator. Like many other new subjects or methods, you will have to learn a few basic rules in order to use them with confidence and accuracy.

In addition to knowing how to do square roots, you should be very familiar with positive and negative numbers. In this lesson we will discuss finding the square roots of numbers, which is really a special type of division. You will also study positive and negative numbers, ratio and proportion, and take a closer look at vectors. Remember, you are not going to try to learn all there is to know about these subjects. You are simply going to look at them from the standpoint of their practical application in electronics.

Even though this is a reference lesson, it is still required for your course. Submit the answers to the questions at the back of the book just as you do for the technical lessons.

Square Roots

In our discussion of coils and capacitors we mentioned that if you knew how to do square roots, you could use a mathematical solution for finding the impedance in ac circuits. We even discussed the formula for this method, which is

$$Z = \sqrt{R^2 + X^2}$$

where Z is the impedance, R is the resistance, and X is the total reactance. The reactance may, of course, be either the inductive reactance, X_L, capacitive reactance, X_C, or a combination of both X_L and X_C.

This is a very handy formula for finding impedance and you will probably use it many times in your work with ac circuits. However, like many good methods of working problems, it is of no use unless you know how to do square roots. So let's take a look at this process, which is known as finding the square root of a number. Even if you have already studied square roots it will still be a good idea to read this section to refresh your memory.

When you studied multiplication you learned that the product of a number multiplied by itself was called a "square." You also learned a special way of indicating the process of finding a square by placing a small "2" above and to the right of the number. Thus, 6 X 6 can be indicated as 6^2, or 136 X 136 as 136^2. Any other number times itself can be indicated the same way.

Many times in your work with electronics you will have the "square" of a number and will want to know the number. There is a special process of division that can be used to find the "squared" number. Since the number that makes a square when it is multiplied by itself is sometimes called the "root" of a square, this special division process is called finding the "square root."

Let's make sure you understand this. A number multiplied by itself, or "squared," makes a product called a "square." The number that is squared is called the "root" of the square. The special division to find the root of a square is called finding the "square root."

SIMPLE SQUARE ROOTS

Now that you have seen what we mean by square root, let's look at a typical example and learn how to solve it. Suppose you are asked to find the square root of the number 576. What you want to know is: "What number multiplied by itself will give me a product of 576?" The main difference between this and any other division problem is that here you are given only the product to work with. Instead of being given a product and one number and being asked what number when multiplied by the given number will equal the product, you are simply given a product and are asked to find the one number that can be multiplied by itself to give this product.

This process is not as difficult as it may sound. It is just a matter of learning a few rules and how to apply them. First, you must set up the number as you would any other division problem, as shown in Fig. 1A. However, you will notice that there is one major difference besides the fact that

$\sqrt{576}$ $\sqrt{5,76}$

Ⓐ Ⓑ

Fig. 1. Setting up a square root problem.

there is no divisor. It's the symbol that looks like a lopsided letter V that is in front of the dividend ($\surd$). It replaces the straight vertical line in a standard division symbol and is called a "radical" sign. This radical sign is the symbol for finding the root of a number and is always used in a square root problem.

In a square root, just as in any other division, you do not tackle the whole number at once. You split it up into smaller numbers and work with them a few at a time. However, in square roots you do it a little bit differently. You will notice that in Fig. 1B we have placed a comma between the 5 and the 7. This breaks our number up into two numbers, 5 and 76. The method for breaking these numbers up in this way is quite simple. You merely start at the extreme right of the whole number and work toward the left, placing a comma after each group of two numbers. Thus, starting with the 6 and working toward the left we have our first group, 76, and then the 5. Since the 5 is the last number on the left in this particular problem, you have only two groups, one of which is a single number.

Grouping the numbers in this way under the radical sign completes the setup. You are now ready to go to work. You will remember that in division you used a basic multiplication table containing all the products for various combinations of the numbers from 1 to 9. After you had a division problem set up, you tried various products to see which one would go into the dividend. In a square root, you do much the same thing except that you need to know the squares of the numbers from 1 to 9. Fig. 2 is a basic multiplication table showing all the squares of the numbers from 1 to 9 marked with stars. This table and these squares are all you need to work any square root problem.

Now, let's look at the problem again, as shown in Fig. 3A, where it is set up and ready to work on. Since we have broken the number up into two groups, and since the number 5 is alone in the first group, we consider the 5 first. We don't have a divisor to divide into the 5, so we must make one. We do this by determining the largest square that will go into 5. Looking at the table, we see that 2 squared is equal to 4, which is smaller than 5, and 3 squared is equal to 9, which is larger than 5. Since the square of 3 is larger than 5, the square of 2 is the largest perfect square that will go into 5.

Therefore, 4 becomes the first trial product and the 2, which is the square root of 4, is the first trial divisor. Now

*1	2	3	4	5	6	7	8	9
2	*4	6	8	10	12	14	16	18
3	6	*9	12	15	18	21	24	27
4	8	12	*16	20	24	28	32	36

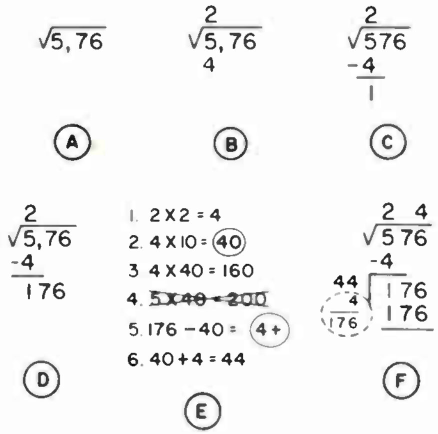

Fig. 3. Steps for working out a square root problem.

that we have found that 4 is the largest square that will go into 5, we place it under the 5 as shown in Fig. 3B. Then, we take the 2, which we squared to get the 4, and place it above the line over the 5 to indicate that it is the first digit of the quotient. This is also shown in Fig. 3B. Next, we subtract the 4 from the 5 to get the first remainder, which is 1, as shown in Fig. 3C. By finding the largest square that will go into the first group in our dividend, we have obtained the first trial product, the first remainder, and the first digit in the quotient.

This first step is the only time we have to use the square of a number when doing square roots. As you can see we never have more than two numbers in any group. The largest number we can possibly have in the first group is 99, and 9 squared, or 81, is the largest square that can go into 99 because 10 squared is 100. This is the reason why we never need more than the basic squares of the numbers from 1 to 9 in order to find the square root of any number.

From now on the problem becomes more like regular division except for the way of obtaining the trial divisors and trial products.

Looking at Fig. 3D, you see that the next step is to bring down the next group of numbers, which is 76. Notice that we bring down the whole group, not just the 7. When we have placed the 76 beside the 1 as shown, we have a trial dividend of 176. Now we must learn the rule by which we establish the next trial divisor. To do this, we take the partial quotient of 2, double it, and then multiply the result by 10.

Following this rule, the partial quotient is 2. If we double it, we get 4. Multiplying the 4 by 10 gives us 40. We use the 40 as the trial divisor. Now we ask ourselves: "How many times will 40 go into 176?" We know that 4 times 40 is 160 which will go into 176 easily. Since 5 times 40 is 200, which is too large to go into 176, 4 is the number we want.

However, we are still not quite finished with the trial divisor. Before we can use it, we have one more step to do. After we have determined that 4 is the largest number of times that 40 will go into 176, we must then *add* the 4 to 40 as shown in Step 6 of Fig. 3E. This gives us 44 which we use as the final trial divisor, as shown in Fig. 3F.

Now, we must multiply 44 by 4 to see if it will still go into 176. As you can see, 4 times 44 is exactly 176 and we will have no remainder when we subtract. Since the trial divisor did go into 176 four times, the second number of the quotient is 4 and can be placed above the line over the second group of numbers. There is no remainder; therefore, the complete quotient is 24, which is the square root of 576. We can prove this by squaring 24, which will give the product of 576.

Although the process of finding the

square root of a number is not difficult, it requires a firm knowledge of some important rules. For this reason we will work out another problem dealing with a larger square. Then you will have a good review of the process as well as some practical experience. Remember, no matter how large the number may be you proceed in the exact same way.

Working Square Root Problems. Let's find the square root of 186,624.

First, set up the problem under the radical sign. Next, separate the number into groups of two numbers, starting at the right and working toward the left, as shown in Fig. 4A. In this problem the radicand (the special name given to the dividend in a square root) is divided evenly into three groups of two numbers each. Since the first group is the number 18, we will find the largest square that will go into 18.

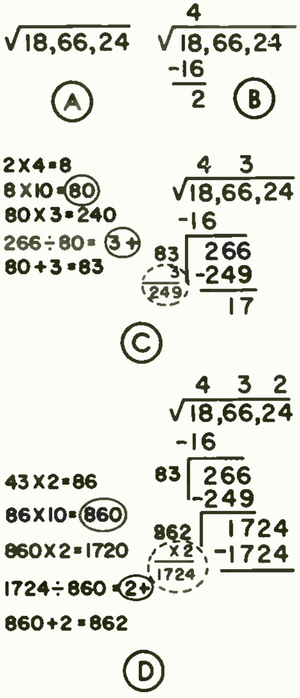

Fig. 4. Finding the square root of a six digit number.

Looking at the multiplication table in Fig. 2 we see that the square of 4 is 16 and that the square of 5 is 25. Twenty-five is larger than 18, so 16 must be the largest square smaller than 18. Therefore, we place the 16 under the 18 in our radicand and subtract, as shown in Fig. 4B. Since 4 is the number that we squared to obtain this trial product, it is the first trial divisor and we place it in the quotient over the number 8 in the first group.

Next, subtract 16 from 18 to get a remainder of 2. Then bring down the next group of two numbers, 66, and place them beside the 2. This gives us a new number, 266, to use as the dividend for the next step, as shown in Fig. 4C. Now you must determine the second trial divisor. Remember, double the existing quotient (4) and then multiply by 10, giving us 80 as shown. Then see how many times 80 will go into 266. For this particular problem, 80 will go into 266 three times. Therefore, we *add* 3 to 80, giving 83 as the second trial divisor. Now, multiply 83 by 3 to get the trial product of 249 which can be subtracted from 266. This subtraction gives a remainder of 17, which is shown in Fig. 4C. Since the trial divisor of 83 went into 266 three times, enter the 3 in the quotient above the line over the second group of numbers, 66.

In this problem we still have another group of two numbers left in our radicand, so we are not finished yet. Therefore, we must bring the 24 down beside the 17 to get the dividend for the next step. As you can see in Fig. 4D, this gives 1724 and you must find a trial divisor for it so that you can find the next number for the quotient.

Proceeding as before, you take the partial quotient, 43, double it to get 86, and then multiply the product by 10, giving you 860. You can see that 860 will go into 1724 only two times. Therefore, you *add* 2 to 860, making 862 the trial divisor. Now, multiplying 862 by 2 gives exactly 1724 and you can subtract without having any remainder. Finally, you place the 2 in the quotient above the 24, giving you the complete square root of 186,624, which is 432. You can check this, of course, by multiplying 432 by itself to see if the product is equal to the radicand you started with.

Although the rules for doing square roots are a little different from those involved in other types of division, they are not any more difficult. Like anything else, it takes practice to become proficient at finding square roots. Most of us don't get this practice after we leave school, so we are likely to forget how to do it. However, in electrical work, square roots can be quite important. Let's try another problem.

In Fig. 5 we have set up the number 7,306,209 to find its square root. Notice that the complete radicand contains seven numbers so it can't be divided evenly into groups of two. Since we always start at the right end of the radicand, we form the groups as shown In this way, a single number will be the first number to the right of the radical sign.

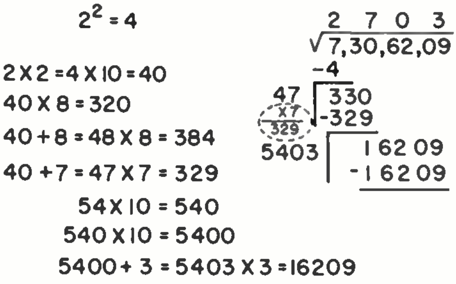

Fig. 5. Another square root problem.

Now, we examine the number in the first group to find the largest square that will go into it. In this problem, the first group is only one number, 7. The largest square that will go into it is 2^2, or 4. Thus, we place a 2 in the quotient or root, directly over the 7. Then we place the square of 2, which is 4, under the 7 and subtract, giving a remainder of 3.

Bring the next group, 30, down beside the 3. Double the root number, 2, making it 4 and multiply it by 10 for the next trial divisor. Now, we determine how many times 40 will go into 330. It looks as if 8 will work because 4 X 8 = 32. However, when we add 8 to 40 to get a trial divisor of 48, we find that 48 X 8 = 384, which is larger than 330. Therefore, we will have to try the next smallest number which is 7.

Notice that we don't multiply 48 X 7. We change the whole trial divisor of 48 to 47 and then multiply 47 X 7 which is equal to 329. In a square root, we often have to reject trial divisors and use new ones that are smaller. Since 329 is smaller than 330, we place the 7 in the root and subtract 329 from 330. This gives a remainder of 1 and we bring down the next group, 62, from the radicand, giving us our new remainder, 162.

We double the two numbers in the root, 27, to get a new trial divisor, which is 54 times 10 or 540. It is obvious at a glance that 540 will not go into 162. Therefore, we place a zero in the root above 62 and then bring down the next two numbers, which are 09. The remainder now becomes 16209.

We double the three numbers in the root, 270, to get the next trial divisor, which is 540 times 10 or 5400. This number (5400) looks as if it will go into

16209 about 3 times. So we add 3 to 5400 to get 5403 and then multiply this number by 3 and get exactly 16209. Since we have no remainder, the problem is completed and we place the 3 in the quotient, or root, above the last group of numbers. Thus, we have found that the square root of 7,306,209 is 2703, which we can prove to be correct by squaring 2703 to get the original radicand.

IMPERFECT SQUARES

So far all the answers have been the roots of perfect squares. Although this is convenient, it does not often happen in practice. There will usually be a remainder, which must be accounted for by making the root end with a decimal number or a fraction. For example, suppose the radicand for the last problem that you worked had been 7,306,976 instead of 7,306,209. If this had been the case, the problem would have worked the same way until you had reached the last part of it, as shown in Fig. 6.

As you can see, the trial product of 5403 X 3 is equal to 16209, but because the original radicand was changed you have a remainder of 767 when you subtract. This is not large enough to increase the root by another whole number to make it 2704, but it does leave a fraction. If the need for accuracy is such that you want to carry the root of 2703 into its fractional part, you would continue the problem as shown in Fig. 6.

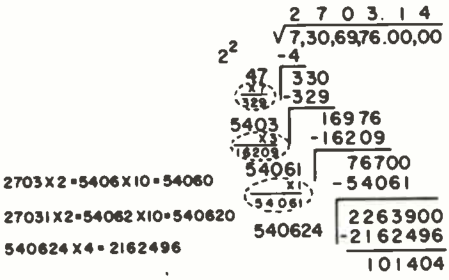

Fig. 6. An imperfect square root carried two places.

To do this, you place a decimal after the last number in the radicand and then add a group of two zeros for each decimal place you want in the root. Notice that there are two zeros added for each decimal place in a square root instead of only one zero, as there is in regular division. In this particular problem, we have carried the answer to two decimal places and have added four zeros as shown.

After you have added the zeros in the radicand and the decimal point in both the radicand and in the root number, you continue in the same manner as before to find the new root numbers. Bring down the first group of two zeros beside the remainder of 767 to give 76700 for the next dividend. Then you double the existing root number, 2703, and multiply the product by 10 to get the trial divisor, 54060. You can quickly see that this will go into 76700 only once, so you add the 1 to it as shown. Then, since any number multiplied by 1 is that same number, you have 54061 for the trial product. Place the 1 in the root.

Subtracting 54061, you get a remainder of 22639. Bring down the next two zeros as shown. Now, double the quotient and multiply by 10, ignoring the decimal in the quotient. In other words, multiply 27031 by 2 to get 54062 and then multiply by 10, making it 540620. Continue as before to find the next root number, which is 4. As you can see, this gives a root of 2703.14 to two decimal places. Since we still have a remainder we do not have a perfect root. Except where extreme accuracy is needed, two decimal places in the answer are enough. Of course, if you do want more accuracy, you would simply continue in the same way by adding two more zeros for each additional decimal place.

You can check your answer in the usual way by squaring the root to see if you get your original radicand. In this problem, if you square 2703.14, you will get an answer of 7,306,965.8596. It is not exactly the same as the original radicand because we did not have a perfect square to start with. However, you can see that the root is close enough and is correct to two decimal places, which is all we are interested in.

FRACTIONS AND DECIMALS

Many times in electronics you will need to find the square root of a fraction or decimal. While the process for finding the roots of fractions or decimals is nearly the same as it is for whole numbers, there is one important thing to remember. The square root of a fraction or decimal will always be larger than its square. You will recall that the product of any two fractions or decimals is always smaller than either of the two numbers. Therefore, the square of any fraction or decimal must also be smaller than the numbers squared.

Finding the square root of fractions is usually very easy, because most fractions have small numbers in both the numerator and the denominator. Also, finding the square roots of small numbers does not involve much work. The first thing to do to find the square root of a fraction is to reduce the fraction as much as possible. Thus, if you wanted to find the root of 6/32, you would first reduce it to 3/16, as shown in Fig. 7A.

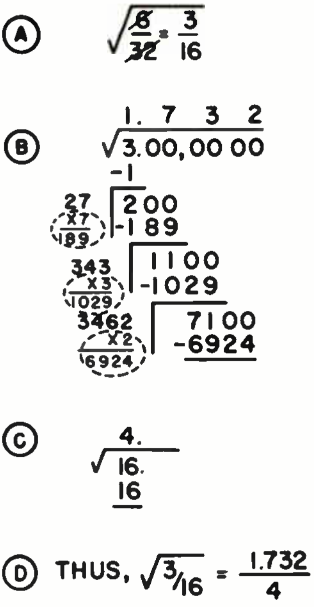

Fig. 7. Finding the square root of a fraction.

Next, separate the numerator and the denominator and find the square root of each one separately, using the same method that you learned for whole numbers. Thus, you would find the square root of 3, which is 1.732 to three places, as shown in Fig. 7B. Then find the square root of 16, which is 4. Now use the root of 3 as the new numerator and the root of 16 as the new denominator. Thus, the square root of 3/16 is 1.732/4 as shown in Fig. 7C. By using this simple method, you can find the square root of any fraction quickly and accurately.

In finding the square root of a decimal, you proceed exactly the same as for a whole number except the grouping will be different when you set up the problem. You still separate the decimal number in groups of two numbers, but with a decimal you start at the decimal point and work to the right. You must always have an even number of digits to the right

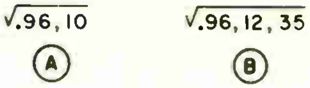

Fig. 8. Setting up a decimal for a square root.

of the decimal place. That is, each group must have two digits. Thus, to set up the decimal .961 for finding its square root, you proceed as shown in Fig. 8A.

After you have placed the number under the radical sign, start at the decimal point and count two numbers to the right and place a comma between the 6 and the 1. Then add a zero after the 1, so that the second group has two digits. If the number were .961235, you would place commas after the 6 and after the 2, as shown in Fig. 8B. The fact that you work from the decimal point to the right in the grouping of the digits is the only difference in the method of finding the square root of a decimal from that of a whole number. In Fig. 9 we have worked out the square root of two decimals. You should not have any trouble in following these examples.

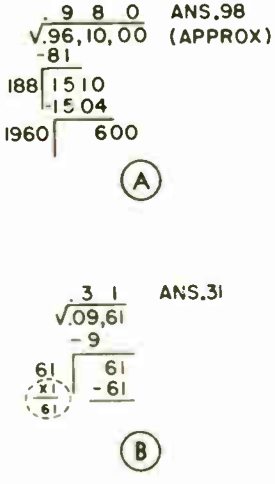

Fig. 9. Finding decimal square roots.

ESTIMATING SQUARE ROOTS

Now that you have seen how to work out the square roots of numbers in detail, let's see how we can apply this process in ac circuits. Suppose, for example, that we want to find the impedance of the circuit shown in Fig. 10. By using the formula

$$Z = \sqrt{R^2 + X^2}$$

and substituting for the values of R and X, we have:

$$Z = \sqrt{50^2 + 60^2}$$

as shown in Step 2 of Fig. 10.

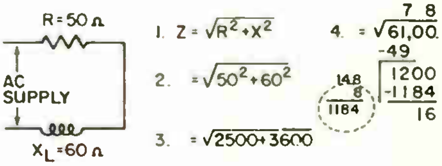

Fig. 10. Using a square root to find impedance.

In working square roots you must follow the rules of order just as in doing any other math. Therefore, the next thing you must do is to perform all the multiplication under the radical sign. This is shown in Step 3. Next add the two squares, which gives 6100. Now go ahead as shown in Step 4. This gives the circuit impedance of 78 ohms and automatically takes care of the phase relationships without having to work with vectors.

Many times, instead of working out the square root of problems accurately, it will be much easier to estimate the answers. For example, take the number 6436. You can see that 80 X 80 is equal to 6400, which gives a remainder of 36. For most purposes this would be close enough, so we would use 80 as the answer.

Likewise, with a number such as 7548, you can see that it is more than 80^2 (6400), but less than 90^2 (8100). Therefore, it would be easy to guess that 84^2 might be close, since 7500 is a little less than halfway between 6400 and 8100. If we square 84, we will find that it is equal to 7056, which is somewhat less than 7548.

When we are this far off in our estimate, the next number we would try would probably be 86 or 87. Let's square 87 and see what we get.

$$\begin{array}{r} 87\\ \underline{87}\\ 609\\ \underline{696}\\ 7569 \end{array}$$

As you can see, this is very close. The difference between 7569 and 7548 is only 21, and unless you require extreme accuracy, you would use 87 as the square root of 7548. By estimating in this way, you can come very close to the square root of any number with a little practice. For large numbers it is generally much easier than working out the root in detail. Try the following problems and see if you can get the answers we have shown:

Find the square root of 625.

Solution:

Ratio and Proportion

There are many times in electronics work when we want to compare quantities. Sometimes we can simply say that something is either larger or smaller than something else, but usually this does not give us enough information. In electronics, as in any other scientific work, we need exact information as to sizes or quantities. For example, saying that one resistor is larger than another is not enough. We must know how much larger it is if we are going to use the resistors for anything practical.

Although we can subtract one quantity from another to find out how much larger it is, there are many times when this type of specific information is not too useful. For example, suppose we want to compare the efficiencies of two electrical circuits. Let's say that one circuit has an input of 400 watts and an output of 300 watts, while the other has an input of 568 watts and an output of 426 watts. If we subtract the input from the output in the first circuit, we find that it has a loss of 100 watts (400 watts – 300 watts). The second circuit, on the other hand, has a loss of 142 watts (568 watts – 426 watts).

By subtracting we find that the loss in the second circuit is 142 watts as compared to a loss of only 100 watts in the first circuit. However, we still don't know which circuit is the more efficient. We know that 42 watts more power is consumed in the second circuit, but since the input and output of this circuit are also larger, this does not tell us anything about its efficiency.

However, there is a method by which we can quickly and accurately compare the losses in the two circuits and determine their relative efficiencies. This is actually a form of division and is known as establishing ratios. For example, if we divide the output of the first circuit by its input and reduce the resulting fraction, we have;

$$\frac{300}{400} = \frac{3}{4}$$

This fractional value of 3/4 tells us that three-quarters of the input power appears as useful output. The remaining one-quarter is the loss in the circuit.

If we do the same thing to the second circuit, we have,

$$\frac{426}{568} = \frac{3}{4}$$

because 142 will go into the numerator 3 times and into the denominator 4 times. Thus, the ratio of the output to the input of the second circuit is exactly the same as the ratio of the output to the input of the first circuit. Their ratios are both 3/4 and, therefore, their efficiencies are the same. In other words, for every 4 watts of input we will get 3 watts of output.

By establishing ratios in this way, we can make many accurate comparisons between various quantities. In addition, through a process known as proportion, we can use an established ratio to compute circuit values much more simply and quickly than we could in any other way. In this section of the lesson, you will learn the rules for establishing ratios and how to apply the ratios in circuit computations.

ESTABLISHING RATIOS

When two quantities are compared by division, we call the ratio of the two quantities the "quotient." Thus, when we divided 426 by 568 and then reduced the resultant fraction to its lowest possible form, we had the ratio of 3/4. We can write such a ratio as the fraction 3/4, or we can use two dots as a ratio sign and write it 3:4. In either case, we say that the ratio is "3 to 4."

In establishing ratios for use in comparing quantities, we must always be sure to express the two quantities in the same units. For example, we can't compare 10 volts with 10 millivolts. We must either change the 10 volts to 10,000 millivolts or change the 10 millivolts to .010 volts before we can establish a ratio between them. Also, the quantities themselves must be of the same kind. We can't, for example, compare a volt with an ampere, or an ohm with a watt. However, there are many times when we can compare seemingly unlike quantities by changing both of them to a third quantity.

For example, suppose a motor's output is 5 horsepower and its input is 4 kilowatts. If we want to establish an output-to-input efficiency ratio for this motor, we can do it quite simply by converting our values. One horsepower is equivalent to 746 electrical watts. To simplify our calculations we will use 750 watts as an approximation. Thus, we can convert 5 horsepower to 5 X 750 or 3750 watts. We also know that 4 kilowatts is equal to 4000 watts. So, by converting both the output and the input to a common unit such as watts, we are able to establish the following ratio:

Given: Output = 5hp
Input = 4kW
Find: Efficiency

$$\text{Efficiency} = \frac{\text{Output}}{\text{Input}}$$

$$= \frac{5\text{hp}}{4\text{kW}} = \frac{5 \times 750}{4 \times 1000}$$

$$= \frac{3750}{4000} = \frac{15}{16} = 15{:}16$$

Thus, the efficiency of the motor can be expressed as the ratio of 15 to 16. If we prefer, we can change the ratio to a percentage value by dividing as follows:

$$\begin{array}{r} .9375 \text{ or } 93.75\% \\ 16\overline{)15.0000} \\ \underline{144} \\ 60 \\ \underline{48} \\ 120 \\ \underline{112} \\ 80 \\ 80 \end{array}$$

In this way, we can express a ratio as a fraction, a decimal value, or a percentage.

The rules for establishing ratios are quite simple. To find the ratio of two similar quantities:

1. Convert the quantities to the same units of measurement.
2. Form a fraction using one quantity as a numerator and the other quantity as a denominator.
3. Reduce the fraction to its lowest possible form.
4. If you wish, you can divide the denominator into the numerator to express the ratio as a decimal or as a percentage.

PROPORTION

Even though ratios are extremely useful for comparing similar quantities, they

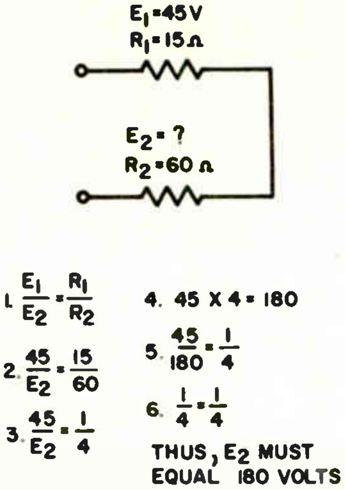

Fig. 11. Using ratio and proportion to solve for circuit values.

are probably even more useful as a computing tool. By setting certain ratios equal to each other in what is known as a proportion, we are able to make many shortcuts in circuit calculations. For example, suppose we had a circuit such as the one shown in Fig. 11 and wanted to know the voltage across R_2. Ordinarily, in a series circuit such as this, we would first find the current through R_1 by using the formula $I = E_1 \div R_1$. Then, since the current is the same in all parts of a series circuit, we would find E_2 by multiplying I by R_2. However, by using ratio and proportion we can find either the voltage across R_2 or the total voltage in one simple operation, without ever knowing the current at all. Thus, ratio and proportion save time and work by eliminating the step of finding the current.

In order to use proportion, you have to remember one simple rule. That is, a proportion is a mathematical statement that two ratios are equal. For example, refer back to the efficiency problem in the two circuits you studied earlier in this lesson. You recall that in the first circuit we had an efficiency of

$$\frac{300}{400} = \frac{3}{4}$$

Likewise, in the second circuit the efficiency was

$$\frac{426}{568} = \frac{3}{4}$$

Thus, both of the ratios are equal and we can actually indicate this mathematically as

$$\frac{300}{400} = \frac{426}{568}$$

because, when we reduce both fractions, we have 3/4 on both sides of the equal sign. Therefore, it is a proportion because it contains two equal ratios.

Now, let's see how we can apply this type of thinking to the circuit in Fig. 11. First, let's establish a resistance ratio for the circuit. We do this by dividing R_1 by R_2 to get the ratio 15/60 or 1/4. Now, let's find the current in the circuit by dividing E_1 by R_1 and then find the voltage across E_2 by using the method we are familiar with. If we do this, we find that:

$$\begin{aligned} I &= E_1 \div R_1 \\ &= 45 \div 15 = 3 \text{ amps} \\ \text{Then, } E_2 &= R_2 \times I \\ &= 60 \times 3 \\ &= 180 \text{ volts} \end{aligned}$$

If we form another ratio from the voltages across E_1 and E_2, we will have

45/180 = 1/4. Notice that this voltage ratio is exactly the same as the resistance ratio and, therefore, the two ratios must be equal. Accordingly, we can establish a proportion with the two equal ratios by stating them mathematically as:

$$\frac{R_1}{R_2} = \frac{E_1}{E_2}$$

or

$$\frac{15}{60} = \frac{45}{180}$$

or

$$\frac{1}{4} = \frac{1}{4}$$

All three expressions are proportions and say exactly the same thing.

Suppose we knew that the resistance and voltage ratios were equal to begin with. Actually, we can easily see that they would be, because the voltage drops around a circuit must distribute themselves in accordance with the size of the resistances. If we had realized this, we could have set up our proportion as shown in Fig. 11 to begin with, and substituted all our known values as follows:

$$\frac{E_1}{E_2} = \frac{R_1}{R_2}$$

Substituting, we have:

$$\frac{45}{E_2} = \frac{15}{60}$$

This, of course, gives us what we call an "equation" that has one unknown value.

Now that we know that the two ratios are equal, we can find the value of E_2 quite simply. If we reduce the 15/60 to its lowest form of 1/4, we have

$$\frac{45}{E_2} = \frac{1}{4}$$

Since one side of our proportion will reduce to 1/4, the other side must also reduce to 1/4 so that the two sides can be equal. Thus, all we have to do is replace the denominator, E_2, in our first ratio, with a number that is equal to 4 times 45. Since 4 X 45 = 180, E_2 must be equal to 180 because 45/180 is the only fraction with 45 as the numerator that will reduce to 1/4. We must be able to reduce both sides to 1/4 in order to have a proportion.

Although this may seem a little complex at first, let's consider the following conditions which should clear it up. If 3 resistors cost 75 cents, we know that 6 resistors must cost $1.50. At the given rate, the cost of the resistors must depend only on the number bought. The more resistors we buy, the larger the cost will be. The fewer we buy, the less the cost will be. When two quantities depend on each other in this way, they are said to be in proportion.

We have already said that a proportion is a mathematical statement that says two ratios are equal. In this problem, the two quantities that make up the ratios are the number of resistors, N, and the cost, C. Since the cost depends on the number of resistors bought, we can write a proportion.

First Purchase	Second Purchase
N_1 = 3 resistors	N_2 = 6 resistors
C_1 = $.75	C_2 = $1.50

The ratio of the number of resistors is:

$$\frac{N_1}{N_2} = \frac{3}{6} = \frac{1}{2}$$

The ratio of the cost is:

$$\frac{C_1}{C_2} = \frac{75}{150} = \frac{1}{2}$$

Since the two ratios are equal, the proportion is written mathematically as:

$$\frac{N_1}{N_2} = \frac{C_1}{C_2}$$

or

$$\frac{3}{6} = \frac{75}{150}$$

or

$$\frac{1}{2} = \frac{1}{2}$$

This is an example of a direct proportion. When two quantities depend on each other so that one increases as the other increases, or one decreases as the other decreases, they are said to be directly proportional. This is what we mean when we say that the current through a fixed resistance is directly proportional to the voltage applied. As the voltage increases, the current increases, etc.

Notice that when we set up two equal ratios as a direct proportion, we must compare the two ratios in the same order. In other words, we used the quantities in the first situation, N_1 and C_1, as numerators, and the quantities in the second situation, N_2 and C_2, as denominators. Thus, they are in the same order because the second ratio, C_1/C_2, is patterned after the first, N_1/N_2. However, we could have written the proportion in the opposite form. For example,

$$\frac{C_1}{C_2} = \frac{N_1}{N_2}$$

or

$$\frac{C_2}{C_1} = \frac{N_2}{N_1}$$

or

$$\frac{N_2}{N_1} = \frac{C_2}{C_1}$$

As you can see, it is not important which ratio is written first or how it is written. However, in a direct proportion, the second ratio must always be written in the same order as the first.

Thus, the rules for setting up a direct proportion for two variables that depend on each other are:

1. Make a ratio of either one of the variables.
2. Make a ratio of the other variable in the same order.
3. Make the two ratios equal to each other.

SOLVING PROPORTIONS

In the first example of a proportion that we solved, we reduced the completed ratio to its smallest possible form. Then we found a number for the unknown in the incomplete ratio that would allow it to be reduced to the same form. While this is actually what we must do in order to find the solution for any proportion, there is a shortcut which we can use that makes it much easier. This shortcut is called "cross-multiplication" and we will learn later how it can be used. It always works and we should learn how to use it.

For example, suppose we have a length of cable that is 78 ft. long and another length of the same kind that is 4 ft. long. We want to know how much the longer piece of cable weighs, but because it is bulky and hard to handle it will be difficult to weigh it. In this case, we could weigh the smaller length of cable and then set up a proportion and find the weight of the longer piece.

Let's say that the shorter piece weighs ten pounds. We would set up the proportion as follows:

$$\frac{L_L}{L_S} = \frac{W_L}{W_S}$$

L_L = length of longer cable
L_S = length of shorter cable
W_L = weight of longer cable
W_S = weight of shorter cable

Now, by substituting values, we have:

$$\frac{L_L}{L_S} = \frac{W_L}{W_S}$$

$$\frac{78}{4} = \frac{W_L}{10}$$

To apply our shortcut using cross-multiplication, we multiply the numerator of one fraction by the denominator of the other as follows:

$$4 \times W_L = 78 \times 10$$
$$4W_L = 780$$

Now we have a familiar equation form to work with and we know that if

$$4W_L = 780\text{, then}$$
$$W_L = 780 \div 4 = 195$$

Therefore, the weight of the large, bulky piece of cable is 195 lbs.

Another example of the same problem in a slightly different situation might be quite common in your work in electronics. Suppose the longer piece of cable were wound on a reel and you wanted to know how long it was without unwinding it. Since it was wound on a reel, it would be easy to handle and we could weigh it quite easily. Then, by weighing the shorter piece, and setting up the proportion using the two weights and the length of the short piece, we could find the length of the long piece. Suppose the cable on the drum weighed 425 pounds, while the short piece was 4 ft. long and weighed ten pounds. First, we would have to subtract the weight of the reel itself, say 25 pounds, and then set up the proportion:

$$\frac{L_L}{L_S} = \frac{W_L}{W_S}$$

$$\frac{L_L}{4} = \frac{(425 - 25)}{10}$$

$$\frac{L_L}{4} = \frac{400}{10}$$

By cross-multiplying, we have:

$$10 \times L_L = 4 \times 400$$
$$10\ L_L = 1600$$
$$L_L = 1600 \div 10$$
$$L_L = 160\text{ ft.}$$

The steps for solving any direct proportion are always the same.

1. Set up the direct proportion:

$$\frac{X_1}{X_2} = \frac{Y_1}{Y_2}$$

2. Substitute numbers where possible:

$$\frac{10}{100} = \frac{50}{X}$$

3. Cross-multiply:

$$10 \times X = 50 \times 100.$$

4. Simplify: $10X = 5000$.

5. Solve for the unknown by dividing:

$$X = 5000 \div 10$$

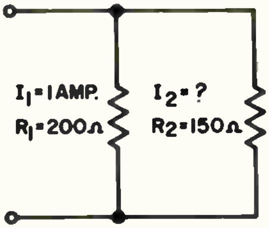
6. Answer: $X = 500$.

Inverse Proportion. So far in our discussion of proportion, we have considered only what happens when two quantities vary directly. Many times two quantities depend on each other, but instead of varying directly they do just the opposite. When one increases, the other must decrease an appropriate amount. When this occurs, we say the two quantities vary indirectly or "inversely" and that they are inversely proportional. The current and resistance in an electrical circuit, with a fixed voltage, is a good example of an inverse proportion. As the resistance increases, the current decreases.

We can set up inverse proportions mathematically just as we do direct proportions except for one major difference. In an inverse proportion, we always set up the second ratio in the opposite or inverse order. For example, consider the parallel circuit shown in Fig. 12.

In this circuit we are given the values of the two resistances and the current through one of them. We could find the current, I_2, by finding the voltage across R_1, and since the voltage across R_2 would be the same we could find I_2 by using this voltage. However, we can solve this problem in a much simpler manner. There is just one thing to remember. The current and the resistance vary inversely and, therefore, we must use an inverse proportion. To do this, we set up the first ratio. It doesn't make any difference which one we use first or how we set it up, as long as we set up the next one in the opposite manner.

For example, in the circuit of Fig. 12, let's use the current ratio first as I_1/I_2. Then, the resistance ratio in the reverse order R_2/R_1, and then set them equal to each other as follows.



1. $\frac{I_1}{I_2} = \frac{R_2}{R_1}$

2. $\frac{1}{I_2} = \frac{150}{200}$

3. $150 \times I_2 = 200 \times 1$

4. $150\, I_2 = 200$

5. $I_2 = 200 \div 150$

6. $I_2 = 1.33$ AMPS

Fig. 12. Using an inverse proportion to solve for current.

$$\frac{I_1}{I_2} = \frac{R_2}{R_1}$$

Substituting, we get:

$$\frac{1}{I_2} = \frac{150}{200}$$

$$\begin{aligned} 150 \times I_2 &= 200 \times 1 \\ 150\, I_2 &= 200 \\ I_2 &= 200 \div 150 \\ I_2 &= 1.33 \text{ amps.} \end{aligned}$$

As you can see, the solution is obtained in exactly the same manner as in a direct proportion. The only difference is that we reversed the order of the second ratio from that of the first when we set up the ratios.

You will recall that when we first discussed establishing ratios we mentioned that a ratio could be written as 5:2 as well as 5/2. We can also write proportions in two ways, depending upon which way we indicate our ratios. For example, the proportion

$$\frac{10}{20} = \frac{50}{100}$$

would be written as 10:20 :: 50:100, using the two dots as ratio signs and the four dots to indicate proportion. When a ratio is written in this way, there is no cross-multiplication indicated, as there is in the fractional form, and we use a different way of indicating the solution.

In the form 10:20 :: 50:100, we give a name to both parts of the proportion. We call the two outside numbers, 10 and 100, the "extremes" of the proportion. The two inside numbers, 20 and 50, are called the "means" of the proportion. Now, we say that the product of the means is equal to the product of the extremes. In other words, the product of the two outside numbers is equal to the product of the two inside numbers. As you can see, remembering this and using it with this form of the proportion gives us exactly the same thing as cross-multiplying a proportion that is written in the fractional form.

$$\frac{10}{20} = \frac{50}{100}$$

$$20 \times 50 = 10 \times 100$$

or

10:20 :: 50:100

$$20 \times 50 = 10 \times 100$$

Using ratios in proportion to solve for unknown quantities is one of the handiest tools in mathematics. It is not only easy to use and work with, but it is easy to remember the rules. No matter where you go or what you do, you can almost always find some use for ratio and proportion in solving problems. You will be very pleased with the amount of work it can save you.

Positive and Negative Numbers

Many of the calculations, graphs, and tables that are used to solve problems in both ac and dc circuits require an understanding of positive and negative numbers. These numbers are commonly called "signed" numbers and are used to indicate opposite amounts. These opposite amounts might be some of the following: gain or loss in voltage, increase or decrease in volume, currents that flow in opposite directions, capacitive or inductive reactance, etc.

In our everyday lives we commonly indicate opposite quantities by various pairs of words, such as north and south, up and down, and gain or loss. In electronics, we use opposite quantities so often that it is much easier to indicate them by using plus (+) and minus (–) signs. For example, 5° above zero is written as +5°, and 5° below zero is written as –5°. A current in one direction would be +10 amps, but a current in the opposite direction would be –10 amps.

Numbers preceded by a minus sign are called negative numbers. A positive number is indicated by a plus sign. However, many times a positive number will not have any sign at all. Thus, a number with no sign is always considered a positive number. A number is never considered to be negative unless it has a minus sign. Generally, increases and gains, and directions to the right and upward are considered to be positive (+). Losses and decreases, directions to the left and downward are considered negative (–).

Since your work in electronics involves signed numbers so often, you must be very familiar with them. You will have to be able to add and subtract them from each other as well as be familiar with multiplying and dividing them. In this section of the lesson you will learn how to perform these basic operations with signed numbers.

ADDING SIGNED NUMBERS

Probably the best way to understand positive and negative numbers is to represent them on a graph as shown in Fig. 13.

Fig. 13. Graph showing arrangement of positive and negative numbers.

As you can see, there is a reference point or zero mark at the center of the scale with the positive numbers extending to the right and the negative numbers to the left. A scale of numbers like this is very handy for showing both addition and subtraction of signed numbers. For example, if we want to add +3 and +5, we start at zero and count three numbers to the right which will bring us to +3. Then, we start at +3 and count five more numbers to the right, which brings us to +8, as shown by the arrows in Fig. 14.

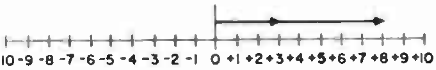

Fig. 14. Adding +3 and +5 graphically.

Thus, adding +3 and +5 gives us +8 which is the same as the addition we studied in basic arithmetic. Likewise, suppose we want to add −4 and −3. We can also do this graphically as shown by the arrows in Fig. 15. Notice that we first count four units to the left of the zero because all negative numbers increase in size as we move toward the left. This brings us to −4. Then we start from −4 and count three more units to the left which brings us to −7. Thus, the sum of −7 is obtained by adding −4 and −3.

Fig. 15. Adding −4 and −3 graphically.

This brings us to the first rule in dealing with signed numbers. When two or more numbers have the same sign (all positive or all negative), they are said to have "like signs."

The first rule for addition of signed numbers is: ***To add two or more numbers with like signs, find the sum of the numbers as you would in ordinary arithmetic and place the sign of the numbers added in front of this sum.*** Thus, the sum of −3, −5, and −7 would be −15; and the sum of +6, +8, +9, and +2 would be +25.

However, we will also be dealing with both positive and negative numbers at the same time. For example, suppose we have to find the sum of +2 and −5. We know how to add two and five when both numbers have the same sign, but here each has a different sign. How will we handle it?

To begin with, let's start with a graph as we did for numbers with like signs. First, we start at the zero reference point and count two units to the right which brings us to +2, as shown by the short arrow in Fig. 16. This takes care of the +2 in our addition and now we can consider the −5. We know that in order to arrive at −5 we would normally start at zero and count five units to the left. However, we are at +2 and must start at +2 instead of zero when we begin to add our −5. Therefore, instead of starting at the zero reference and counting five units to the left, we start at +2 and count five units to the left, as shown by the long arrow in Fig. 16.

This brings us to −3 on the graph. Accordingly, since we have added two arrows, one which is +2 units long and the other −5 units long, and arrived at −3, it follows that the sum of +2 and −5 must be −3. If we look at this addition of two numbers with "unlike" signs closely, we can see that we have actually found the difference between the two numbers (5 − 2 = 3) and then used the sign of the largest number (−5) in front of our answer (−3).

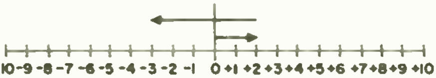

Fig. 16. Adding numbers with unlike signs graphically.

The second rule for addition of signed numbers is: ***The sum of two signed numbers with unlike signs is equal to the difference between the two numbers, preceded by the sign of the largest number.*** Remember that although we find the difference of the two numbers, it is not subtraction. It is the addition of numbers with unlike signs.

Here are a few examples of the addition of signed numbers following the two rules which we have learned. Try them and see if you get the same answers that we do.

$$\begin{array}{rrrrr} -\ 7 & -9 & +10 & -63 & +1/2 \\ \underline{-\ 8} & \underline{+7} & \underline{-\ 6} & \underline{+46} & \underline{-1/4} \\ -15 & -2 & +\ 4 & -17 & +1/4 \end{array}$$

$$\begin{array}{rrrr} -.25 & +\ 5 & +6 & -20 \\ \underline{+.05} & \underline{+\ 6} & \underline{-5} & \underline{+18} \\ -.20 & +11 & +1 & -\ 2 \end{array}$$

SUBTRACTING SIGNED NUMBERS

When you studied basic subtraction in earlier lessons, you asked, "What number must be added to a given number to give another given number?" In other words, in subtracting 5 from 9 you asked, "What number added to 5 will give 9?" The answer is 4, because 4 + 5 is equal to 9. In subtracting signed numbers you do exactly the same, but you have to be very careful to watch the signs.

For example, consider the problem of subtracting –4 from –9. In order to do this, we ask what number added to –4 will give us –9. Of course, there is only one number and that is –5, because –4 + (–5) is equal to –9. Therefore, –4 from –9 is equal to –5.

We can also illustrate this graphically as shown in Fig. 17. First, we draw an arrow from the zero point to –9 as shown by the long arrow. Then, we draw an arrow from zero to –4 to represent the value (–4) that we are subtracting, as shown by the short arrow. Now, if we count the units between –4 and –9 as shown by the dotted arrow, we can see that we have five units to the left which means that –5 is our answer.

Now that we know what happens when we subtract a positive number from a positive number, (+9) – (+5) = +4, and also what happens when a negative number is subtracted from a negative number, (–9) – (–4) = –5, let's consider the subtraction of numbers with unlike signs. Suppose that we want to subtract –3 from +6. First, we ask ourselves, "What number added to –3 will give us +6?" If we look at this closely, we will see that +9 is the only number that can be added to –3 to give us +6 because,

$$(+9) + (-3) = +6$$

Therefore, (+6) – (–3) must be equal to +9.

Fig. 18 shows this graphically. First, we draw an arrow from zero to +6 to represent +6. Then, we draw an arrow from zero to –3 to represent –3. Now, we start at the –3 and count towards the right to see how many units would have to be added to –3 to give us +6. If we count off these units, we will find that there are nine of them. Since we move from left to right, the 9 must be +9. Thus, we can prove that

$$(+6) - (-3) = +9$$

Suppose, however, that we have the same numbers with the signs reversed. What is (–6) – (+3) equal to? Once again,

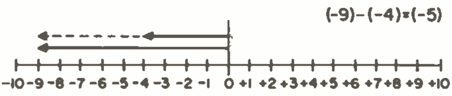

Fig. 17. Subtracting signed numbers graphically.

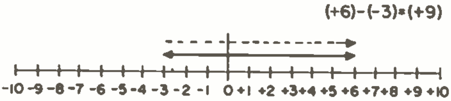

Fig. 18. Subtracting numbers with unlike signs.

we ask ourselves, "What number added to +3 will give −6? Of course +3 plus −9 is the only answer. Therefore, (−6) − (+3) must be equal to −9. Graphically, we can show this in Fig. 19. We draw an arrow from zero to −6. Then we draw an arrow from zero to +3. Now, we can see that −6 is nine units to the left of +3, as shown by the dotted arrow. Since we go to the left, this 9 must be −9.

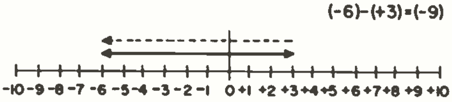

Fig. 19. Subtracting +3 from −6 graphically.

Now look carefully at the examples that we have just discussed:

$$\begin{array}{r} +9 \\ -(+5) \\ \hline +4 \end{array} \quad \begin{array}{r} -9 \\ -(-4) \\ \hline -5 \end{array} \quad \begin{array}{r} +6 \\ -(-3) \\ \hline +9 \end{array} \quad \begin{array}{r} -6 \\ -(+3) \\ \hline -9 \end{array}$$

Notice that they all have one thing in common. That is if we change the sign in the subtrahend (the number subtracted), and then add the two numbers, we will get the proper answer. For example, consider the problem of:

$$\begin{array}{r} -9 \\ -(-4) \\ \hline -5 \end{array}$$

If we set this up and change the −4 to a +4 as

$$\begin{array}{r} -9 \\ +4 \\ \hline \end{array}$$

and then add, we will get −5 for the answer.

The rule for subtracting signed numbers is: ***To subtract signed numbers, change the sign of the number you wish to subtract (subtrahend) and then add the two numbers.*** This rule will work for subtracting any two signed numbers no matter how small or large they may be. We have given some examples for you to try. Notice that the numbers and their signs are enclosed in parentheses so they will not be confused with the subtraction (−) sign.

1. $(-25) - (-15)$
   $= (-25) + (+15) = -10$
2. $(-18) - (+6)$
   $= (-18) + (-6) = -24$
3. $(+29) - (+7)$
   $= (+29) + (-7) = +22$
4. $\left(-\dfrac{1}{8}\right) - \left(+\dfrac{1}{16}\right)$
   $= \left(-\dfrac{2}{16}\right) + \left(-\dfrac{1}{16}\right) = -\dfrac{3}{16}$
5. $(+.36) - (-.05)$
   $= (+.36) + (+.05) = +.41$

MULTIPLYING SIGNED NUMBERS

You learned that multiplication is the addition of a number to itself an indicated number of times. Thus, 5 × 6 tells us to either add 6 to itself five times or to add 5 to itself six times. The multiplication of positive and negative numbers is just the same, except that we must consider what to do about the signs. In order to do this, let's consider all the possible combinations of signs that we might have in multiplying two numbers.

There are only four possible combinations and they are as follows:

(1) $(+2) \times (+3) = ?$
(2) $(-2) \times (+3) = ?$
(3) $(+2) \times (-3) = ?$
(4) $(-2) \times (-3) = ?$

Now, you already know that the first situation is the same as saying that +2 is to be added three times, or:

$$(+2) + (+2) + (+2) = +6$$

Therefore,

$$(+2) \times (+3) = +6.$$

In the same manner, the second situation simply states that −2 is to be added together three times, or:

$$(-2) + (-2) + (-2) = -6$$

Therefore,

$$(-2) \times (+3) = -6.$$

From what we have seen so far, multiplying two positive numbers together gives us the product of the two numbers preceded by a plus sign. Also, in a similar manner, the product of a negative number multiplied by a positive number is the product of the two numbers preceded by a minus sign. Thus, we have taken care of the first two situations.

The third situation says that we must add +2 to itself −3 times. If we stop to consider this for a minute, we can see that if we add a number to itself a minus number of times, it will be the same as subtracting the +2 from zero three separate times. Therefore, $(+2) \times (-3)$ is the same as $-(+2) - (+2) - (+2)$. If we change the signs and add as we do in any problem of subtracting signed numbers, we have:

$$(-2) + (-2) + (-2) = -6.$$

Thus, $(+2) \times (-3)$ must be equal to −6. This is the same answer we got for the second situation which was

$$(-2) \times (+3) = -6.$$

This is right because you learned that the order in which the numbers are arranged does not make any difference in multiplication. Thus, we can now say that the product of any two numbers with unlike signs is always negative.

Now, let's look at the fourth situation. Here we have $(-2) \times (-3)$, which is the same as saying −2 added to itself −3 times. Once again, adding a number to itself a minus number of times must be the same as subtraction. Therefore, we can write it as

$$-(-2) - (-2) - (-2) = ?$$

However, once again we are subtracting signed numbers and we must change the signs and add. Consequently, we would rewrite the problem

$$(+2) + (+2) + (+2) = ?$$

which of course equals +6. From this, we can say that

$$(-2) \times (-3) = +6$$

and, accordingly, the product of any two negative numbers is always positive.

Reviewing all that we have just discussed, we find that there are two simple rules for the multiplication of two signed numbers:

1. The product of any two numbers with like signs is always positive.

2. The product of any two numbers with unlike signs is always negative.

With these two rules you can handle the multiplication of any two signed numbers.

Sometimes you may have more than two signed numbers to multiply together. In such a case, you simply take the numbers two at a time and then multiply the product by the next number. For example:

$$(-2) \times (+3) \times (-4) = ?$$

First take $(-2) \times (+3)$, which equals -6, then the product $(-6) \times (-4) = +24$. Therefore, $(-2) \times (+3) \times (-4) = +24$.

Another example is:

$$(+2) \times (-5) \times (-7) \times (+11) = ?$$

First, $(+2) \times (-5) = (-10)$
Then, $(-10) \times (-7) \times (+11) = ?$
Now, $(-10) \times (-7) = +70$
Then, $(+70) \times (+11) = +770$

DIVIDING SIGNED NUMBERS

Because division is just the reverse of multiplication, you should not have any trouble learning to divide signed numbers. Remember, when you divide one number by another you ask, "What number, when multiplied by the divisor (the number you divide by), will equal the dividend?" In other words, if you wish to divide 30 by 5 you say, "Since 5 X 6 is equal to 30, then 30 ÷ 5 must equal 6."

In dividing signed numbers you do the same thing, except that you must be careful to obtain the proper sign for the quotient. Once again, let's consider all the possible combinations of signs that we might have in dividing one number by another. There can be only four combinations as follows:

(1) $(+30) \div (+6) = ?$
(2) $(-30) \div (+6) = ?$
(3) $(+30) \div (-6) = ?$
(4) $(-30) \div (-6) = ?$

Because division is the opposite of multiplication, we must have the following:

(1) $(+30) \div (+6) = +5$ because $(+5) \times (+6) = +30$
(2) $(-30) \div (+6) = -5$ because $(-5) \times (+6) = -30$
(3) $(+30) \div (-6) = -5$ because $(-5) \times (-6) = +30$
(4) $(-30) \div (-6) = +5$ because $(+5) \times (-6) = -30$

Therefore, our two rules for division of signed numbers are as follows:

1. If both numbers have like signs, the quotient is always positive.

2. If the numbers have unlike signs, the quotient is always negative.

This is all you need to know in order to handle the division of any two signed numbers.

EXPONENTS AND ROOTS

Let's consider the effect of signs on numbers with exponents or roots. You have already learned that the square of a number is the product of a number that is multiplied by itself. You also learned that you can use a small number "2" written above and to the right of the number to indicate that it is to be squared. Thus, 13^2 means 13 X 13, which is 169. We call the small "2" above the 13 an exponent. When we use 2 as an exponent to indicate the operation of squaring a number, we sometimes say that it means raising the number to its second power.

Just as we can raise a number to its second power by multiplying it by itself, we can also raise numbers to other powers. For example, 13^3 means that the number is to be raised to its third power, or 13 X 13 X 13, which equals 169 X 13 or 2197. In this case, the exponent is a 3 and indicates that the number must be raised to its third power. In the case of the third power of a number, we have a special name for the operation just as we do for the second power (square). For the third power, we call it "cubing" a number, or finding the cube of a number.

Of course, we can raise a number to any power that we desire, simply by multiplying it by itself the proper number of times. In each case, the exponent indicates the power to which the number must be raised. Thus, 23^4 means 23 X 23 X 23 X 23, and 17^6 means 17 X 17 X 17 X 17 X 17 X 17. However, beyond the third power (cube) we have no special names because the operation is not common enough. We simply say the "fourth power of the number" or the "sixth power" or whatever power the exponent may indicate.

If a number has a sign in front of it, we proceed just as we would in multiplying any series of signed numbers. For example, $(-3)^2$ would be

$$(-3) \times (-3) = +9$$

and $(-3)^3$ would be

$$\begin{aligned} & (-3) \times (-3) \times (-3) \\ = & (+9) \times (-3) \\ = & -27 \end{aligned}$$

Likewise, $(-2)^4$ would be

$$\begin{aligned} & (-2) \times (-2) \times (-2) \times (-2) \\ = & (+4) \times (-2) \times (-2) \\ = & (-8) \times (-2) \\ = & +16 \end{aligned}$$

It is interesting to notice that a negative number squared always gives a positive product, while a negative number cubed always gives a negative product. This is true because any two negative numbers multiplied always give a positive product and any three negative numbers multiplied always give a negative product. With a negative number, any even-numbered exponent, such as 4, 8, 28, or 32, always gives a positive product and any odd-numbered exponent gives a negative product.

Just as every number can be raised to any power, every number has an infinite number of roots. You learned earlier in this lesson what is meant by the square root of a number and that this operation is indicated by the use of the radical sign $\sqrt{\quad}$. Therefore, if $13^2 = 13 \times 13$ or 169, then $\sqrt{169}$ is equal to 13. You also learned that $-13^2 = (-13) \times (-13)$ which is also 169. Therefore, we have two possible square roots of 169, either +13 or −13. In fact, any positive square has two possible square roots: a positive root or a negative root. If there is any question as to the sign of a square root, we write the root and use both signs. Thus, we would indicate the square root of 169 as ±13. We read this as "plus or minus 13."

The symbol for a square root is the radical sign $\sqrt{\quad}$. The same basic sign is used to indicate the root of any number, except that we use an "index" number in the notch of the sign to indicate that particular root. Thus, $\sqrt[3]{27}$ means the cube root of 27. We find that it is 3, because 3 X 3 X 3 equals 27. Likewise, $\sqrt[4]{16}$ means that we are to find the fourth root of 16 which is 2, because 2 X 2 X 2 X 2 equals 16. Of course the square or second root of any number should be indicated with an index of 2 in the radical sign as $\sqrt[2]{4}$. However, in square roots it is common practice not to write 2 as the index so we just use the radical sign by itself. Thus, a radical sign with no index always indicates a square or second root and any other desired root must be indicated by using the proper index.

Just as the root of any positive square may be either positive or negative, the even-numbered roots of any number raised to a power may also be either positive or negative. In other words, $\sqrt[4]{16}$ may be either ± because either -2^4 or $+2^4$ is equal to +16. Cube roots, however, or any other odd-numbered roots will be positive or negative depending on the sign of the number. Thus, $\sqrt[3]{27}$ must be +3 because $(+3) \times (+3) \times (+3)$ equals 27. Therefore, $(-3) \times (-3) \times (-3)$ can never be equal to +27; it will always equal −27. So $\sqrt[3]{-27}$ equals −3. The cube root of any negative number must be equal to a negative number. Other odd-numbered roots follow the same rule. For example, $\sqrt[5]{32}$ always equals +2 because;

$$(+2) \times (+2) \times (+2) \times (+2) \times (+2) = +32$$

while

$$(-2) \times (-2) \times (-2) \times (-2) \times (-2) = -32$$

You will notice that we have not mentioned how to find the square root of a negative number. This is because it is impossible. As far as we know, there is no number multiplied by itself which can give a negative square. A negative number squared is always positive, and a positive number squared is always positive. The product $+2 \times (-2)$ is not a square because, if you notice the signs, we are not multiplying the same number by itself. We will learn more about this later in the course.

MULTIPLYING AND DIVIDING BY POWERS OF TEN

One of the greatest advantages of the decimal system is that in multiplying or dividing by 10 we simply move the decimal point. For example, if we multiply 237 by 10 the answer is 2370 because we move the imaginary decimal point, which is after the seven, one place to the right. To divide by 10, we move the decimal point one place to the left. Thus, 237 ÷ 10 is 23.7; in other words 10 goes into 237 twenty-three and 7/10 times.

You know that 2×2 is often written 2^2. Also, $2 \times 2 \times 2$ is written 2^3. Similarly 10×10 is written 10^2. Also, $10 \times 10 \times 10 = 10^3$, and $10 \times 10 \times 10 \times 10 = 10^4$ and so on. Thus, summarizing:

$10^0 = 1$
$10^1 = 10$
$10^2 = 10 \times 10 = 100$
$10^3 = 10 \times 10 \times 10 = 1000$
$10^4 = 10 \times 10 \times 10 \times 10 = 10{,}000$
$10^5 = 10 \times 10 \times 10 \times 10 \times 10 = 100{,}000$
$10^6 = 10 \times 10 \times 10 \times 10 \times 10 \times 10 = 1{,}000{,}000$

Why $10^0 = 1$ will be explained later in this section.

To multiply 237 by 10 we move the decimal point one place to the right. To multiply by 100, or 10^2, we move the decimal point two places to the right. To multiply by 1000, or 10^3, we move the decimal point three places to the right, etc.

To divide, we do the opposite. To divide by 100, or 10^2 we move the decimal point two places to the left, etc. Thus:

$237 \times 10 = 2370$
$237 \times 100 = 237 \times 10^2 = 23700$
$237 \times 1000 = 237 \times 10^3 = 237000$
$237 \div 10 = 23.7$
$237 \div 100 = 237 \div 10^2 = 2.37$
$237 \div 1000 = 237 \div 10^3 = .237$

Any number can be expressed in terms of a number between 1 and 10 times a power of 10. For example, 237 can be written as $2.37 \times 10 \times 10$. Rather than write the number out this way we usually write it 2.37×10^2. Similarly, 7648 can be written 7.648×10^3. Also, you can write 93486 as 9.3486×10^4.

Now consider the problem of multiplying 237×393. We rewrite 237 as 2.37×10^2, and 393 as 3.93×10^2. This breaks the problem down to:

$$2.37 \times 10^2 \times 3.93 \times 10^2$$

which we can regroup as:

$$2.37 \times 3.93 \times 10^2 \times 10^2$$

When two powers of 10 are multiplied together, you perform the multiplication simply by adding the exponents. In the expression 10^2, the exponent is 2. In 10^3 the exponent is 3. To multiply $10^2 \times 10^3$, you simply add the exponents and the problem becomes:

$$10^2 \times 10^3 = 10^{2+3} = 10^5$$

To multiply $10^3 \times 10^5$ proceed the same way:

$$10^3 \times 10^5 = 10^{3+5} = 10^8$$

If this seems somewhat confusing to you, or if you doubt that $10^3 \times 10^5 = 10^8$, you can write out 10^3 as $10 \times 10 \times 10$, and write out 10^5 as $10 \times 10 \times 10 \times 10 \times 10$, and then multiply them together, and you'll find that the answer is 10^8.

Now to get the rest of our answer we have to determine the value of $10^2 \times 10^2$. The term 10^2 is equal to 10×10, and therefore:

$$10^2 \times 10^2 = 10 \times 10 \times 10 \times 10$$

Since there are four tens, then $10^2 \times 10^2 = 10^4$ and our complete answer is:

$$9.31 \times 10^4$$

Another example is 767×839. Again, we write our factors in powers of 10, and so the problem becomes:

$$7.67 \times 8.39 \times 10^2 \times 10^2$$

We know from our previous problem that $10^2 \times 10^2$ is 10^4, so immediately it becomes:

$$7.67 \times 8.39 \times 10^4$$

Thus, our answer becomes:

$$64.4 \times 10^4$$

We can leave the answer in this form, but the usual procedure is to write the answer in terms of a number between 1 and 10. We can do this by writing our answer as:

$$6.44 \times 10^1 \times 10^4$$

There is no point in leaving the answer like this, because it is more complex than it need be, so we simply multiply $10^1 \times 10^4$ by adding the exponents to get:

$$6.44 \times 10^5$$

Multiplying Negative Numbers by Powers of Ten. When 347 is a positive number it can be written as:

$$347 = 3.47 \times 10^2$$

But what about -347? How would you write it? You might think you would write it as -3.47×-10^2. But if you go back to our rules of multiplication you'll see that $-10^2 = -10 \times -10 = 100$. Thus, there's no point in writing the minus sign in front of the ten unless we write it as $-(10)^2$. This means $-(10 \times 10) = -100$. Is this what we want? Let's look and see:

$$-3.47 \times -100 = 347$$

Obviously, we do not want to write our power of ten as $-(10)^2$. However,

$$-3.47 \times 100 = -347$$

so we can write -347 as -3.47×10^2. Similarly -47 is -4.7×10, and -5762 is -5.762×10^3. A negative number in powers of ten is written as a negative number between 1 and 10 times a power of ten.

The problem 347×-162 is written in powers of ten as:

$$3.47 \times 10^2 \times (-1.62) \times 10^2$$

The problem -114×-262 can be handled in the same way:

$$\begin{aligned} & -114 \times -262 \\ = & -1.14 \times 10^2 \times (-2.62) \times 10^2 \\ = & \ 2.99 \times 10^4 \end{aligned}$$

The 2.99 is positive, because a negative number times a negative number gives a positive product.

Division by Powers of Ten. You might wonder how we handle decimal numbers using this system. The number .147 is equal to $1.47 \div 10$. However, rather than leaving it in that form we write the number 1.47×10^{-1}. Notice the minus sign in front of the exponent 1. This indicates the number is divided by 10, or that the decimal point has been moved to the right one place. We write the number .0756 as 7.56×10^{-2}. This indicates that 7.56 is divided by 10^2 or 100.

Consider the problem of multiplying $.342 \times .266$. We rewrite the problem as:

$$3.42 \times 2.66 \times 10^{-1} \times 10^{-1}$$

The product 3.42×2.66 is approximately 9.10. Now to handle $10^{-1} \times 10^{-1}$, we simply add the exponents, and get 10^{-2}. Thus, our answer is 9.10×10^{-2}. If we want to express the number as a decimal number we simply divide it by 100, and we do this by moving the decimal point two places to the left. Notice that the exponent tells you how many places to move the decimal point. Thus,

$$9.10 \times 10^{-2} = .0910$$

Now consider the problem $.0187 \times -475$. We can write these numbers as powers of ten as follows:

$$1.87 \times 10^{-2} \times -4.75 \times 10^2$$

Notice in one case we have a negative exponent, in the other a negative number. There is no connection between the minus signs in front of the exponent and the number. They mean different things. The minus sign in front of the exponent means the number is divided by 10^2, but the entire number 1.87×10^{-2} is positive. The minus sign in front of 4.75

means the entire number, -4.75×10^2, is negative. Thus $1.87 \times 10^{-2} \times -4.75 \times 10^2$ is handled as two separate problems.

$$1.87 \times -4.75 = -8.88$$

and

$$10^{-2} \times 10^2 = 10^0 = 1$$

Therefore, our answer is −8.88.

You may wonder about 10^0 being equal to 1. You may think it should be zero. Let's see why it isn't.

We said earlier that when a number is multiplied by ten with a negative exponent, it indicates the number is to be divided by that power of ten. Therefore, $10^{-2} \times 10^2$ could be written as $10^2/10^2$, which equals 1. Also, $10^{-2} \times 10^2$ can be written as 10^0, because to multiply by powers of ten we add the exponents, and adding a +2 and a −2 gives us zero. Therefore, $10^0 = 1$. In fact, in the same way you can prove that any number to the zero power is equal to 1. Thus, $2^0 = 1$, $3^0 = 1$, $500^0 = 1$, $5{,}000{,}000^0 = 1$, and so on.

For now, we have all we need to know about signed number and their exponents and roots.

Vectors

You learned in your technical lessons that an ac voltage actually consists of a series of different instantaneous values of voltage and that these different voltages all occur at specified times in the ac cycle. You also learned that the current forced through a complete electrical circuit by an ac voltage was likewise made up of a series of instantaneous values of current that occurred at specified times in a cycle. However, one of the most important factors that we must consider in dealing with ac circuits is that these peak ac voltages and peak ac currents do not necessarily occur at the same instant of time.

In your study of coils you found that the current actually lags the voltage by 90° in a purely inductive circuit. Conversely, you discovered that in a purely capacitive circuit the current leads the voltage by 90°. In fact, the only time that the instantaneous values of the current and voltage can be in phase with each other throughout the entire circuit is in a purely resistive circuit. Actually, most practical circuits contain some combination of resistance, inductance, and capacitance, and the phase relationship between the ac current and voltage is a result of the combined action of these effects.

Because of this difference in phase between the voltage and current in ac circuits, we cannot use ordinary arithmetic in our circuit calculations. In ordinary arithmetic we have only simple numbers or "scalars", as they are sometimes called, which we can use. The numbers or scalars can only indicate the size or the magnitude of the voltage or current quantities. They cannot, in any way that we know of, indicate the time difference or phase angle which we must also consider. However, through the use of what we call "vectors" and vector arithmetic, we can indicate both the size of the quantities and the times at which they occur. Actually, the vectors used in ac circuit calculations are not vectors at all, but are phasors. However, they are similar to vectors and are usually called vectors, so we will use that name instead. By using these vectors, we are able to perform any ac circuit calculation quite simply and accurately.

In this section of the lesson, you will learn about vectors and how they can be used in ac circuit calculations. You will apply many of the rules of ordinary arithmetic, square roots, signed numbers, and even some ratio and proportion in working with vectors. Vectors are extremely important in work with ac circuits, because without them any of the methods used for solving ac circuit calculations would be useless. They are all based on vector principles and you will discover later that many of the explanations for circuit characteristics are easier to understand if you use vectors.

DEFINITION OF A VECTOR

A vector is a straight line having a definite length and direction. Fig. 20 shows several different vectors, each with a certain length and direction. Although these vectors do not represent any particular values or functions, they are all true vectors and could be used for any

Fig. 20. Vectors showing definite length and direction.

number of purposes. Notice that each vector starts at a certain point and ends a certain distance away in a specific direction. The starting point of any vector is usually represented by a dot and is called the "tail" of the vector. The ending point of the vector is represented by an arrowhead and is called the "head" of the vector.

The distance between the head and tail of the vector is used to indicate or designate the magnitude of a quantity. The direction of the vector, from a common reference point or line, represents the second factor which we must consider. This second factor may be either "direction" or "time." For example, the vectors in Fig. 21 represent the flight of an airplane. They are drawn so that vector A represents a 125-mile flight to the south, while vector B represents a 150-mile flight to the east. The tail of vector A shows where the airplane started, and the head of vector B shows where the flight ended. The fact that the tail of vector B starts from the head of vector A, tells us that the airplane flew south first and then east. The arrow in the diagram shows us where north is and becomes the reference line from which the direction of the vectors may be determined. The notation "Scale: 1/4″ = 25 mi." tells how far the airplane traveled in each direction, because each quarter-inch of vector length is equal to 25 miles of travel. Thus, the vector diagram gives an accurate and descriptive picture of where the airplane went. As you can see, this is much more valuable than saying the airplane flew 275 miles.

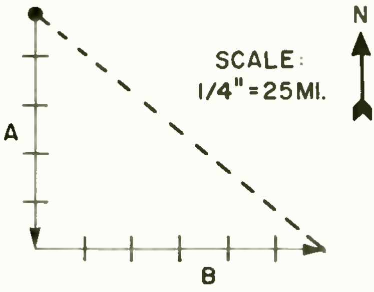

Fig. 21. Use of vectors to show results of motion.

Another thing about this vector diagram is that it can show how far the airplane actually went from the starting point. Notice in Fig. 21 that even though the airplane actually flew 275 miles, it did not end its flight 275 miles from the starting point. The head of vector B is not 275 miles away from the tail of vector A. Since the diagram is drawn to scale, you can measure this distance with a ruler, as shown by the dotted line in Fig. 21. If you do this carefully, you will find that it is just under 2 inches from the tail of A to the head of B. Since each quarter-inch on the diagram equals 25 miles, you know that the airplane ended its flight less than 200 miles from the starting point even though it flew 275 miles to get there.

Further, by comparing the direction of this dotted line with the reference arrow, you can determine the direction of the end of its flight from the starting point. If you do this, you can see that the flight ended approximately southeast of the starting point. Therefore, the vector diagram gives a complete picture of the airplane's flight as well as giving its progress away from the starting point.

Vectors in Electronics. In electronics work, we do not use vectors very often to indicate motion. Instead, we use the direction of vectors to indicate the time of an occurrence. For example, suppose that we have a series circuit containing a coil and a resistor as shown in Fig. 22. The ammeter in the circuit shows that there is an ac current of 5 amps flowing through the circuit and we know that the current in a series circuit is the same through any part of the circuit. Therefore, there is a current of 5 amps through the coil.

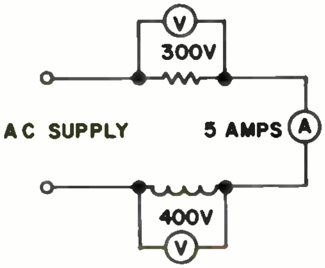

Fig. 22. AC circuit containing resistance and inductance.

The voltmeter across the resistor indicates 300 volts and the one across the coil indicates 400 volts. You know from your studies of ac circuits that these voltages across the coil and resistor do not occur at exactly the same instant of time. For example, if we were to draw a sine wave diagram of the ac current through the circuit, we might have a wave shape like the solid line in Fig. 23A. This sine wave rises from zero to a maximum of such a value that the effective value of the alternating current is 5 amperes. Using this ac sine wave as a reference point for time, and comparing the rise and fall of the voltage sine waves with it, we can actually see that the two voltages do not occur at the same instant.

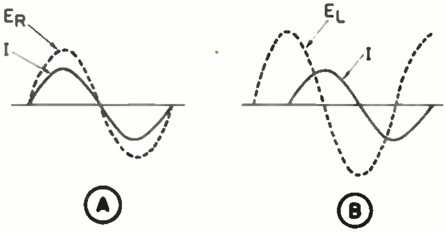

Fig. 23. Sine waves of voltage and current in a resistor (A), and a coil (B).

We know that in a purely resistive circuit the current and voltage actually rise and fall together. We say that they are in phase. Therefore, the voltage across the resistor, E_R, must rise and fall so that it will be maximum when the current is maximum. Further, the maximum value of this ac voltage must be large enough so that its effective value will be 300 volts, as measured by the voltmeter. Accordingly, if we were to draw a voltage sine wave for the voltage E_R, using the current sine wave as a time reference, we would have a wave shape like that shown by the dotted line in Fig. 23A.

On the other hand, the current and the voltage do not rise and fall together as far as the coil is concerned. The coil current actually lags the coil voltage by 90°. Therefore, we would draw their respective sine waves 90° out-of-phase, as shown in Fig. 23B, where the solid line, I, represents the coil current and the dotted line, E_L, represents the coil voltage. The current sine wave is the same sine wave that we used in Fig. 23A and occurs at exactly the same instant. The current is common throughout the circuit. The voltage wave, E_L, has a maximum value necessary to produce the effective value of 400 volts, as indicated by the voltmeter in Fig. 22.

Since the current sine waves in Figs. 23A and 23B represent the same current at the same instant of time, we can combine the two drawings as shown in Fig. 24. Here the one current sine wave, I, represents the common circuit current through both the coil and the resistor. The voltage wave, E_R, represents the sine wave voltage that gives the effective value of 300 volts across the resistor. The voltage wave, E_L, represents the sine wave that produces the effective value of 400 volts across the coil. It is easy to see from this drawing that the two voltages do not rise and fall together. They are 90° out-of-phase.

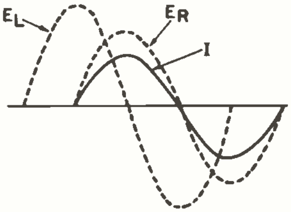

Fig. 24. Sine waves showing E_R lagging E_L.

Through the use of vectors, we are able to represent this difference in "time" between the two voltages and between the current and the coil voltage much more simply than by using sine waves. We do this by means of a rotating vector. As the vector rotates through 360°, the projection from the end of the vector traces out a sine curve. Looking at the current waveform in Fig. 23A, we see that the current is zero at the start of the cycle. This is represented by the vector shown in Fig. 25A. One-quarter of a cycle later, the current has reached its peak positive value. This is represented by rotating the vector 90° (one-quarter of a turn) to the position shown in Fig. 25B. At the end of another quarter-cycle, the current waveform will have gone through one-half of a cycle, and will be back to zero. This is represented by the vector shown in Fig. 25C. Here the vector has rotated through 180° (one-half turn). The vector in Fig. 25D represents the current waveform one quarter-cycle later when the current is at its peak negative value. The vector in Fig. 25E represents the current at the end of one complete cycle. Here the vector has rotated through 360° (one complete turn) and is back at the starting point.

Notice that we rotated the vector in Fig. 25 in a counterclockwise direction. Be sure to remember the direction of rotation; you'll need to know this to understand the vector diagrams in the rest of this lesson and in later lessons.

Now that you've seen how we use a rotating vector to show the current phase throughout a cycle, let's see how vectors can be used to show the phase relationship between the voltage and current across the resistor in Fig. 22, throughout a cycle.

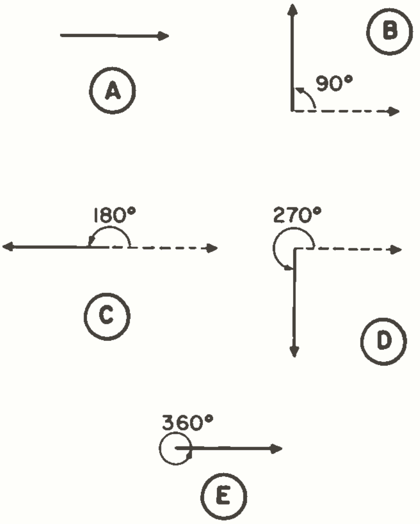

Fig. 25. A rotating vector showing one complete ac cycle.

At the start of the cycle at 0°, E_R and I are in phase. We show the phase relationship by drawing the two vectors, E_R and I, as shown in Fig. 26A. Notice that the vectors are drawn superimposed on each other because at the start of the cycle both the voltage and current are zero. One quarter-cycle later, the voltage and current have reached their maximum position values. This is shown by the vectors in Fig. 26B. Again the vectors are superimposed because the voltage and current are in phase - - they are both at their maximum values at the same instant, one quarter-cycle or 90° after they were both zero. In Fig. 26C we have shown the vectors at the end of one half-cycle, in Fig. 26D at the end of three quarter-cycles and in Fig. 26E at the end of a complete cycle.

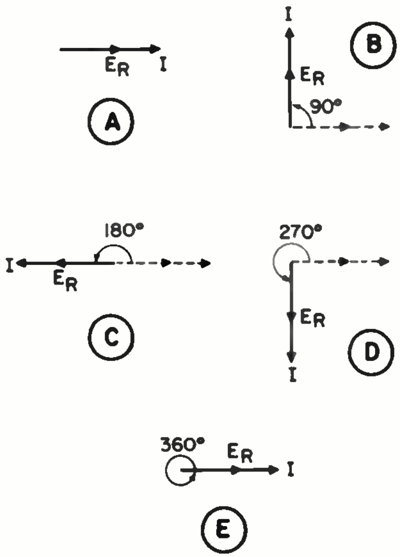

Fig. 26. Vector diagrams showing phase relationship between the voltage across and the current through a resistor, throughout a complete cycle.

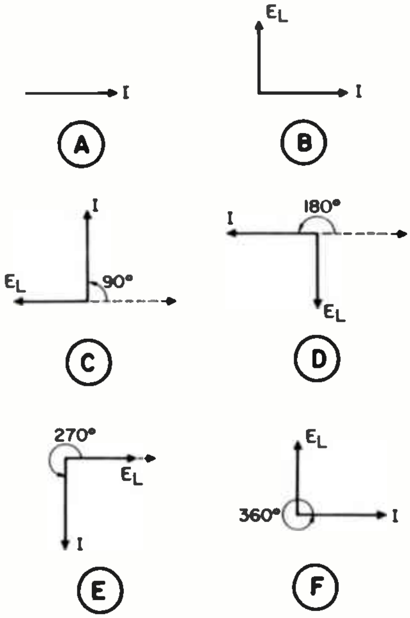

Fig. 27. Vector diagrams showing phase relationship between the voltage across and the current through a coil, throughout a complete cycle.

Now, let's see how vectors can be used to show the phase relation between the voltage across the coil and the current through it. Let's start with the current vector at zero representing the start of the current cycle, as shown in Fig. 27A. This vector is the same as the current vector in Fig. 25A. Now, to draw the vector representing the voltage across the coil we must consider the phase relationship. You will remember that the voltage across a coil leads the current by 90°. This is shown in Fig. 23B. Thus, if the current vector is drawn at zero, we must advance the voltage vector 90° (rotate it counterclockwise) as shown in Fig. 27B. Thus, the vectors in Fig. 27B show the phase of the voltage and current at the start of the current cycle.

One quarter-cycle later, both vectors will have rotated through 90°, as shown in Fig. 27C. At that point, the current is at its peak position value and the voltage has dropped to zero, as shown in Fig. 23. The vector diagram indicates this condition. A quarter-cycle later, when the current has gone through one half-cycle, the current will be zero again and the voltage will be at its peak negative value. This is shown in Fig. 23 and also in Fig. 27D by means of vectors. Fig. 27E shows the phases one quarter-cycle later when the voltage is back to zero and the current is at its peak negative value. Fig. 27F shows the voltage and current vectors at the end of a complete cycle.

Notice that throughout the illustrations in both Figs. 26 and 27, the phase relations remain constant. Fig. 26 shows the resistor voltage and current in phase through the entire cycle. Fig. 27 shows the coil voltage leading the current by 90° through the entire cycle.

In Fig. 24 we have shown the current, coil voltage, and resistor voltage on the same diagram. It does not matter whether we start working with the current, coil voltage, or resistor voltage in constructing our diagram, as long as we show the correct phase relationship. However, in circuits of this type the usual practice is to start by drawing the current vector I, as shown in Fig. 28A. Let's draw the vector to represent zero current at the start of the current cycle. We can draw the current vector any convenient length because we are not going to use it for anything other than a reference vector.

Now, let's draw a vector to represent the voltage across the resistor. In Fig. 22 we see that the voltage is 300 volts. Let's draw the vector to scale so the length of the vector represents 300 volts. If we use a scale of 1/2″ = 100 volts then the vector should be 1-1/2″ long. Since the voltage across the resistor is in phase with the current, the voltage vector is drawn superimposed on the current vector, as shown in Fig. 28B.

To draw the vector representing the coil voltage we first note, from Fig. 22, that the voltage is 400 volts. Therefore, using the scale of 1/2″ = 100 volts, the vector should be 2″ long. Since the coil voltage leads the current by 90°, we draw this vector as shown in Fig. 28C. Now we have a vector diagram showing the phase relationship between the current and the two voltages at the start of the current cycle. As a matter of fact, this diagram shows the phase difference between the coil voltage, the resistor voltage, and the current throughout the entire cycle because, as we saw from Figs. 26 and 27, these relationships did not change. The coil voltage always leads the resistor voltage and current by 90°.

We can use the vector diagram of Fig. 28C to determine the total voltage across the coil and the resistor. This is equal to the source voltage in Fig. 22. We do this by adding the vector representing the coil voltage to the vector representing the resistor voltage. Since we have drawn these vectors to scale, we should be able to scale the resulting vector to get the total voltage.

There are two ways of making this addition. The first way is to place the coil voltage vector at the end of the resistor voltage vector, like we did in Fig. 21, to determine how far the plane traveled. This addition is shown in Fig. 28D. Notice the resultant vector, E_T, which represents the total voltage that leads the current by a value somewhat less than 90°. This is what we might expect. In a circuit with pure resistance, the voltage and current will be in phase -- in other words the phase difference will be 0°. In a circuit with pure inductance, the volt-

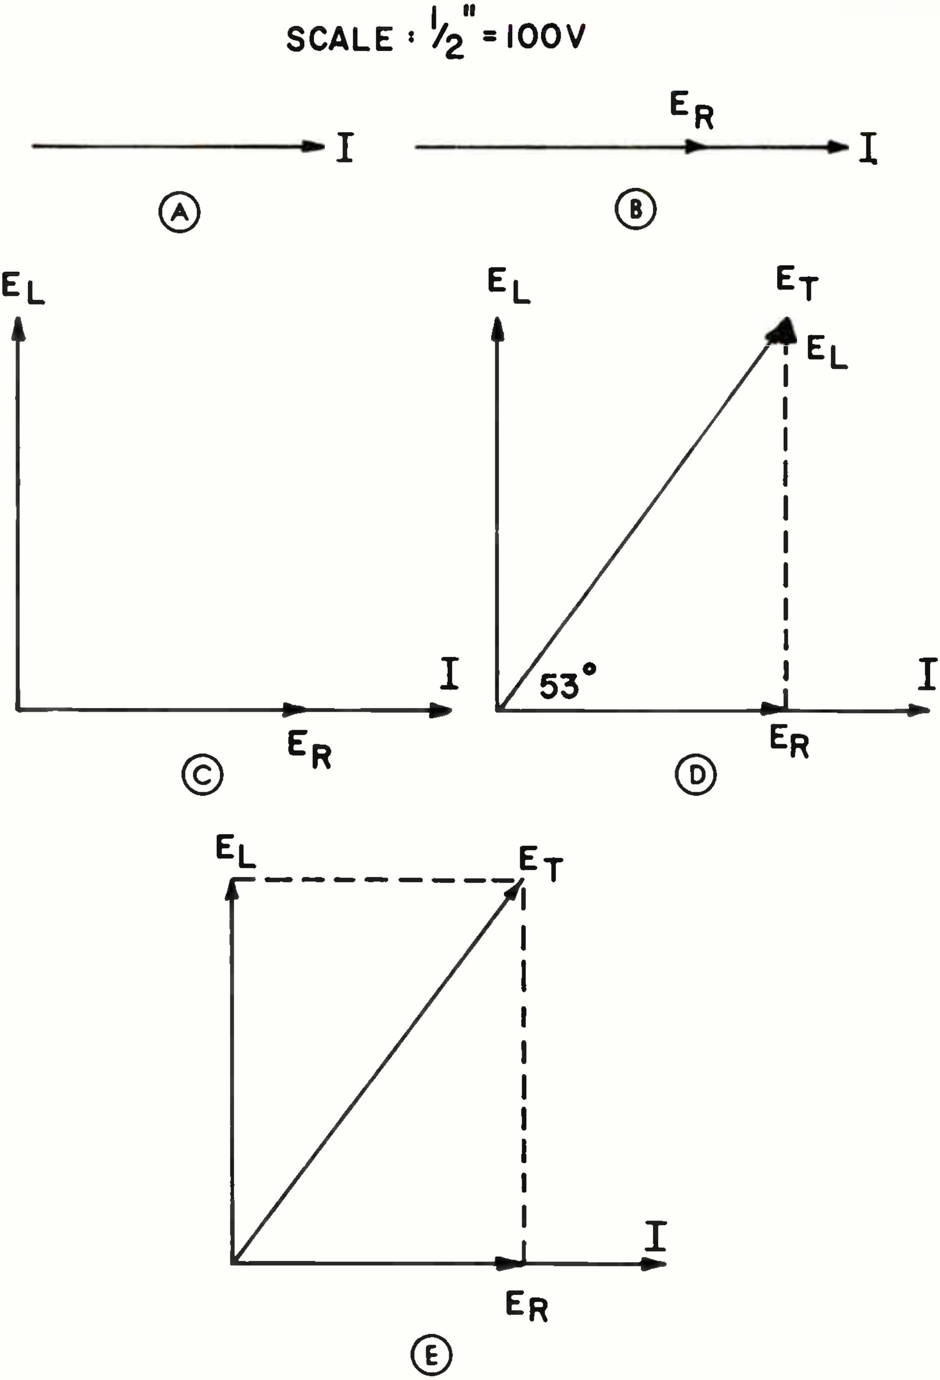

Fig. 28. Vector addition of resistor and coil voltages.

age leads the current by 90°. Thus, in a circuit with both resistance and inductance, we would expect both to influence the phase relationship between the voltage and current so that the phase difference will be somewhere between 0° and 90°. If you construct the diagram carefully and measure the angle between E_T and I, you will find that it is about 53°.

To determine the amplitude of E_T, measure the length of the vector. You will find it is 2-1/2" long. Since the scale used in constructing the diagram is 1/2" = 100 volts, the amplitude of E_T must be 500 volts.

The other method of adding the two vectors is shown in Fig. 28E. Here a dotted line is drawn from the end of vector E_R parallel to vector E_L. A second dotted line is drawn from the end of vector E_L parallel to E_R. The point where the two dotted lines meet locates the end of vector E_T. The angle between it and vector I will be the same when obtained by this method as it would be using the previously discussed method.

To really see the advantage of the vector method of representing these voltages, look at Fig. 29. Fig. 29A shows the sine waves of the two voltages and the current, and Fig. 29B shows how these sine waves can be added to get the total voltage. To do this, many instantaneous values must be added to enable you to plot the curve of E_T. This is tedious and, in addition, is not nearly as easy to evaluate as was Fig. 28D or Fig. 28E.

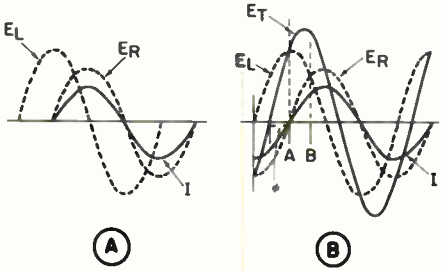

Fig. 29. Adding sine waves to obtain voltage total, E_T.

You might wonder why we started our construction of Fig. 28 by putting I in the 0° position. We did this simply because it was convenient. We could actually put I in any position. As long as we keep the correct position between I, E_R, and E_L, the value of E_T and the phase angle between it and I will be the same.

VECTOR ARITHMETIC

Now that we have seen what vectors are and how they can be used in electronics to represent size and phase or time for ac circuit calculations, let's learn more about handling them. Actually, the rules for working with vectors are quite simple and are similar to any arithmetic that involves signed numbers. The most important differences are learning to deal with the angles and establishing the qualifications for lead and lag.

To begin with, we have seen that any vector diagram must have a reference line so that the directions of the individual vectors can be established in accordance with a common reference for comparison. The reference we used in the preceding example was the current. The best type of reference to use when learning about vectors is a scale similar to the one we used when learning to deal with positive and negative numbers. In Fig. 30, we have drawn such a scale with a center reference point. All positive values extend to the right of the center and all negative values extend to the left.

Now suppose that we have two quantities representing the same direction or instant of time: one is +5 units long and

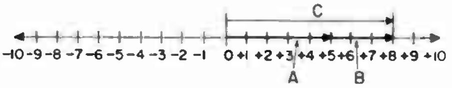

Fig. 30. Adding in-phase vectors.

the other +3 units long. In order to add them vectorially, we simply lay them out along the reference line (to scale) in the same direction, with the tail of one starting at the head of the other, as shown in Fig. 30. Vector A starts at the reference point, 0, and continues for five units. Vector B starts at the head of vector A and continues along the reference for three units. To add the two vectors, we simply draw a new vector, C from the tail of A to the head of B. Since A and B both point in the same direction, this new vector lays along the same line as A and B and is +8 units long. Therefore, we have a rule which states: ***The sum of two vectors extending in the same direction is a new vector equal to the combined length of the two vectors and pointing in the same direction.***

In Fig. 31, we have added two vectors [(–6) + (–3)] that point in the same direction, but both of them are negative so their direction is just opposite to those in Fig. 30. Therefore, their sum is a new vector that is –6 units long plus –3 units long which makes it –9 units long. Thus, as long as two or more vectors point in the same direction, regardless of what that direction is, their sum is a new vector, pointing in that direction, that is equal to the combined length of the individual vectors.

Another problem in working with vectors is when they point in opposite directions. This will often come up when two voltages or other circuit quantities are exactly 180° out-of-phase. For example, suppose we have two opposing voltages working against each other in an ac circuit. One of these has a peak value of 90 volts and the other a peak of 40 volts. The two are exactly out-of-phase at all times, so we can lay them out vectorially, as shown in Fig. 32, by using a scale of 1 unit equals 10 volts. Notice that since the two are 180° out-of-phase, one vector points from the reference point 0, along the reference line in one direction, while the other starts at the reference point and extends in the opposite direction.

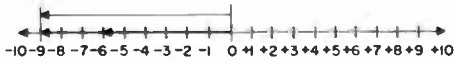

Fig. 31. Adding in-phase vectors.

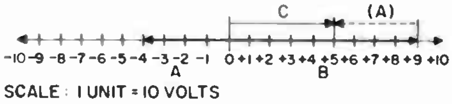

Fig. 32. Adding vectors 180° out-of-phase.

It does not make any difference which vector we use for which direction in this particular case. We know that each one changes sign during every cycle and we are just stopping the action at a particular time. No matter what we get for an answer, its sign will automatically change during the next alternation because we are working with ac. The thing that really does matter is that both vectors represent the same instant of time so that the 180° phase difference is represented by the vector directions.

To add these two vectors we must do the same thing that we did in other vector additions. We place the tail of one vector against the head of the other, being careful not to change the direction or length of the vector that we relocate. In this problem, we have drawn a dotted line from the head of the 90-volt vector B that is exactly the same length and points in the same direction as the 40-volt vector A. Notice that we have drawn the dotted line slightly above the reference line so that we can see it better. Now, we complete our addition by drawing a new vector, C, from the tail of the 90-volt vector. This new vector is 5 units, or 50 volts long, and points in the direction of the longest vector. Thus, we can see that the vector sum of the two out-of-phase voltages is a new vector, extending from the tail of one vector to the head of the other, after they have been properly joined (head to tail) for addition.

Representing Lead or Lag. As you can see, all the vector addition that we have considered so far follows the same basic pattern. We lay the vectors out to their proper scale length and orient them in their proper direction. Then, we lay them head to tail, being careful not to alter either their length or direction in the process, and draw a resultant vector, between the tail of the first vector and the head of the last, to represent their sum. The length of this resultant represents the magnitude of the vector sum, and its direction in relation to the reference line indicates the phase or time of the resultant quantity.

All vector computations follow these same basic rules. However, the problems that we have considered so far have dealt with vectors that are exactly in phase or exactly 180° out-of-phase. As you know, many of our problems in electronics deal with reactance calculations where the phase shift will be only 90°. Also, this reactance phase shift may be either 90° leading, in the case of the capacitance, or it may be 90° lagging in problems dealing with inductance. Accordingly, we must now consider what to do about laying out and computing vectors that are affected by reactance.

To do this let's go back to our basic idea of a phasor. A phasor is a rotating vector. We have shown that this vector rotates counterclockwise. Thus, if we start a vector at 0°, as in Fig. 33A, and rotate it 90° to represent one-quarter of a cycle, it will move to the position shown in Fig. 33B. The vector at B has passed through one-quarter of a cycle more than the one at A. Thus, vector B is leading vector A by 90°. The vector diagram in Fig. 33C shows how the voltage leads the current by 90° in a coil.

In Fig. 34 we have shown an example of a lagging voltage. We started with our current vector at A and then drew a second vector 90° behind it at B. Vector B is following vector A by 90°. A complete vector diagram showing how the current leads the voltage in a capacitor is shown in Fig. 34C.

You might think that since the two

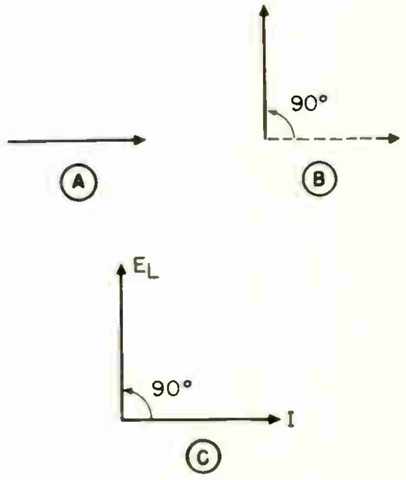

Fig. 33. Vector diagrams showing 90° phase shift where the voltage leads the current.

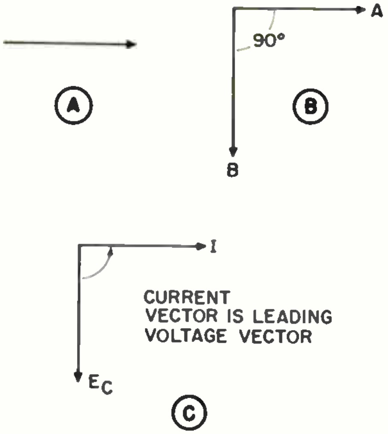

Fig. 34. Vector diagrams showing a 90° phase shift where the voltage lags the current.

vectors are rotating counterclockwise, the voltage vector is leading the current by 270°. Since the voltage is lagging one current cycle by 90°, it will indeed be leading the following current cycle by 270°. However, it is the 90° phase difference we are interested in.

Now it is fairly easy to see that, if we consider our discussions of vectors up to this point, we can call the right-hand end of the scale the "in-phase reference line." Likewise, the end of the horizontal line extending to the left of the center towards 180° can be called the "180° out-of-phase reference line." If we do this, all vectors parallel to the horizontal reference and pointing to the right will be in-phase vectors, and those pointing to the left will be 180° out-of-phase. Thus, our horizontal line, divided in the center in this way, can represent a phase shift or time lag of 180°, depending on whether we point our vectors from the center to the right of 0° or from the center to the left of 180°.

The vertical line represents a phase shift of 90°. Since our vector rotates counterclockwise, the vector representing the voltage in Fig. 33C is leading the current vector by 90°. It's not always necessary or even advisable to place the current vector at 0°. However, regardless of how we start the diagram and what we place on the 0° axis, all voltages or current leading the reference value are shown rotated in a ***counterclockwise*** direction. Voltages or currents lagging the reference value are shown in a ***clockwise*** direction. Any voltage or current can be taken as our reference value, but in most series circuits it is easiest to use the current as a reference.

Sometimes we may want to construct an impedance diagram of resistance, and inductive or capacitive reactance. You might wonder if one of these reactive elements should be drawn above or below the reference line. The rule is to draw inductive reactance above and capacitive reactance below. Inductive reactance is considered positive and capacitive reactance negative. You'll see later, when you study the j-operator, that this is necessary in order to get the currents to have the correct phase. Thus, if we consider our reference line extending from the center right towards 0°, as our current reference line in ac circuit problems, our inductive reactance (voltage leading current) values will go above the reference and our capacitive reactance (voltage lagging current) values will go below the reference. Another thing that will help you to remember this rule is to notice that vectors are always considered to rotate counterclockwise from zero.

Also notice that the 90° head point from the center can also be considered to lag the 0° reference line by 270°. It doesn't make any particular difference which way you think of it. The important thing is to make sure that when you construct a scale like this and use the current as the reference vector, you should remember:

1. Right from center: in phase I, R, or E_R.
2. Left from center: 180° out-of-phase.
3. Straight up from center: 90° lead, X_L or E_L.
4. Straight down from center: 90° lag, X_C or E_C.

VECTOR CALCULATIONS

Now that we have discussed some of the basic rules and principles for laying out vectors and computing with them, we need to gain a little practice to become thoroughly familiar with this type of computation. We considered a problem dealing with a coil and a resistor a little earlier. Now, let's consider a circuit containing a resistor and capacitor in series like the one shown in Fig. 35A. In this circuit we are told the capacitor voltage and the resistor voltage and are asked to find the supply voltage, E_T, and the phase angle, θ.

In order to do this, we first lay out the current vector as the reference vector because the current in the circuit, I, is the same in all parts of the circuit. Using the horizontal line extending to the right toward 0° to represent the current, as we have learned to do, completes our preliminary setup for the problem, as shown in Fig. 35B. Notice that we do not have the value of this current. It is not needed to work the problem. We are only using I as a reference line from which to indicate our voltage-phase relationships. Its value is not important. Its position as the common reference is what concerns us here.

Using the scale of 1/2″ = 100V, we can lay out the voltage vector, E_R, to scale along the reference line to show that the voltage across the resistor is in phase with the current through it. We call this voltage the in-phase component of the total voltage. The vector diagram of this stage is shown in Fig. 35C. Then we can lay out the voltage vector, E_C, to scale 90° behind the reference current because I will be leading it by 90°. The diagram at this point is shown in Fig. 35D. To add these two vectors, we can move one of them so that the two are head to tail, as shown by the dotted vector, E_C, in Fig. 35E and then draw in E_T, the total voltage. Notice that we are careful to construct the dotted vector, E_C, so that its length and direction are not changed. We can also get E_T by drawing a line parallel to E_R from the end of E_C, and a second line parallel to E_C from the end of E_R. Where the two lines meet locates the end of E_T, as shown in Fig. 35F.

Now, we can draw the resultant vector, E_T, that represents the vector sum of the two quantities. If we measure E_T carefully and our other vectors are to scale, we will find that E_T is 2-1/8″ long. Since 1/2″ = 100V, 1″ must equal 200 volts, and 2″ must equal 400 volts. Now, since 1/8″ is equal to 1/4 of 1/2″, 1/8″ is equal to 25 volts. Accordingly, our E_T vector, which is 2-1/8″ long, must equal 400 + 25 or 425 volts.

We are also asked to find the phase angle, θ, for our supply voltage. We can do this by using a protractor which measures angles. We will find that the angle between E_T and the reference I is 45°. As a matter of fact, we can estimate that E_T lies about halfway between E_C and I, which are 90° apart, so E_T must be approximately 45° out-of-phase with the current. Thus, through the use of vectors, we have determined that E_T is 425 volts and is 45° out-of-phase with the current. Since E_T is below the reference I, the

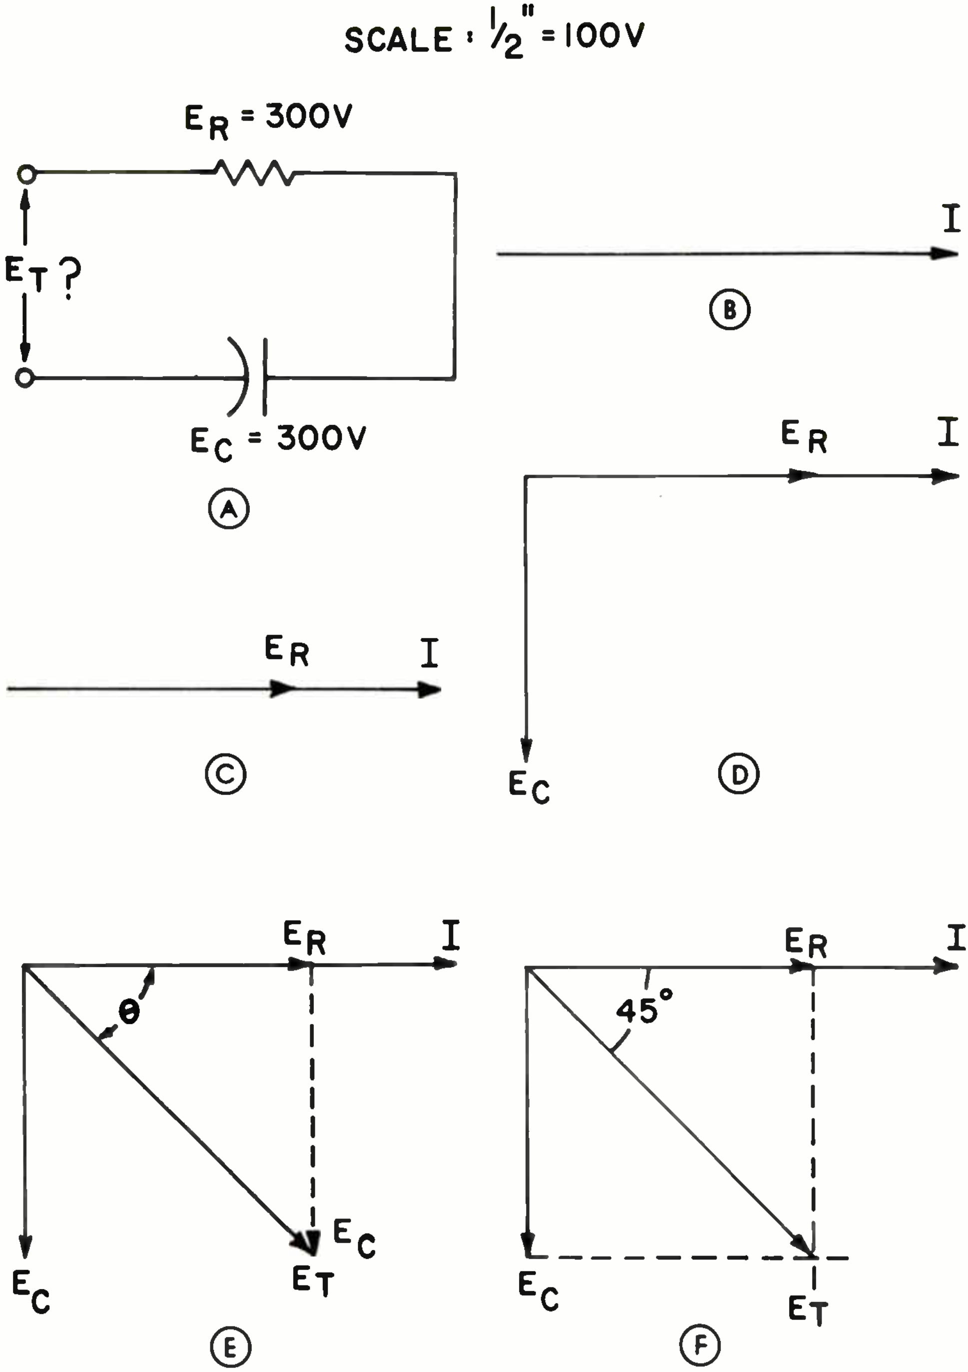

Fig. 35. Vector addition of the voltage E_R and E_C in the circuit at (A) shown in detail.

current must *lead* the voltage (or the voltage lags the current, whichever you prefer) by 45°.

Before we leave this circuit, let's consider one other thing. In converting our length of E_T of 2-1/8" to 425 volts, we went through a series of steps. Ratio and proportion would have saved us a lot of time. For example, we could have set up two ratios as follows:

$$\frac{\frac{1}{2}''}{2\frac{1}{8}''} \quad \text{and} \quad \frac{100\text{V}}{E_T}$$

Now our proportion:

$$\frac{\frac{1}{2}''}{2\frac{1}{8}''} = \frac{100\text{V}}{E_T} \quad \text{or}$$

$$\frac{\frac{1}{2}''}{\frac{17}{8}''} = \frac{100\text{V}}{E_T}$$

Now cross-multiplying, we have:

$$\frac{17}{8} \times 100 = \frac{1}{2} \times E_T$$

$$\frac{1700}{8} = \frac{E_T}{2}$$

and then:

$$8 \times E_T = 1700 \times 2$$
$$8E_T = 3400$$
$$E_T = \frac{3400}{8} = 425 \text{ volts}$$

This is just another example of a good use for ratio and proportion.

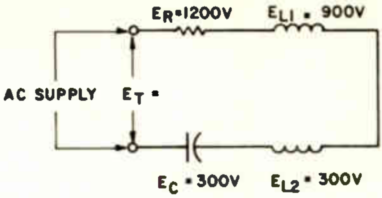

Fig. 36. Finding E_T in a simple series ac circuit containing R, L, and C.

In Fig. 36, we have shown a more difficult problem. Here we have a resistor, two coils, and a capacitor in series with each other. Let's see how we would handle the problem of finding the total voltage for this circuit vectorially.

First, we lay out our vector reference scale and call the horizontal line, which is from center to 0°, the current reference. This is shown in Fig. 37. Then we can draw in the voltage vector E_R superimposed on I to show the two in phase. Since E_R is 1200 volts, we used a scale of 1/4" = 100 volts, instead of 1/2" = 100 volts as before, in order to keep the diagram a reasonable size in the book. If you try drawing this diagram you can use a scale of 1/2" = 100 volts if you wish. Then E_R would be twice as long. Next, we draw vector E_{L1} leading I by 90°. This vector represents 900 volts. Using the scale of 1/4" = 100 volts, we make it 9 X 1/4" = 9/4 = 2-1/4" long.

The next step is to add the vector E_{L2} to the diagram. Since this voltage also leads I by 90°, we draw E_{L2} starting at the head of E_{L1} to add these two in-phase voltages. E_{L2} is made 3/4" long to represent 300 volts.

The next vector we draw is E_C. Since this represents 300 volts we know it should be 3/4" long. Also, since it represents a voltage across a capacitor, we know it will lag I by 90°. The position of this vector is shown on the diagram. Notice that it is 180° out-of-phase with

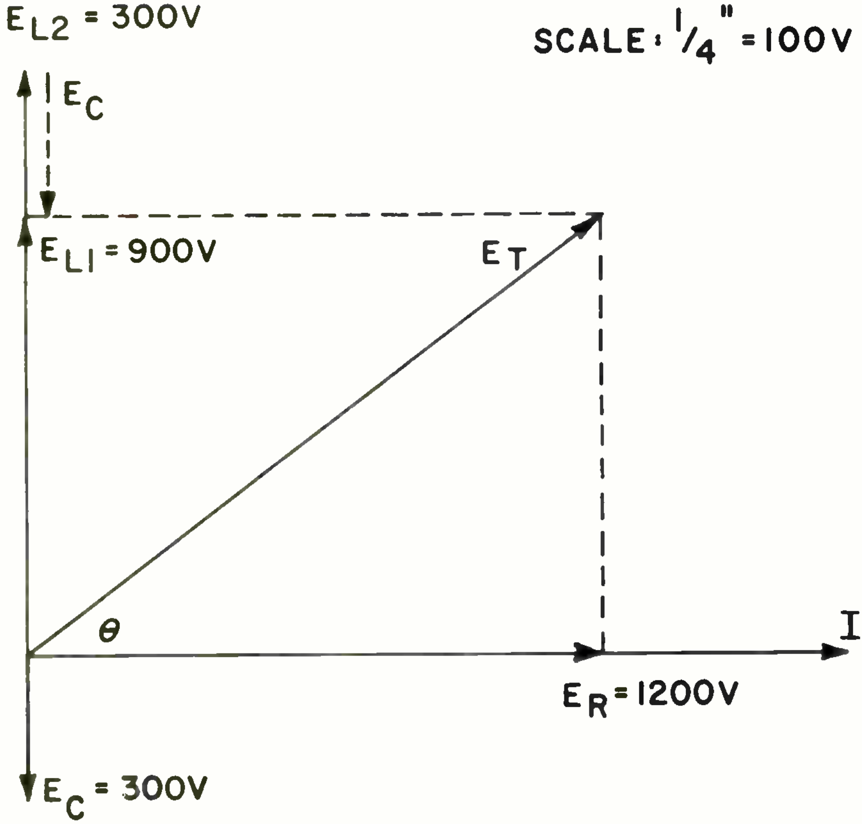

Fig. 37. Vector solution of multiple reactance circuit.

E_{L1} and E_{L2}. We now add this vector to the sum of E_{L1} and E_{L2} following the same procedure as shown in Fig. 32. We move vector E_C to the head of E_{L2} as shown by the dotted line. Then the head of E_C represents the total reactive voltage. We have shown E_C dotted and slightly to one side of E_{L2} so you can see it; actually it should be superimposed on E_{L2}.

To complete the vector diagram and get E_T, we draw a line parallel to vector E_R from the end of the vector representing the sum of E_{L1} + E_{L2} + E_C. Then we draw a second line parallel to the E_{L1} vector from the end of E_R. The point where these two lines intersect locates the end of E_T. Now we can draw vector E_T to represent the sum of our reactance and resistance vectors and carefully measure it. We find that it is exactly 3-3/4" long. Now, by setting the ratios and proportion between our scale values and our measurements, we can convert our vector measurements to volts as follows:

$$\frac{\frac{1}{4}''}{3\frac{3}{4}''} = \frac{100}{E_T}$$

$$\frac{1}{4}'' \times E_T = 3\frac{3}{4}'' \times 100$$

$$\frac{E_T}{4} = \frac{15}{4} \times 100$$

$$\frac{E_T}{4} = \frac{1500}{4}$$

$$4E_T = 4 \times 1500$$

$$E_T = 1500 \text{ volts}$$

We can then determine the value of θ by measuring it: $\theta = 36\text{-}1/2^\circ$.

So far, in working with vectors, we have considered only the addition of vectors to find a total. We can also break down a given resultant vector to find some of its components. In other words, if we have E_T, we can find E_R and the total circuit reactance voltage. This process is important when working with parallel ac circuits, so let's see how it is done.

Suppose we are given a statement regarding the voltage of a circuit as follows: "The voltage applied to a series circuit is equal to 140 volts and it leads the current by a phase angle of 45°. What is the value of the resistance in the circuit if the current is 5 amperes?" Although this might seem difficult at first glance, it is really quite easy to solve. First, let's see what we know about the voltage.

We can see that it leads the current (or that the current lags the voltage) and, therefore, the total reactance in the circuit must be inductive. We know the phase angle is 45° and that the voltage value is 140 volts. With this information we can lay out our standard reference diagram for vector solutions and construct a vector that represents the total voltage applied. Using a scale of 1/4″ = 20 volts, our total voltage vector, E_T, can be laid out to scale as shown in Fig. 38. We

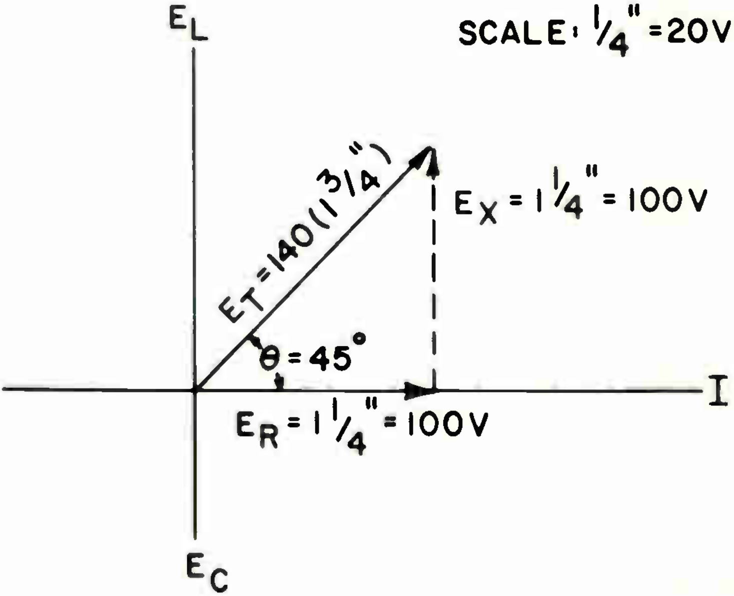

Fig. 38. Breaking a vector down into two components.

have drawn this vector above the reference line I, at the phase angle of 45°, to show that it is inductive and leads the current. Now this vector, E_T, is a resultant vector and must be made up of at least two component vectors; one resistive, and one reactive. Any vector that is not out-of-phase with the reference by some multiple of 90° can always be broken down into at least two components that are at right angles to each other. Because of this rule, we can separate the vector E_T into two component vectors.

Doing this, we find that in the circuit the reactive component, E_X, is equal to 100 volts and the resistive component, E_R, is also equal to 100 volts. Now that we have the resistive voltage drop of 100 volts, it is easy to find the resistance. We know that it is a series circuit and, therefore, the current is common. Accordingly,

$$R = \frac{E_R}{I} = \frac{100}{5} = 20 \text{ ohms}$$

Thus, by breaking down the vector value of applied voltage into its two components, we are able to determine quite a lot about the circuit. You will find that

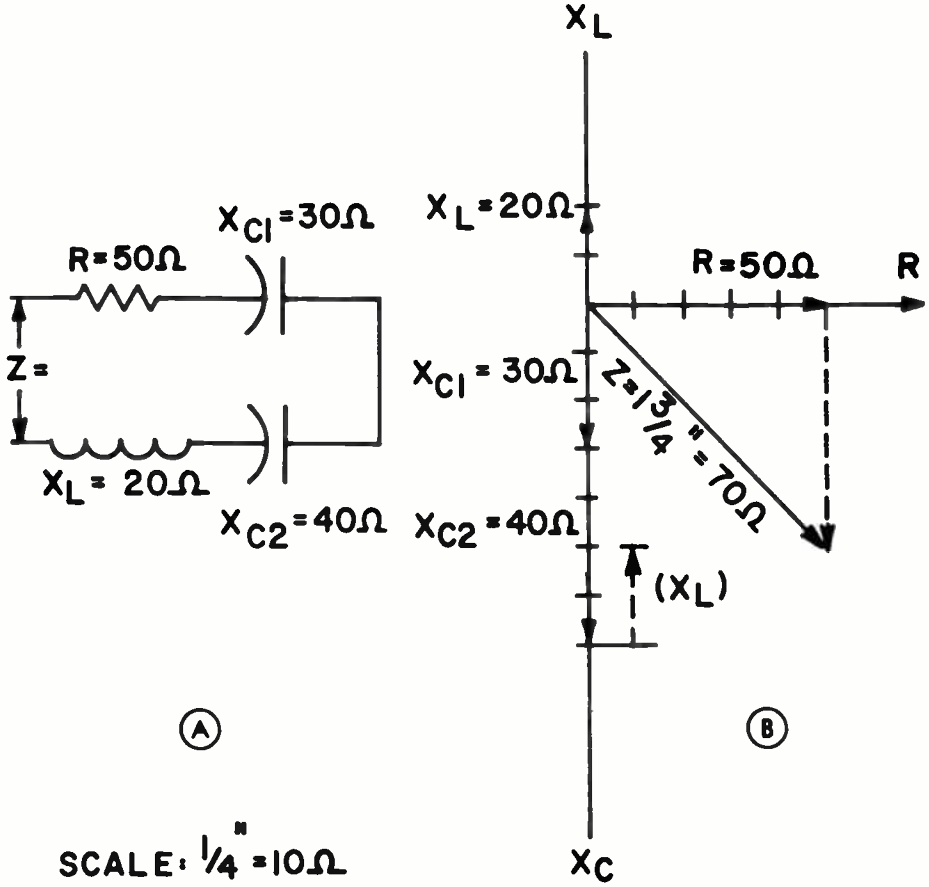

Fig. 39. Solving for impedance with vectors.

this is a very valuable process in your electronics work.

Up until now, we have been working primarily with the voltages in a circuit. We can use our vector diagrams and computation methods to find the impedance of a circuit. For example, suppose we wanted to find the total impedance of the circuit shown in Fig. 39A. We would simply lay out our vector diagram and add the component vectors just as we did when we were working with voltage, as shown in Fig. 39B. Notice that we use R as the reference line because it represents the in-phase component of the impedance Z. You should have no trouble following the solution of this simple vectorial computation.

PYTHAGOREAN THEOREM FOR VECTOR SOLUTIONS

You will remember that earlier in this lesson and in your technical lessons, we mentioned that we could use formulas instead of vectors for ac circuit solutions. One of the most familiar is the formula for impedance which is,

$$Z = \sqrt{R^2 + X^2}$$

This formula is really just a mathematical solution of a vector diagram. By using it, we involve ourselves in the problem of finding a square root, but it is often much more desirable and usually more accurate than solving vectors by measurement. In measuring vectors for the solution of vector diagrams, we need to take care in laying out the diagrams, and measuring the angles and lengths of the vectors.

In working with the formulas, we are given a method of solving for the lengths of the vectors, but not the angles. Since the formula allows us to use a mathematical solution for the length of the vectors in vector diagrams, it eliminates the need for the accuracy of layout and measurement. Let's look at a typical vector diagram and see how it is possible to consider the formula $Z = \sqrt{R^2 + X^2}$ as the mathematical solution.

In Fig. 40A, we have laid out the solution of a typical vector diagram for finding the impedance of an ac circuit. The vector representing R, the dotted vector representing X_L, and the resultant vector Z, representing the impedance of the circuit, forms a three-sided, completely enclosed figure. Such a three-sided figure, as you probably know, is called a triangle. However, this is a special type of triangle, called a right triangle. Any triangle that contains one angle that is equal to 90°, such as the angle between vectors X_L and R, is a right triangle, no matter what the other two angles or the lengths of the sides may be. Any triangles involved in vector solutions for ac circuits will also be right triangles, because two of the sides must be 90° displaced from each other.

It is important that you realize this and understand it, since many of the laws for ac circuit solutions depend on this fact. In Fig. 40B, we have drawn the triangle of Fig. 40A, leaving out the arrowheads and values so that we can show you a very important fact about all right triangles. First of all, notice that we have given names to the sides of our right triangle in Fig. 40B. The longest side, or the side opposite the right angle, is always called the hypotenuse. The other two sides are simply known as legs or sides.

Many years ago, a mathematician named Pythagoras discovered a very interesting fact about right triangles. He discovered that if you squared each side

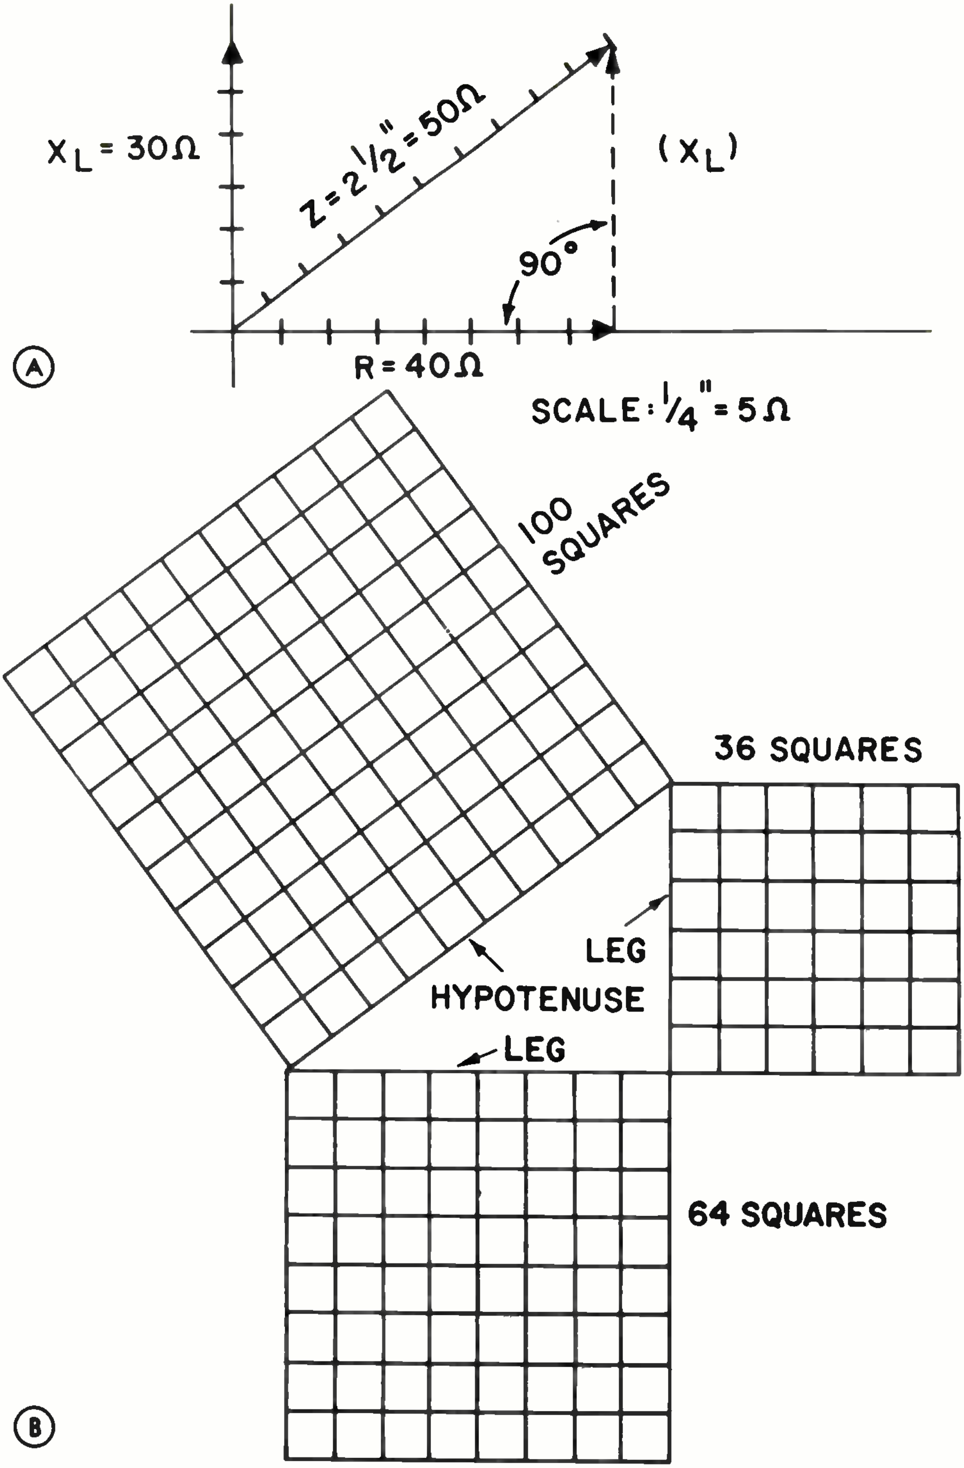

Fig. 40. The derivation of the Pythagorean Theorem.

of the right triangle and filled in all the squares in between as we have shown, the sum of all the squares (created by squaring the two legs) is exactly equal to the number of squares created by squaring the hypotenuse. You can actually prove this to yourself by counting all the squares in the two legs. You will find that there are 64 squares in the bottom leg and 36 squares in the vertical leg. The sum of 64 and 36 is, of course, 100. Now, if you count all the squares made by squaring the hypotenuse, you will find that there are also exactly 100. Thus, we have the theorem which Pythagoras discovered:

The square of the hypotenuse of any right triangle is equal to the sum of the squares of the other two sides.

If we apply this theorem to our vector diagram in Fig. 40A, we have:

$$Z^2 = R^2 + (X_L)^2$$

Then, by substituting our values, we have:

$$\begin{aligned} Z^2 &= 40^2 + 30^2 \\ &= 1600 + 900 = 2500 \end{aligned}$$

Then, if $Z^2 = 2500$, $Z = \sqrt{2500} = 50$. You will notice that this is the same answer we obtained by measurement. You will also notice that our statement $Z^2 = R^2 + X_L{}^2$ is the same as one of our formulas; $Z = \sqrt{R^2 + X_L{}^2}$. We usually use the general formula;

$$Z = \sqrt{R^2 + [X_L + (-X_C)]^2}$$

because we always find our total reactive component, X, before we find our squares. In this way, we can solve for any right angle vector diagram without using a measurement solution.

SELF-TEST QUESTIONS

(38) What is a vector?

(39) Draw a simple vector diagram which shows the phase relationship between the voltage across and the current through a coil.

(40) A coil and resistor are connected in series across an ac generator. The voltage drop across the coil is 10 volts and the drop across the resistor is 20 volts. Draw a vector diagram which shows the amplitude and phase relationship of the two voltages.

(41) Find the total voltage from the generator using the vector diagram in Question 40.

(42) Draw a vector diagram which shows the phase relationship between the voltage across and the current through a capacitor.

(43) A coil, resistor, and capacitor are connected in series across an ac generator. The coil drops 12.5 volts, the resistor 15 volts, and the capacitor 7.5 volts. Draw a vector diagram showing amplitude and phase relationship of the 3 voltages.

(44) Find the total voltage supplied by the generator described in Question 43.

(45) State the Pythagorean Theorem.

(47) What quantity is represented by the hypotenuse of a right triangle which has one side representing resistance and the other side representing reactance?

Circuit Calculations

In this lesson and in your previous lessons you have learned many of the important facts concerning ac circuits. You have also studied some of the mathematical procedures that can be used in considering these facts in ac circuit calculations. Although you may feel that at the present time you have mastered all this information, it is quite possible that you will forget many of the details. One of the best ways to prevent forgetting this information and to insure that you really do understand it thoroughly is to get some practice using it.

Therefore, at the end of this section we will present several typical circuit problems and ask you to solve them. Remember that many times it may be necessary to solve for intermediate values in order to obtain the necessary factors for use in finding the answers. If you have learned and understood the mathematics and electronics that you have studied so far, you should be able to obtain all the answers without too much difficulty.

Most of the information in this lesson parallels the technical lessons from 6 through 9. Therefore, the problems will deal mainly with the formulas and data covered in these same technical lessons. If you have any real difficulty with the solutions of these problems, it will be a good idea to review the appropriate subjects in other lessons that you have had. Remember, only by working out the solutions of these problems will you be sure that you have thoroughly understood the material presented. It is very important for you to do this before you continue with your remaining lessons.

To help refresh your memory and prevent your having to look up too much information regarding these problems, we have listed some of the more important formulas that you have studied. If you find that you do not thoroughly remember and understand these useful and common formulas, it will be a good idea to review them before you start working the problems.

Inductance of coils in series:

$$L_T = L_1 + L_2 \pm 2M$$

Inductance of coils in parallel:

$$L_T = \frac{L_1 \times L_2}{L_1 + L_2}$$

Inductive reactance:

$$X_L = 2\pi fL$$

(f = Hertz, L = henrys)

Q of a coil:

$$Q = \frac{X_L}{R}$$

Capacitance of capacitors in series:

$$C = \frac{C_1 \times C_2}{C_1 + C_2}$$

Capacitance of capacitors in parallel:

$$C = C_1 + C_2 + C_3$$

Capacitive reactance:

$$X_C = \frac{1}{2\pi fC} \text{ or}$$

$$X_C = \frac{159000}{fC}$$

where f is in Hertz and C is in mfd.

Ohm's law for ac circuits:

$$E = I \times Z$$

Impedance in ac circuits:

$$Z = \sqrt{R^2 + X^2}$$

Total voltage in ac circuits:

$$E_T = \sqrt{E_R{}^2 + E_X{}^2}$$

Resonant frequency:

$$f = \frac{1}{2\pi\sqrt{L \times C}}$$

or

$$f = \frac{.159}{\sqrt{L \times C}}$$

Turns ratio of transformers:

$$\frac{N_1}{N_2} = \frac{E_1}{E_2}$$

$$\frac{N_1}{N_2} = \frac{I_2}{I_1}$$

$$\frac{N_1}{N_2} = \sqrt{\frac{Z_1}{Z_2}}$$

EXAMPLES

Study the following examples carefully. They are purposely difficult to give you practice and show you how to get the correct answers in an orderly manner. Break down a problem into smaller parts and solve for each part step by step. You will note that it is necessary to find a quantity not asked for but required before you can get the final answer. Review of these examples, although quite advanced for you at this time, will give you the confidence to tackle the exercise at the end of this section. Do not be discouraged should you not get the right answer on the first try.

Be sure you have all quantities in the correct units. If you are asked to find power in a circuit and are given the voltage in volts and the current in milliamps, you must convert the current to amperes by moving the decimal point three places to the left. When you need to find either inductive or capacitive reactance, be sure that you have frequency in Hertz and inductance in henrys or capacitance in farads. To convert microhenrys to henrys or microfarads to farads, move the decimal point six places to the left.

Example 1: Find the current in a series circuit consisting of a 150-ohm resistor, a 292 millihenry coil, and a 7 microfarad capacitor if the line voltage is 120 volts and the line frequency is 150 Hertz.

Solution: To find the current in an ac circuit, you divide the voltage by the impedance of the circuit. This is Ohm's Law for ac circuits.

$$I = \frac{E}{Z}$$

We know E, but do not know Z so we must find Z.

$$Z = \sqrt{R^2 + [X_L + (-X_C)]^2}$$

We know R, but we do not know X_C or X_L so we must find these values.

$$X_L = 2\pi fL$$

and

$$X_C = \frac{1}{2\pi fC}$$

Since we know f, L, and C we can find X_L and X_C. Then we can get Z, and Z is used to find I. Therefore, our first steps in the problem are to find X_L and X_C. Let's do that now:

$$X_L = 2\pi fL$$

$2\pi = 6.28$, f = 150 Hertz and L = 292 millihenrys.

To use our formula, f must be in Hertz, which it is, and L must be in henrys. So we must convert 292 millihenrys to henrys by moving the decimal three places to the left.

Thus, 292 millihenrys = .292 henrys. Now $X_L = 6.28 \times 150 \times .292$.

$$\begin{array}{r} 6.28 \\ \underline{1\,50} \\ 314\,00 \\ \underline{628} \\ 942.\,00 \end{array}$$

$$\begin{array}{r} 942 \\ \underline{.292} \\ 1884 \\ 8478 \\ \underline{1884} \\ 275.064 \end{array}$$

Thus, X_L = 275.064 ohms, which we can round off to 275 ohms.

Now let's find X_C using the formula

$$X_C = \frac{1}{2\pi fC}$$

Again $2\pi = 6.28$, f = 150 Hertz and C = 7 microfarads. C must be in farads so we move the decimal six places to the left.

Thus, 7 microfarads = .000007 farad.

$$X_C = \frac{1}{6.28 \times 150 \times .000007}$$

6.28 × 150 = 942 (we did this when we were finding X_L).

$$\begin{array}{r} 942 \\ \underline{.000007} \\ .006594 \end{array}$$

Now dividing $.006594 \overline{)\,1}$

$$\begin{array}{r} 151.6 \\ 6594\overline{)1000000.} \\ \underline{6594} \\ 34060 \\ \underline{32970} \\ 10900 \\ \underline{6594} \\ 43060 \end{array}$$

Thus, X_C = 151.6 ohms, which we round off to 152 ohms. Now that we know R, X_L, and X_C, we can get Z using

$$Z = \sqrt{R^2 + [X_L + (-X_C)]^2}$$

To add X_L and X_C we must remember they are opposite reactances. X_L is positive and X_C is negative. Thus, when we add we have 275 + (−152) so, because of the negative number, we subtract

$$\begin{array}{r} 275 \\ -152 \\ \hline 123 \end{array}$$

Therefore, $X_L + X_C = 123$ ohms.

Now, squaring 123 we get

$$\begin{array}{r} 123 \\ 123 \\ \hline 369 \\ 246 \\ 123 \\ \hline 15129 \end{array}$$

And squaring R we get

$$\begin{array}{r} 150 \\ 150 \\ \hline 7500 \\ 15 \\ \hline 22500 \end{array}$$

Now, adding $R^2 + [X_L + (-X_C)]^2$

$$\begin{array}{r} 22500 \\ 15129 \\ \hline 37629 \end{array}$$

To find Z we must take the square root of 37629.

$$\begin{array}{rl} & 1\ \ 9\ \ 3.\ 9 \\ & \sqrt{3,76,29.00} \\ & 1 \\ 29 & \overline{\big|\,276} \\ & 261 \\ 383 & \overline{\big|\,1529} \\ & 1149 \\ 3869 & \overline{\big|\,38000} \\ & 34821 \end{array}$$

Thus, Z is 193.9 ohms, which we can round off to 194 ohms.

Now, to find I we use

$$I = \frac{E}{Z}$$

$$I = \frac{120}{194}$$

$$\begin{array}{r} .618 \\ 194\overline{\big)120.0} \\ 1164 \\ \hline 360 \\ 194 \\ \hline 1660 \\ 1552 \\ \hline 108 \end{array}$$

The line current is .618 amps. Notice how we solved this problem. We worked backwards to find what we had to determine in order to get the required answer and then began by evaluating the terms needed to get the final solution.

Example 2: Find the voltage across the inductance in a series circuit having an inductive reactance of 4 ohms, a capacitive reactance of 12 ohms and a resistance of 6 ohms, if the voltage applied to the circuit is 50 volts at 60 Hertz.

Solution: To find the voltage across the coil we need to know the current flowing in the circuit. Then we can use the formula

$$E_L = I \times X_L$$

To get I, we need the impedance. Then we can use

$$I = \frac{E}{Z}$$

We start by getting Z.

$$Z = \sqrt{R^2 + [X_L + (-X_C)]^2}$$

$X_L = 4$ and $X_C = -12$ so we have

$$\begin{array}{r} 4 \\ +(-12) \\ \hline -\ 8 \end{array}$$

Thus, $Z = \sqrt{6^2 + (-8)^2}$.

Remember the $(-8)^2$ is $(-8) \times (-8)$ and your rules for multiplying signed numbers tell you that $(-8) \times (-8) = 64$

Therefore,

$$\begin{aligned} Z &= \sqrt{36 + 64} \\ &= \sqrt{100} \\ &= 10 \text{ ohms} \end{aligned}$$

Thus, $I = 50/10 = 5$ amps and the voltage across the coil is $E_L = I \times X_L = 5 \times 4 = 20$ volts.

You might wonder about the 60 Hertz. We didn't use this, because we didn't have to. We had the reactance of the coil and capacitor so we could get the impedance directly. Often, in problems and in actual practice, you'll find you have more data than you need. You have to learn to take what information is needed and use it and ignore unneeded information.

(11) A ratio is a comparison of two numbers or similar quantities. For example, the efficiency of a motor is expressed as the ratio of output power to input power. A proportion is a comparison of two ratios. To be more precise, a proportion is a mathematical statement that two ratios are equal.

(12) $$\text{Efficiency} = \frac{\text{Output power}}{\text{Input power}}$$

$$= \frac{2 \text{ horsepower}}{1.75 \text{ kW}}$$

(1 horsepower equals approximately 750 watts.)

$$= \frac{2 \times 750}{1.75 \times 1000}$$

$$= \frac{1500}{1750}$$

$$= \frac{6}{7}$$

$$= .857 \text{ or } 85.7\%$$

(13) $$\frac{6\text{V}}{18\text{V}} = \frac{1}{3} = 1{:}3$$

(14) $$\frac{250 \text{ mV}}{1\text{V}} = \frac{250 \text{ mV}}{1000 \text{ mV}} = \frac{1}{4} = 1{:}4$$

(15) $$\text{Efficiency} = \frac{\text{Output power}}{\text{Input power}}$$

$$= \frac{3\text{hp}}{2.5\text{kW}}$$

(1 horsepower equals approximately 750 watts.)

$$= \frac{3 \times 750}{2.5 \times 1000}$$

$$= \frac{2250}{2500}$$

$$= \frac{9}{10}$$

$$= .9 = 90\% \text{ efficiency}$$

(16) $$\frac{A_1}{A_2} = \frac{B_1}{B_2}$$

$$\frac{15}{6} = \frac{90}{B_2}$$

$$15B_2 = 540$$

$$B_2 = 36$$

(17) $$\frac{A_1}{A_2} = \frac{B_2}{B_1}$$

$$\frac{A_1}{4} = \frac{150}{100}$$

$$100A_1 = 600$$
$$A_1 = 6$$

(18) The battery voltage is equal to the sum of the voltage drops across the two resistors. The voltage across R_1 is 10 volts. Therefore, we can find the voltage across R_2 using direct proportion:

$$\frac{E_1}{E_2} = \frac{R_1}{R_2}$$

$$\frac{10}{E_2} = \frac{1200}{240}$$

$$1200E_2 = 2400$$
$$E_2 = 2 \text{ volts}$$

The applied battery voltage is the sum of $E_2 + E_1$ or $2V + 10V = 12V$.

(19) Since current is inversely proportional to resistance, our equation is:

$$\frac{I_1}{I_2} = \frac{R_2}{R_1}$$

$$\frac{2}{2.2} = \frac{R_2}{66}$$

$$2.2R_2 = 132$$
$$R_2 = 60 \text{ ohms}$$

(20) To add two or more numbers with like signs, find the sum of the numbers as you would in ordinary arithmetic and place the sign of the numbers added in front of this sum.

(21) The sum of two signed numbers with unlike signs is equal to the difference between the two numbers, preceded by the sign of the larger number.

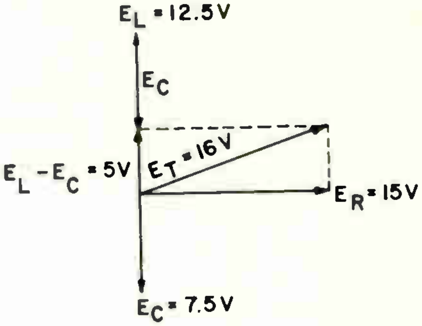
(44) Approximately 16 volts.



(45) The Pythagorean Theorem states that the square of the hypotenuse of any right triangle is equal to the sum of the squares of the other two sides.

(46) Any triangle which contains one angle that is equal to 90°.

(47) Impedance.

(48) 51 ohms.

L_L = Length of long wire
L_S = Length of short wire
R_L = Resistance of long wire
R_S = Resistance of short wire.

Now, since the resistance of a wire is directly proportional to its length, we can establish a proportion.

$$\frac{L_L}{L_S} = \frac{R_L}{R_S}$$

$$\frac{\overset{17}{\cancel{850}}}{\underset{10}{\cancel{500}}} = \frac{R_L}{30}$$

$$10R_L = 510$$
$$R_L = 51 \text{ ohms}$$

(49) 160 volts. First convert 8K-ohms to ohms.

8K-ohms = 8000 ohms

Then use Ohm's Law to find the voltage.

$E = IR$
$E = .02 \times 8000$
$E = 160$ volts

(50) .0318 amps. Use Ohms's Law for ac circuits.

$$I = \frac{E}{Z}$$

The only impedance in the circuit is the X_L of the coil. Therefore, $I = E/X_L$, so we must first find X_L.

$X_L = 2\pi fL$
$f = 60$ Hertz
$L = 10$ henrys
$X_L = 6.28 \times 60 \times 10$
$X_L = 3768$ ohms

Now,

$$I = \frac{E}{X_L}$$

$$I = \frac{120}{3768}$$

$I = .0318$ amps

(51) 1 amp.
$X_L = 2\pi fL$
$f = 1$ kHz or 1000 Hertz
$L = .03$ henry
$X_L = 6.28 \times 1000 \times .03$
$X_L = 188.4$ ohms

$$I = \frac{E}{X_L}$$

$$I = \frac{188.4}{188.4}$$

$I = 1$ amp.

(52) $R_1 = 100$ ohms.

$$\frac{R_1}{R_2} = \frac{E_1}{E_2}$$

$$\frac{R_1}{1800} = \frac{\overset{1}{\cancel{20}}}{\underset{18}{\cancel{360}}}$$

$18R_1 = 1800$
$R_1 = 100$ ohms

(53) 12 volts. First find X_C.

$$X_C = \frac{.159}{fC}$$

$f = .4$ kHz or 400 Hertz
$C = 10$ mfd or .00001 farad

$$X_C = \frac{.159}{400(.00001)}$$

$$X_C = \frac{.159}{.004}$$

$X_C = 39.75$ ohms or approximately 40 ohms

$E = IX_C$
$I = 300$ ma or .3 amps
$E = .3 \times 40$
$E = 12$ volts

(54) 7 to 1.

$$\frac{N_1}{N_2} = \sqrt{\frac{Z_1}{Z_2}}$$

$$\frac{N_1}{N_2} = \sqrt{\frac{490}{10}}$$

$$\frac{N_1}{N_2} = \sqrt{49}$$

$$\frac{N_1}{N_2} = 7$$

Therefore, the turns ratio is 7 to 1.

(55) 1 henry.

$$L_T = L_1 + L_2 \pm 2M$$
$$L_T = .2 + .8$$
$$L_T = 1 \text{ henry}$$

(56) 10 ohms.

$$Z = \sqrt{R^2 + [X_L + (-X_C)]^2}$$

$$Z = \sqrt{6^2 + [14 + (-6)]^2}$$

$$Z = \sqrt{6^2 + 8^2}$$

$$Z = \sqrt{36 + 64}$$

$$Z = \sqrt{100}$$

$$Z = 10 \text{ ohms}$$

(57) Approximately 580 kHz.

$$f = \frac{.159}{\sqrt{LC}}$$

$$f = \frac{.159}{\sqrt{1.5 \times 10^{-4} \times 5 \times 10^{-10}}}$$

$$f = \frac{.159}{\sqrt{7.5 \times 10^{-14}}}$$

$$f = \frac{.159}{2.74 \times 10^{-7}}$$

$$f = 5.8 \times 10^5$$

$$f = 580 \text{ kHz}$$

(58) 7.6 ohms.

$$Z = \sqrt{R^2 + X_L{}^2}$$

$$Z = \sqrt{3^2 + 7^2}$$

$$Z = \sqrt{9 + 49}$$

$$Z = \sqrt{58}$$

$$Z = 7.6 \text{ ohms}$$

(59) 9 microfarads.

$$C_T = C_1 + C_2 + C_3$$
$$C_T = 1 + 3 + 5$$
$$C_T = 9 \text{ mfd.}$$

(60) Approximately 3.3 henrys. First find the X_L of the coil.

$$X_L = \frac{E}{I} = \frac{110}{.215} = 512 \text{ ohms}$$

Now, since $X_L = 2\pi fL$
Then,

$$L = \frac{X_L}{2\pi f}$$

$$L = \frac{512}{6.28(25)}$$

$$L = \frac{512}{157}$$

$$L = 3.3 \text{ henrys.}$$

(61) 5 microfarads. First find the X_C of the capacitor.

$$X_C = \frac{E}{I} = \frac{240}{.452} = 531 \text{ ohms}$$

And since $X_C = \dfrac{.159}{fC}$

Then

$$C = \frac{.159}{fX_C}$$

$$C = \frac{.159}{60(531)}$$

$$C = \frac{.159}{31860}$$

$$C = .000005 = 5 \text{ mfd}$$

(62) .472 amps. $I = E/Z$, so we must first find Z. But to find Z we must find X_C.

$$Z = \sqrt{R^2 + X_C{}^2}$$

$$X_C = \frac{.159}{fC}$$

$$X_C = \frac{.159}{120(.000005)}$$

$$X_C = \frac{.159}{.0006}$$

$X_C = 265\Omega$. Now find Z.

$$Z = \sqrt{R^2 + X_C{}^2}$$

$$Z = \sqrt{175^2 + 265^2}$$

$$Z = \sqrt{30625 + 70225}$$

$$Z = \sqrt{100850}$$

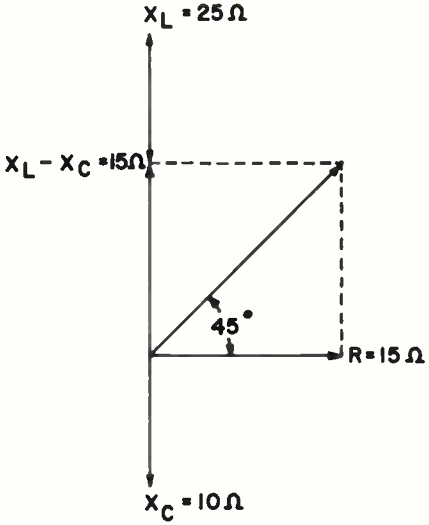
$Z = 318$ ohms. Now find I.

$$I = \frac{E}{Z}$$

$$I = \frac{150}{318}$$

$I = .472$ amps.

(63) 45° inductive.



(64) 170 ohms. There are two ways to work this problem. We will consider both ways. The easier method is to set up and solve a proportion. We know that X_C is inversely proportional to frequency. Therefore,

$$\frac{X_{C_1}}{X_{C_2}} = \frac{f_2}{f_1}$$

$$\frac{X_{C_1}}{300} = \frac{680}{1200}$$

$$1200\, X_{C_1} = 204000$$

$$X_{C_1} = \frac{204000}{1200} = 170 \text{ ohms.}$$

The second method is to find the capacitance of X_C and frequency given. Then find X_C of that capacitance at the new frequency.
That is,

$$C = \frac{.159}{fX_C} = \frac{.159}{680{,}000(300)}$$

$$= \frac{.159}{204{,}000{,}000}$$

C = 780 picofarads. Now find the reactance of this capacitance at the new frequency.

$$X_C = \frac{.159}{1{,}200{,}000(.000000000780)}$$

$$X_C = \frac{.159}{.000936}$$

X_C equals approximately 170 ohms. The answer does not work out exactly because we rounded off 2π and the value of C. By working both methods, it becomes obvious that the first method is not only easier, it is also more accurate.

(65) 40 volts. First find the impedance of the circuit.

$$Z = \sqrt{R^2 + [X_L + (-X_C)]^2}$$

$$Z = \sqrt{4^2 + [4 + (-1)]^2}$$

$$Z = \sqrt{16 + 9}$$

$$Z = \sqrt{25}$$

$$Z = 5 \text{ ohms.}$$

Now, find the current in the circuit.

$$I = \frac{E}{Z}$$

$$I = \frac{50}{5}$$

$$I = 10 \text{ amperes.}$$

Now, find the voltage across the coil (E_L).

$$E_L = I(X_L)$$
$$E_L = 10(4)$$
$$E_L = 40 \text{ volts.}$$

Lesson Questions

Be sure to number your Answer Sheet X109.

Place your Student Number on every Answer Sheet.

Most students want to know their grades as soon as possible, so they mail their set of answers immediately. Others, knowing they will finish the next lesson within a few days, send in two sets of answers at a time. Either practice is acceptable to us. However, don't hold your answers too long; you may lose them. Don't hold answers to send in more than two sets at a time or you may run out of lessons before new ones can reach you.

THE VALUE OF KNOWLEDGE

Knowledge comes in mighty handy in the practical affairs of everyday life. For instance, it increases the value of your daily work and thereby increases your earning power. It brings you the respect of others. It enables you to understand the complex events of modern life, so you can get along better with other people. Thus, by bringing skill and power and understanding, knowledge gives you one essential requirement for true happiness.

But what knowledge should *you* look for? The first choice naturally goes to knowledge in the field of your greatest interest – electronics. Become just a little better informed than those you will work with, and your success will be assured.

It pays to know – but it pays even more to know how to use what you know. You must be able to make *your* knowledge of value to others, and to the rest of the world, in order to get cash for knowledge.

The NRI Course gives you knowledge, and in addition shows you how to use what you learn. Master thoroughly each part of your course, and you'll soon be getting cash for *your* knowledge.

SIMPLE CIRCUIT ALGEBRA

In many ways the study of tube and transistor circuits is just an extension of your study of ac and dc circuits. The tuning circuits, coupling circuits, filter circuits, and voltage dividers that are used with tubes and transistors are simply special designs of circuits that you are already familiar with to a certain extent. In these circuits, coils and capacitors and resistors of various values are assembled in different series and parallel combinations to give special effects. Either ac, dc, or both may be applied to these circuits depending on their function and use.

For the most part, the basic arithmetic and operations with signed numbers and vectors that you studied for use with ac and dc circuit calculations can be applied in the calculations for tube and transistor circuits. However, as the equipment and circuits that you study become more involved, it will become increasingly difficult to keep up with their operation and maintenance if you rely only on the mathematical processes that you have already learned. You will need many new shortcuts and some new mathematical tools to keep your studies and work in electronics simple and straightforward.

In your previous lessons, you saw how important vectors are in analyses and calculations dealing with ac circuits. As you continue with your studies, these simple vectors will become even more important. However, the simple measurement solutions that you have been using to solve vector problems will become very awkward to use as the circuits become more complex. In addition to requiring careful construction and measurement, they require a lot of space and can become very involved, especially in parallel circuits. Although we can overcome these problems to some extent by using the Pythagorean Theorem, it also has its limits.

However, there is a handy method for working with ac circuit vectors so they can be solved mathematically. It involves using a special tool known as the "j" operator. This simple operator allows us to easily add, subtract, multiply, and divide vectors, regardless of their complexity. No course in electronics can really be considered complete without at least a working knowledge of this method of determining the solutions to circuit problems.

In order to use the j operator successfully, you should have at least a basic understanding of the essentials of another mathematical process known as algebra. As many of you already know, algebra is simply a form of mathematics that simplifies complex operations in arithmetic by using letters. Through these letter solutions of practical problems, we are able to speed up and simplify operations that would take a long time and involve a lot of tedious work if we used numbers alone. Thus, time spent learning the fundamentals of algebra will be worthwhile.

Therefore, in this lesson on circuit calculations, you will learn to use and apply the fundamentals of algebra and the j operator in electronic circuit calculations. If you have never studied these subjects, you may be a little uneasy about tackling them. However, you have already seen that math makes a lot more sense and becomes much easier when you have a practical use for it, such as your work in electronics.

As you study this lesson, remember these subjects are like all the others. All you have to do is learn a few rules and get some practice using them. Once you have done this, you have accomplished your goal of learning new processes that will help make your work much easier and more efficient. If you have already studied these subjects, you will find that this lesson will give you a good review and some valuable pointers on circuit applications.

Basic Algebra

Anyone who can add and subtract, multiply and divide, and perform the other operations of basic arithmetic should find algebra easy to understand. The only difference between algebra and arithmetic is that in algebra you work with letters as well as with numbers. Therefore, we can consider that algebra is simply arithmetic with letters. Consequently, all we have to do is get used to applying the rules of arithmetic to combinations of letters.

You are probably wondering just how we can use letters to compute with, because letters have no indicated values such as numbers have. We merely select letters and let them represent the values that we wish to work with. For example, you are already accustomed to working with formulas such as Ohm's Law which states that $E = I \times R$. Here we have simply used certain letters to indicate various quantities in our circuit and have used these letters in an equation that represents their relationship in an electrical circuit. This is algebra.

In ordinary arithmetic, the next step would be to substitute the actual number values in place of the letters and solve the problem. In algebra, we may also do this, but many times we will find that it is easier to work with the letters awhile before we substitute the numbers. In this section of the lesson, we will start at the very beginning and learn just what algebra is all about.

THE LANGUAGE OF LETTERS

In your earlier lessons you learned how to substitute numbers for letters in certain formulas. As you continue in your work in electronics, it will be handy to know more about the process of computing with both numbers and letters. You are already familiar with this sort of reasoning: "If I have one resistor and you give me another resistor, I will have two resistors." Or, "If you give me four capacitors and then someone else gives me five more capacitors, I will have nine capacitors." This is simply addition as applied to physical things.

Addition, as you know, can only be performed with like things. We can add resistors to resistors, or capacitors to capacitors, but we can never add a number of resistors to a number of capacitors and get a sensible answer. Thus, the result of any addition is the sum of the number of things added followed by their name. We know that it is possible to represent various quantities by letters. For example, suppose that we receive three orders of parts as follows:

(1) 5 choke coils, 7 resistors, 4 capacitors.

(2) 3 choke coils, 2 resistors, 3 capacitors.

(3) 7 choke coils, 4 resistors, 5 capacitors.

If we want to know the total number of parts received in these orders we can simply add the number of like parts in each order together to give us a total of 15 choke coils, 13 resistors, and 12 capacitors.

However, in doing this we must be very careful to keep the numbers associated with the coils separated from the numbers associated with the resistors, and resistors separated from the capacitors, etc. Otherwise, there is a possibility that we might get the numbers confused and start adding the coils to one of the other parts. To keep them separated, we can list them carefully in separate columns and write down the names of the parts as we just did. While this will work very well, you can easily see that it would require a lot of tedious writing if we needed to add a number of different things.

A much simpler way would be to choose abbreviations for the parts. For example, we could decide to let the letter "c" stand for the coils, the letter "r" stand for the resistors, and then let another letter such as "a" stand for the capacitors to be sure that the coils and capacitors are kept separate, since they both begin with "c." Now our additions and notations would look something like this (where c = choke coils, r = resistors, a = capacitors):

(1) 5c, 7r, 4a

(2) 3c, 2r, 3a

(3) 7c, 4r, 5a

15c,13r,12a

By doing this we could save ourselves a lot of work and still perform the addition in such a way that it would make sense and eliminate the chance of getting the different parts confused with each other.

In this way, it is possible to represent any number of different things or quantities with letters. Once we have chosen letters to indicate quantities, we can add or subtract them, or multiply and divide them by simply performing the operations with the letters instead of using the quantities themselves.

For example, let's say that we choose the letter "a" to represent a quantity. This means that the letter "a" written by itself will always mean "1 a," the term "2a" will mean "2 a's," "3a" will mean "3 a's," etc. Thus, a term such as "5a" means that the quantity represented by the letter "a" is to be multiplied by 5. When we get ready to substitute and actually find the value or the meaning of the term "5a," we will need to know what the letter "a" stands for. In the meantime, we can go along and work with the term itself without worrying about what it means.

Another example of a term that we are likely to meet is one such as "6ab." This simply means that a quantity represented by "a" is to be multiplied by a quantity represented by "b." Then the product of quantity "a" times quantity "b" is to be multiplied by 6. Thus, 6ab means "6" times "a" times "b" or 6 × a × b. In working with algebra we usually do not use the symbol × as a "times" sign because it can be confused with the letter "x" which can be used to represent a quantity. Sometimes dots are used between letters to indicate multiplication, as "6 · a · b," but generally the letters are simply written close together without any sign between them.

Before we go on to learn the rules of using letters, there are some special names given letter combinations that we should be familiar with. A letter by itself is called a "term." Thus "a" is a term, "b" is a term, "x" is a term, etc. The indicated product of a group of letters such as "6ab" is also called a term. In this term, the 6, the a, and the b, are all factors of the indicated product, just as 6 and 8 are factors of 48.

We may have "like" terms or "unlike" terms in algebra. For example, 6ab, 3ab, and 5ab are all like terms because their letter factors are all the same. Terms such as 6xy, 10ax, 7ab, are unlike terms because their letter factors are not all the same.

The number tells you how many times the letter term is to be multiplied. It is called the "numerical coefficient" of the term or, more simply, just the "coefficient." Thus, a term may be a single letter, or it may consist of an indicated product between two or more letters, or between one or more letters and a numerical coefficient. Remember, a term may consist of one or more letters and numbers, but if more than one letter appears, it is a term only if multiplication is indicated. The expression, "a + b", is two separate terms because addition is indicated between the two letters. Likewise, an expression such as 6ab – cd is also made up of two terms.

An algebraic expression made up of one term such as "7xyz" is called a "monomial" term. An expression made up of two or more terms, such as 6ir + 7abc, or 8yx + 7cd – ab is called a "polynomial." If a polynomial has only two terms, it is usually called a "binomial" and one with three terms is often called a "trinomial." Thus, ab + ac is a binomial, and ab + ac + ad would be called a trinomial. We have no special names for polynomials that consist of more than three terms. For example, an expression such as xy + ab – ac – yb would simply be called a four-term polynomial.

Now, with the names given to these various expressions firmly in mind, let's see how to perform simple arithmetic with letters.

Addition of Letters. The rules for performing arithmetic with letters are the same as those with numbers. We can add like terms to each other, but we cannot add unlike terms. The rules for working with signed numbers also apply to working with letters. Likewise, the rules of order for performing a series of operations apply to letter arithmetic, or algebra, just as they do to numbers.

A term consisting of a letter with a coefficient, such as 5a, means that "a" is to be taken five times, or a+a+a+a+a. A term such as 6a means a+a+a+a+a+a. Therefore, to add 5a and 6a together really means (a+a+a+a+a) + (a+a+a+a+a+a), or a total of 11 a's which we would write as 11a. Accordingly, we can say that 5a + 6a = 11a. We can perform the indicated addition because the letter factors are the same and we can add like things together. Notice that in adding these like terms, we simply added their numerical coefficients (6 and 5) and used this sum as the new coefficient for the common letter. Thus, *the sum of like terms is the sum of the coefficients of the terms followed by the common letters.* For example,

$$6ab + 3ab = 9ab$$

$$4abc + 3abc + 5abc = 12abc$$

$$xy + 3xy + 8xy = 12xy$$

When working with unlike terms, however, we can only indicate the addition to be performed. Thus, a + b can only be written as a + b. Likewise, 6a + 5b must remain as 6a + 5b as far as the addition is concerned. Thus, addition of unlike terms always results in a polynomial term. Consequently, when we have addition indicated in a problem such as

$$6a + 7b + 9ab + 4a + 3b + b,$$

we would proceed as follows.

First, we would arrange the terms so that all the like terms were grouped together. Thus, we would have $6a + 4a + 7b + 3b + b + 9ab$. Now, adding the like terms gives us

$$6a + 4a = 10a,$$

and

$$7b + 3b + b = 11b.$$

Since we now have $10a + 11b + 9ab$, which are all unlike terms and cannot be added any further, our answer to our problem of

$$6a + 7b + 9ab + 4a + 3b + b$$

is simply

$$10a + 11b + 9ab.$$

Thus, to add a group of terms in algebra arrange the like terms so that they are together, then add all the like terms by adding their coefficients and then use these sums in an indicated addition of the unlike terms. The process of rearranging and adding the like terms is often called "collecting" terms.

In working with letters, we will often run into terms with negative signs just as in working with numbers. We handle these signed algebraic terms like signed numbers. For example, to add two terms with like signs, we add the coefficients and use the common sign in front of the sum. Thus, $(-6ab) + (-4ab)$ would be equal to $-10ab$, just as $+3ab$ plus $+4ab$ would equal $+7ab$.

If we have to add terms with unlike signs, we simply find the difference between the coefficients and use the sign of the largest coefficient. Thus,

$$+5c + (-3c) = +2c$$

and

$$-7cd + 4cd = -3cd.$$

In a more complicated problem that consists of like and unlike terms as well as like and unlike signs, we would simplify the problem by collecting all like terms with like signs and then perform the addition. Thus, for a problem such as

$$4c + (-9d) + 6e + (-3e) + 12d + (-4x) + 2c + (-c) + 3d + 4e + (-3c) + (-3d),$$

we would first collect all our like terms and like signs as follows:

$$4c + 2c + (-c) + (-3c)$$

$$+ 12d + 3d + (-3d) + (-9d)$$

$$+ 6e + 4e + (-3e) + (-4x).$$

$$+ (-4x).$$

Then, combine like terms:

$$6c + (-4c)$$

$$+ 15d + (-12d)$$

$$+ 10e + (-3e) + (-4x).$$

$$+ (-4x).$$

Now,

$$6c + (-4c) = 2c$$

$$15d + (-12d) = 3d$$

$$10e + (-3e) = 7e$$

$$+ (-4x) = -4x$$

and our answer would be

$$2c + 3d + 7e + (-4x)$$

or simply $2c + 3d + 7e - 4x$.

We will also find terms like this to add:

$$(6ab-7xy) + (5ab-xy) + (-3ab+4xy).$$

Here we have to add three binomials but the terms in each binomial are alike, so we can add them quite easily like this:

$$\begin{array}{rrr} & 6ab & -\ 7xy \\ + & 5ab & -\ \ xy \\ & -3ab & +\ 4xy \\ \hline & 8ab & -\ 4xy \end{array}$$

Or, collecting terms like this:

$$6ab + 5ab + 4xy - 3ab - 7xy - xy$$

then:

$$11ab + 4xy - 3ab - 8xy$$

and:

$$11ab - 3ab + 4xy - 8xy = 8ab - 4xy.$$

Now suppose we had a problem like this:

$$(4x - 3y + 6c) + (-3x + 2y - 3d) + (2x - 7c + 2d).$$

Here we have three trinomials with terms that are not all alike. In a case like this we can set up our problem as follows:

$$\begin{array}{rrrrr} & 4x & -\ 3y & +\ 6c & \\ + & -\ 3x & +\ 2y & & -\ 3d \\ & 2x & & -\ 7c & +\ 2d \\ \hline & 3x & -\ \ y & -\ \ c & -\ \ d \end{array}$$

Since we cannot add unlike terms, this is as far as we can go with our answer. Notice that we could also have proceeded like this:

$$(4x - 3y + 6c) + (-3x + 2y - 3d) + (2x - 7c + 2d)$$

Collecting like terms and like signs:

$$4x + 2x - 3x + 2y - 3y + 6c - 7c + 2d - 3d$$

Then:

$$3x - y - c - d$$

which is the same answer we got before.

Now you should be able to add the following terms without any trouble:

(1) $3x - 2y + 4z + 2x + 8y - 2z + 12x + y + z =$

(2) $5ab - 6xy - 3ab + 12xy + 3ax - 5xb + ab - 3xy - 2xb =$

(3) $(12a + 6c - 3d) + (-20a + 8c - 5d) + (10a - 2c + d) =$

Answers:

(1) $17x + 7y + 3z$

(2) $3ab + 3xy + 3ax - 7xb$

(3) $2a + 12c - 7d$

Subtraction of Letters. When you

learned to subtract signed numbers, you found by experimenting with numbers of various signs that a simple rule would apply to all subtraction with signed numbers. This rule stated that: *To subtract signed numbers, change the sign of the number in the subtrahend (the number you are subtracting) and then proceed as in adding signed numbers.* Following this rule, + 7 minus – 6 would be handled this way:

$$\begin{array}{r} +7 \\ -\ (-6) \\ \hline \end{array} = \begin{array}{r} +7 \\ +6 \\ \hline +13 \end{array}$$

Thus, $+7-(-6)=13$.
To prove this, add the subtrahend, – 6, and the answer, + 13, which gives $-6+13=+7$, which is the minuend. Likewise, $-7-(-6)=$

$$\begin{array}{r} -7 \\ -\ (-6) \\ \hline \end{array} = \begin{array}{r} -7 \\ +6 \\ \hline -1 \end{array}$$

The proof is that $-1+(-6)=-7$.

Subtracting terms in algebra is just like subtracting signed numbers in arithmetic. Thus, if we want to subtract 6a from 8a we would have: + 8a minus + 6a, which is written $(+8a)-(+6a)$. Now, changing both signs in front of 6a, we get

$$(+8a)+(-6a).$$

Adding:

$$\begin{array}{r} +8a \\ -6a \\ \hline +2a \end{array}$$

To prove this, we add + 6a (the subtrahend) and + 2a which gives us the + 8a that we started with. As with addition in algebra, we can subtract only like terms. Thus, we can state a rule for subtraction in algebra which is: *To subtract in algebra, change the sign of the terms in the subtrahend and then add the coefficients of the like terms.*

This rule for subtraction in algebra holds true for either single terms or for polynomials. For example, to subtract $(2a-2b-3c)$ from $(3a-4b+5c)$ we would first change the sign of the subtrahend. $2a-2b-3c$ then becomes $-2a+2b+3c$. Now, we proceed to add:

$$(3a-4b+5c)+(-2a+2b+3c)$$

collecting terms

$$=3a-2a-4b+2b+5c+3c$$

$$=a-2b+8c.$$

Or, we could set it up like this:

$$\begin{array}{lr} & 3a-4b+5c \\ + & -2a+2b+3c \\ \hline & a-2b+8c \end{array}$$

In either case, the difference is equal to $a-2b+8c$, which is the correct answer. To prove it, add the difference of $a-2b+8c$ to the subtrahend $2a-2b-3c$ which, by collecting terms, gives the sum:

$$a+2a-2b-2b+8c-3c$$
$$=3a-4b+5c$$

Thus, the important thing to remember in subtracting letters is to change the sign of the subtrahend and then add.

Now that we have seen how to add and subtract with letters, let's prove that what

LETTERS	NUMBER SUBSTITUTES
(5a+3b)+(-2a-6b)	[5(115)+3(95)]+[-2(115)-6(95)]
=5a-2a+3b-6b	=(575+285)+(-230-570)
=3a-3b	= 860-800=60

Fig. 1. Substituting numbers in place of letters in addition.

we are doing with the letters is correct by substituting numbers in place of the letters. Suppose that we want to add 5a + 3b to − 2a − 6b. Collecting terms, this gives us:

$$5a - 2a + 3b - 6b = 3a - 3b.$$

Now, let's substitute some numbers in this same problem. For example, suppose that we have chosen the letter "a" to represent "115" and the letter "b" to represent "95." We would set up the problems side by side, one using the coefficients and letters, and the other using the number values as shown in Fig. 1.

In this way, we find that the term answer is 3a − 3b, while the answer we got by substituting numbers is 60. Therefore 3a − 3b must be equal to 60. To prove this substitute the letter values in our answer 3a − 3b. Doing this, we have:

$$3a - 3b$$

$$= 3(115) - 3(95)$$

$$= 345 - 285$$

$$= 60$$

Thus, if we substitute the numbers in place of the letters in the beginning, we get an answer of 60. If we wish to work with the letters as long as we can, we get an answer 3a − 3b. However, we find that this is also equal to 60 when we substitute at the end of the problem. Since we get an answer of 60 either way, our process of adding letters must be correct.

Now, let's check a problem in subtraction the same way. Again, let a = 115 and b = 95. This time the problem is to subtract 3a − 2b from 5a − 7b as shown in Fig. 2. As you can see, the answer with the letters is 2a − 5b and the answer with the number substitutes is −245. Now let's substitute in our letter answer to see if we also get −245 for our final solution. Doing this, we have:

LETTERS:	NUMBER SUBSTITUTES:
FROM 5a − 7b TAKE 3a − 2b	5(115) − 7(95) TAKE 3(115) − 2(95)
5a − 7b − (3a − 2b)	5(115) − 7(95) − [3(115) − 2(95)]
CHANGING SIGNS:	
= 5a − 7b + (−3a + 2b)	= 575 − 665 + [−3(115) + 2(95)]
= 5a − 7b − 3a + 2b	= 575 − 665 − 345 + 190
= 5a − 3a − 7b + 2b	= 575 − 345 − 665 + 190
= 2a − 5b	= 230 − 475 = −245

Fig. 2. Substituting numbers in place of letters in subtraction.

$$2a - 5b$$

$$= 2(115) - 5(95)$$

$$= 230 - 475$$

$$= -245$$

Consequently, our method of handling subtraction with letters must also be correct, since in either case we get -245 for the final solution.

Next, let's take a look at multiplying and dividing with letters.

Multiplication of Letters. Multiplication with letters such as 3 times "a" may be indicated simply as 3a, which means "a" taken three times, or $a + a + a$. Likewise, $2 \times b$ is written 2b, which means "b" taken two times, or $b + b$. In multiplying two letters together such as "a" X "b" we write "ab", which means "a" taken "b" times, or "b" taken "a" times. For multiplication of two terms with coefficients, such as 3a times 2b, we actually perform the multiplication of the coefficients and then indicate the letter multiplication. We can do this because $3a \times 2b$ really means

$$3 \times a \times 2 \times b$$

$$= 6 \times a \times b$$

$$= 6 \times ab$$

$$= 6ab$$

Following this method,

$$3a \times 4b \times 2c$$

would equal

$$3 \times 4 \times 2 \times a \times b \times c = 24abc.$$

Now suppose that we want to multiply two like terms such as $2a \times 3a$. This can be rewritten as

$$2 \times 3 \times a \times a$$

or

$$6 \times a \times a = 6aa.$$

However, in arithmetic when we wanted to multiply a number by itself such as 5×5, we found that we would simply say, 5^2. The small "2" indicated the 5 was to be raised to the second power (multiplied by itself) or squared, and we called the "2" an exponent. We can also use exponents in algebra to indicate that a letter is to be multiplied by itself. Thus, $2a \times 3a = 6aa$ or $6a^2$. A multiplication such as $a \times a \times a$ is aaa or a^3 (read "a cubed"), and $a \times a \times a \times a \times a$ is aaaaa or a^5 (read "a to the fifth").

Using exponents in this way saves time. For example, 4a times 3ab becomes $4 \times 3 \times a \times a \times b$ or $12a^2b$. Now, there is an interesting thing about exponents that we should know. When we write the letter "a" alone, we really mean "a" taken once or a^1. However, just as we never indicate a coefficient of one, we never indicate an exponent of one. We say that the one is understood. For right now though, let's use the exponent "1" for a moment in order to examine the exponents as we multiply.

When we multiply $a \times a$, we can say that we have $a^1 \times a^1$. We know that this is equal to aa or a^1a^1 or a^2. Now, notice that the exponent "2" in a^2 is the sum of the exponents in the indicated multiplication.

$$a^1a^1 = a^{1+1} = a^2$$

Likewise,

$$a \times a \times a$$

$$= a^1 \times a^1 \times a^1$$

$$= a^{1+1+1}$$

$$= a^3$$

Thus, we have a rule for exponents in multiplication which states that: *To find the product of two or more powers of the same base, add the exponents.* According to this rule, $a^2 \times a^3 = a^{2+3}$ or a^5. If we do it the long way, we find that $a^2 = a \times a$ and

$$a^3 = a \times a \times a.$$

Therefore, $(a \times a) \times (a \times a \times a)$ = a taken five times, which is:

$$a \times a \times a \times a \times a = a^5.$$

Therefore, the rule for adding exponents must be correct.

Accordingly, a multiplication such as $5ab \times 3a^2b$ must equal:

$$5 \times 3 \times a^{1+2} \times b^{1+1}$$

$$= 15 \times a^3 \times b^2$$

$$= 15a^3b^2.$$

Likewise,

$$(3a^2b^3c^4) \times (25ab^2c^3)$$

$$= 3 \times 25 \times a^{2+1} \times b^{3+2} \times c^{4+3}$$

$$= 75a^3b^5c^7$$

Can you multiply $6a^3b^4$ by $5a^2b^3c$? The answer is $30a^5b^7c$.

These few simple steps cover the process of multiplying one single term (monomial) by another. However, in algebra, we must not only consider multiplying one monomial by another monomial, but we must also consider multiplying one polynomial by a monomial, and a polynomial by another polynomial. In considering the multiplication of a polynomial by a monomial, let's go back to our work with numbers for a moment.

For example, consider a number problem such as: $7 \times (3 + 2 + 5)$. We can write this down and solve it in a number of different ways. We can do the addition separately first, which gives us $7 \times (3 + 2 + 5) = 7 \times 10 = 70$, or we can multiply each number by seven and then add. This would give:

$$(7 \times 3) + (7 \times 2) + (7 \times 5) = 21 + 14 + 35$$

which also equals 70. Since this is true with numbers, it must also be true with letters.

Let's multiply the polynomial

$$b + c + d$$

by the monomial a. We would set it up like this:

$$a \times (b + c + d)$$

$$= a(b + c + d)$$

$$= ab + ac + ad$$

Thus, we can say that the product of a monomial and a polynomial is the sum of the products of the monomial and each term of the polynomial. Accordingly,

$$a(b - c + d - e) = ab - ac + ad - ae.$$

Notice that, as with signed numbers,

multiplication of unlike signs in algebra always gives a negative product, while the product of two terms with like signs is always positive. Or,

$$-b(a-c+d-e)=-ab+cb-db+eb.$$

With this in mind, we are ready to do a multiplication problem such as $3a^2b(2a+3b-7c)$. This equals

$$(3a^2b \times 2a)+(3a^2b \times 3b)$$

$$+[(3a^2b)\times(-7c)]$$

$$=6a^3b+9a^2b^2-21a^2bc$$

Or, we can set up the problem a different way. Let's try it with this problem: $4I^2R(3IR+5I+6R)$. Now, multiplying each term of the polynomial by the monomial gives us:

$$4I^2R \times 3IR = 12I^3R^2$$

$$4I^2R \times 5I = 20I^3R$$

$$4I^2R \times 6R = 24I^2R^2$$

The sum of the products is $12I^3R^2+20I^3R+24I^2R^2$.

Multiplying one polynomial by a binomial or by another polynomial is much the same. For example, multiplying the polynomial $(a+b-c)$ by the binomial $(a-b)$, we can think of $(a-b)$ as being a single multiplier. Thus, multiplying $(a-b)$ by each of the terms in the polynomial, we would have $(a-b)a$, then $(a-b)b$, and then $(a-b)(-c)$. Putting them together, we have

$$(a-b)a+(a-b)b+(a-b)(-c).$$

Now, the partial products would be:

$$(a-b)a=a^2-ab$$

$$(a-b)b=ab-b^2$$

$$(a-b)(-c)=-ac+bc$$

Then, adding these products gives us $a^2-ab+ab-b^2-ac+bc$. Collecting terms, we get $a^2-b^2-ac+bc$ as the answer. Notice that the $-ab$ and the $+ab$ cancel each other out just as $+2+(-2)$ would do.

In this way, we can say that the product of

$$(a-b)(a+b-c)=a^2-b^2-ac+bc.$$

We can prove that the solution to this problem is correct by substituting any numbers we want in place of the letters. For example, let's have $a=5$, $b=3$, and $c=2$. If we do this and substitute these values for the letters we have:

$$(a-b)(a+b-c)=a^2-b^2-ac+bc.$$

Then,

$$(5-3)(5+3-2)=$$
$$5^2-3^2-(5\times 2)+(3\times 2)$$

and

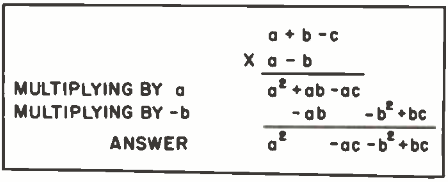
$$2\times 6=25-9-10+6$$

$$12=25-19+6=6+6=12$$

Since the problem works out so that 12 = 12, our multiplication of the letters must be correct.

We can also perform the multiplication by setting it down as in Fig. 3.

As you can see, we simply multiply all the terms in the polynomial by each term of the binomial. We do this by multi-



$$\begin{array}{lllll} & & a & +b & -c \\ & \times & a & -b & \\ \hline \text{MULTIPLYING BY } a & & a^2 & +ab & -ac \\ \text{MULTIPLYING BY } -b & & & -ab & \quad -b^2 + bc \\ \hline \text{ANSWER} & & a^2 & & -ac - b^2 + bc \end{array}$$

Fig. 3. Multiplying a polynomial by a binomial.

plying $a + b - c$ first by a, then by $-b$, and then adding the two partial products.

There are three polynomial products that we will find quite often in our work with algebra. They are:

(1) $(a + b)(a - b) = a^2 - b^2$

(2) $(a + b)(a + b)$ or $(a + b)^2$
$= a^2 + 2ab + b^2$

(3) $(a - b)(a - b)$ or $(a - b)^2$
$= a^2 - 2ab + b^2$

If we work each one of these out, we will find that the listed products are correct. Thus:

$$(1)\quad \begin{array}{lll} a & +b & \\ a & -b & \\ \hline a^2 & +ab & \\ & -ab & -b^2 \\ \hline a^2 & & -b^2 \end{array}$$

$$(2)\quad \begin{array}{lll} a & +b & \\ a & +b & \\ \hline a^2 & +ab & \\ & +ab & +b^2 \\ \hline a^2 & +2ab & +b^2 \end{array}$$

$$(3)\quad \begin{array}{lll} a & -b & \\ a & -b & \\ \hline a^2 & -ab & \\ & -ab & +b^2 \\ \hline a^2 & -2ab & +b^2 \end{array}$$

Sometimes these products are stated in words and used as rules:

1. The product of the sum of two terms $(a + b)$ *and the difference of the same two terms* $(a - b)$ *is equal to the square of the first term minus the square of the second term* $(a^2 - b^2)$.

This is a handy rule, because any time that we have to multiply the sum of two terms by the difference of the same two terms, we can just set down the answer without working it out. For example,

$$(4abc + 6xyz)(4abc - 6xyz)$$

must equal

$$(4abc)^2 - (6xyz)^2.$$

Likewise,

$$(4a^2b^3c^5 + 7x^2yz^3)(4a^2b^3c^5 - 7x^2yz^3)$$

must equal

$$(4a^2b^3c^5)^2 - (7x^2yz^3)^2.$$

The second example stated in words is:

2. The square of the sum of two terms $(a + b)^2$ *is equal to the square of the first term plus the square of the second term plus twice the product of the terms* $(a^2 + 2ab + b^2)$.

By using this rule, we automatically know that a binomial such as

$$(5xy + 3ab)^2$$

is equal to

$$(5xy)^2 + 2(15xyab) + (3ab)^2.$$

The third example covers the square of the difference of two terms:

3. The square of the difference of two terms $(a - b)^2$ is equal to the square of the first term plus the square of the second term minus twice the product of the terms.

Thus,

$$(16cd - 5x^2y)^2$$

is equal to

$$(16cd)^2 - 2(80cdx^2y) + (5x^2y)^2.$$

Since we often have to work with either the square of the sum or the square of the difference of two terms, we will use these rules quite a lot.

Can you find the products for the following problems?

(1) $(2x - 3)(3x + 7)$

(2) $(2x + 3)^2$

(3) $(5x^2 - 4y^2)(5x^2 + 4y^2)$

(4) $(6ab - c^2)^2$

Answers:

(1) $6x^2 + 5x - 21$

(2) $4x^2 + 12x + 9$

(3) $(5x^2)^2 - (4y^2)^2$ or $25x^4 - 16y^4$

(4) $(6ab)^2 - 2(6abc^2) + (c^2)^2$ or

$$36a^2b^2 - 12abc^2 + c^4.$$

Division with Letters. Division in algebra is just the reverse of multiplication. In division, we are given a product and one of the factors of the product and are asked to find the other factor. Remember, there are special names for the quantities in a division problem. The dividend is the product that is to be divided. The divisor is the factor by which the dividend is to be divided. The quotient is the result of the division, or the factor which we are to find. Thus: dividend ÷ divisor = quotient.

Also, multiplication is the proof of a division problem. Thus, $24 \div 6 = 4$ because $4 \times 6 = 24$; likewise,

$$24 \div 4 = 6$$

because $4 \times 6 = 24$. Accordingly, we can say that $ab \div a = b$ because $a \times b = ab$. The rules for the division of signed numbers also apply to the division of signed terms in algebra. Thus:

$+24 \div +6 = +4$ because $+4 \times (+6) = +24$

$-24 \div +6 = -4$ because $-4 \times (+6) = -24$

$+24 \div -6 = -4$ because $-4 \times (-6) = +24$

$-24 \div -6 = +4$ because $+4 \times (-6) = -24$

Accordingly, our rules for division of signed numbers and signed terms are:

If the dividend and the divisor have like signs, the quotient is positive.

If the dividend and the divisor have unlike signs, the quotient is negative.

Thus:

$ab \div b = a$ because $a \times b = ab$

$-ab \div b = -a$ because $-a \times b = -ab$

$ab \div -b = -a$ because $-a \times -b = ab$

$-ab \div -b = a$ because $a \times -b = -ab$

With this review and application of the general rules for division to letter problems, we are ready to look at the rules for handling exponents in division. You are already familiar with the fact that a^4 means

$$a \times a \times a \times a$$

and a^2 means $a \times a$. With this in mind, let's divide a^4 by a^2 and see what we get for an answer.

$$\begin{aligned} a^4 \div a^2 &= \frac{\cancel{a} \times \cancel{a} \times a \times a}{\cancel{a} \times \cancel{a}} \\ &= \frac{a \times a}{1} \\ &= a \times a \\ &= a^2 \end{aligned}$$

Likewise:

$$\begin{aligned} b^6 \div b^4 &= \frac{b^6}{b^4} \\ &= \frac{\cancel{b} \times \cancel{b} \times \cancel{b} \times \cancel{b} \times b \times b}{\cancel{b} \times \cancel{b} \times \cancel{b} \times \cancel{b}} \\ &= \frac{b \times b}{1} = b^2 \end{aligned}$$

And:

$$c^3 \div c^2 = \frac{c^3}{c^2} =$$

$$\frac{\cancel{c} \times \cancel{c} \times c}{\cancel{c} \times \cancel{c}} = \frac{c}{1} = c.$$

If you look at these examples closely, you will see that we could have obtained the same results by subtracting exponents.

$$a^4 \div a^2 = a^{4-(+2)} = a^2$$

$$b^6 \div b^4 = b^{6-(+4)} = b^2$$

$$c^3 \div c^2 = c^{3-(+2)} = c$$

Thus, just as we can multiply powers with the same base by adding exponents, we can divide two powers with the same base by subtracting exponents. Consequently,

$$a^6 b^3 \div a^5 b^2 = ab$$

and

$$x^3 y^2 \div xy = x^2 y$$

We can prove these answers by multiplying the quotients by the divisors to see if we get the original dividends. Doing this, we would have

$$ab \times a^5 b^2 = a^{1+5} b^{1+2} = a^6 b^3$$

and

$$(xy)(x^2y) = x^{1+2}y^{1+1} = x^3y^2$$

As we start working with division, we will find a few new situations regarding exponents. We know that any number divided by itself is equal to one. Thus,

$$\frac{6}{6} = 1, \frac{a}{a} = 1, \frac{3}{3} = 1$$

Now, if we follow our rules for dividing by subtracting exponents, we can see that if

$$\frac{a^3}{a^3} = 1,$$

that

$$a^3 \div a^3 = a^{3-(+3)} = a^0$$

which must also equal one. Likewise,

$$\frac{a}{a} = 1$$

$$a \div a = a^{1-(+1)}$$

$$= a^0 = 1$$

and

$$\frac{a^6}{a^6} = 1$$

$$a^6 \div a^6 = a^{6-(+6)}$$

$$= a^0 = 1$$

Thus, we have a new situation brought on by division which gives us an exponent of zero, and any factor with a zero exponent must equal 1. Remember, a factor by itself, such as "x", is considered to have an exponent of one, or x^1, and is equal to itself; but, a factor with an exponent of zero, such as b^0, can only be equal to the number 1.

If we look further into this problem of dividing by subtracting exponents, we will find that we can not only have positive exponents, such as 1, 2, 5, etc., and zero exponents, but we can also have negative exponents. This would occur if we had a division problem, such as $a^2 \div a^5$. This would be written either as

$$\frac{a^2}{a^5} = \frac{\cancel{a} \times \cancel{a}}{\cancel{a} \times \cancel{a} \times a \times a \times a}$$

$$= \frac{1}{a \times a \times a}$$

$$= \frac{1}{a^3}$$

or it could be written as

$$a^2 \div a^5 = a^{2-(+5)} = a^{-3}$$

If our answer can be either $1/a^3$ or a^{-3}, then a^{-3} must equal $1/a^3$. Thus, we can say that any factor with a negative exponent is equal to one divided by the factor with the exponent positive. Accordingly, $x^{-5} = 1/x^5$ and $c^{-3} = 1/c^3$.

Once again, we can prove that the reasoning behind negative exponents is correct by multiplying. For example, $x^4 \div x^7 = x^{4-(+7)} = x^{-3}$ because $x^{-3} \times x^7 = x^{-3+7} = x^4$ or $(x^4/x^7) = (1/x^3)$ because

$$\frac{1}{x^3} \times x^7$$

$$= \frac{x^7}{x^3} = x^4$$

The problems of division in algebra can be broken down into three general considerations the same as multiplication. First, we have the division of one monomial by another. Second, we have the division of a polynomial by a monomial. Third, we have the division of a polynomial by another polynomial.

In our review of division in general and our studies of handling exponents in division, we have covered the problem of dividing one monomial by another monomial. There is only one more thing that we must learn and that is what to do with the coefficients of terms. For example, suppose we want to divide $-12a^3x^4y$ by $4a^2x^2y$. We can set this up as

$$-12a^3x^4y,$$

$$4a^2x^2y$$

and then break it up into

$$\left(\frac{-12}{4}\right)\left(\frac{a^3}{a^2}\right)\left(\frac{x^4}{x^2}\right)\left(\frac{y}{y}\right)$$

We can see that this will reduce to:

$$(-3)(a)(x^2)(1).$$

Now, putting the quotients together we have $-3ax^2 1$ or just $-3ax^2$, since any quantity times one equals itself.

By breaking up our division problems in this way and following the rules for division of signed numbers and exponents, we can see how division is accomplished. As a general rule, we will not need to do this, because the division of most monomials by another monomial can be worked out mentally. For example, see if you can follow these monomial divisions:

(1) $$\frac{-14a^2b^4c}{-7ab^2c^3} = \frac{2ab^2}{c^2}$$

(2) $$\frac{4x^3y^5}{8x^5y^2} = \frac{y^3}{2x^2}$$

(3) $$\frac{28a^2b^4c^3}{-7b^3c^3} = -4a^2b$$

(4) $$\frac{-16e^3i^2r^5}{-4e^2i^2r^3} = 4er^2$$

In order to divide a polynomial by a monomial, let's consider numbers for a moment. 16 ÷ 2 = 8 because 2 × 8 = 16. Thus, if $3(a + 4) = 3a + 12$, then $(3a + 12) \div 3$ must equal

$$\frac{3a + 12}{3} = a + 4.$$

Similarly, if

$$3x(2x + 3y) = 6x^2 + 9xy,$$

then

$$\frac{6x^2 + 9xy}{3x}$$

must equal

$$2x + 3y.$$

Thus, we have a very simple rule for dividing a polynomial by a monomial. It is: *Divide each term in the polynomial dividend by the divisor, and then collect the terms in the quotient with the proper signs.*

For example,

$$8a^2b^3c - 12a^3b^2c^2 + 4a^2b^2c$$

divided by $4a^2b^2c$ can be set up as follows:

$$\frac{8a^2b^3c - 12a^3b^2c^2 + 4a^2b^2c}{4a^2b^2c}$$

equals

$$\frac{8a^2b^3c}{4a^2b^2c} = 2b$$

and

$$\frac{-12a^3b^2c^2}{4a^2b^2c} = -3ac$$

and

$$\frac{4a^2b^2c}{4a^2b^2c} = 1$$

Now, collecting terms we have

$$2b - 3ac + 1$$

for our answer.

Another example:

$$-27x^3y^2z^5 + 3x^4y^2z^4 - 9x^4y^3z^5$$

divided by $-3x^3y^2z^4$ is equal to:

$$\frac{-27x^3y^2z^5}{-3x^3y^2z^4} = 9z$$

and

$$\frac{3x^4y^2z^4}{-3x^3y^2z^4} = -x$$

and

$$\frac{-9x^4y^3z^5}{-3x^3y^2z^4} = 3xyz$$

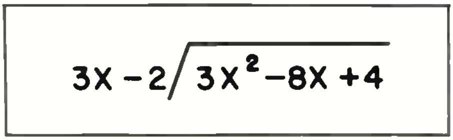


Fig. 4. Setting up a polynomial for division by another polynomial.

Now, collecting our quotient terms, we have our answer: 9z − x + 3xyz. Any polynomial can be divided by any monomial in this way.

In order to divide one polynomial by another polynomial, we must arrange the terms in a certain order before we actually divide. To do this, we simply make sure that all the terms in the dividend are arranged in the same order as those of the divisor. In doing this, we always place the term with the largest exponent first. Thus, in the problem $3x^2 + 4 - 8x$ divided by $3x - 2$, the divisor is correctly arranged, but the dividend isn't. Therefore, we must arrange it properly before we can proceed. Properly

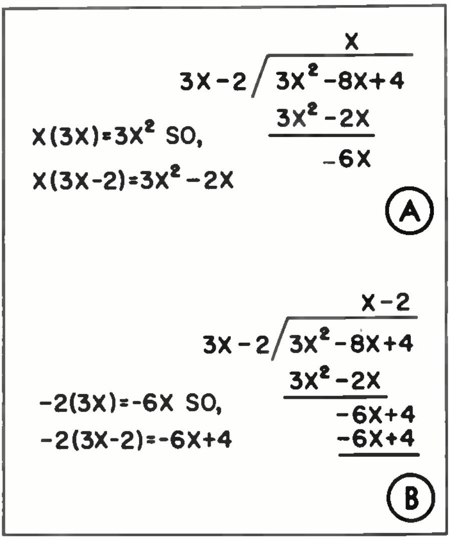

Fig. 5. (A) First steps in polynomial division. (B) Next step in polynomial division.

arranged, it should be written

$$3x^2 - 8x + 4.$$

Now that we have our terms arranged properly, we can set up our problem exactly as we did with long division of numbers shown in Fig. 4. Notice that we have the dividend set up under the division sign and the divisor at the left. Our process now is really just plain long division, as shown in Fig. 5A.

First, we see how many times the first term of our divisor will go into the first term of our polynomial dividend. For example, $3x$ will go into $3x^2$ x times, because $3x$ times x is equal to $3x^2$. Thus, x becomes our first term in our quotient as shown. Now we multiply our entire divisor, $3x - 2$, by x to give us our first trial product of $3x^2 - 2x$. We place this trial product under the proper terms of the divident and subtract.

Our remainder from this subtraction, plus the other term which we bring down from the dividend, can be considered to be a new dividend, as shown in Fig. 5B. Notice the sign of the first term. Signs are very important in algebra. Now, we see how many times the first term in our divisor will go into the first term in this new dividend. Since -2 times $3x$ equals $-6x$, we will try' the number 2 as the second term in our quotient. To do this, we place the -2 beside the x in our quotient, as shown, and then multiply our entire divisor by -2. As you can see, this gives us $-6x + 4$ as a trial product to subtract from the dividend. Since $-6x + 4$ from $-6x + 4$ leaves no remainder, our division is complete.

$$\begin{array}{r} 3X-2 \\ X-2 \\ \hline 3X^2-2X \\ -6X+4 \\ \hline 3X^2-8X+4 \end{array}$$

Fig. 6. Checking the answer in polynomial division.

$$\begin{array}{r|l} & 2X^2+3X+14 \\ \hline X-3 & 2X^3-3X^2+5X-42 \\ & \underline{2X^3-6X^2} \\ & +3X^2+5X \\ & \underline{3X^2-9X} \\ & +14X-42 \\ & \underline{14X-42} \end{array}$$

$X(2X^2) = 2X^3$ SO,
$2X^2(X-3) = 2X^3-6X^2$

$X(3X) = 3X^2$ SO,
$3X(X-3) = 3X^2-9X$

$X(14) = 14X$ SO,
$14(X-3) = 14X-42$

Fig. 7. Another problem in polynomial division.

In this way, we find that $3x^2 - 8x + 4$ divided by $3x - 2$ is equal to $x - 2$. To check our answer, we simply multiply the divisor by the quotient to see if we can get our dividend, as shown in Fig. 6. Since our answer checks, our problem is correct.

To make sure that we understand this, let's do another problem following the rules. Divide

$$5x - 42 + 2x^3 - 3x^2$$

by $x - 3$. Our first step is to rearrange the dividend in the proper order, which would give us

$$2x^3 - 3x^2 + 5x - 42$$

Now, we set up the problem for division, as shown in Fig. 7. Then, we see how

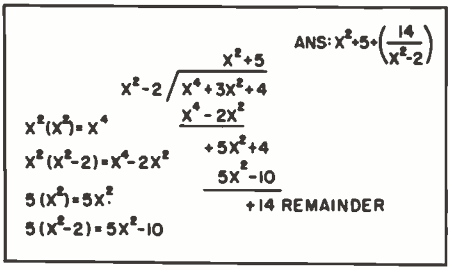

Fig. 8. Polynomial division with a remainder.

many times x will go into $2x^3$. Since $2x^2$ times x is equal to $2x^3$, we place $2x^2$ in our quotient and multiply the entire divisor by it. Since $2x^2(x - 3) = 2x^3 - 6x^2$, we use this as our first trial product and subtract it from the proper terms in the dividend.

Our remainder from this subtraction, plus the next term of our dividend, gives us a new dividend of $3x^2 + 5x$ to work with. x will go into $3x^2$, 3x times, so 3x becomes our next quotient term.

$$3x(x - 3) = 3x^2 - 9x,$$

which is the term we subtract from our new dividend. This makes our next dividend 14x – 42, as shown, and x – 3 will go into it exactly 14 times. Thus, our answer is $2x^2 + 3x + 14$. We can check this in the usual way, by multiplying the quotient and the divisor.

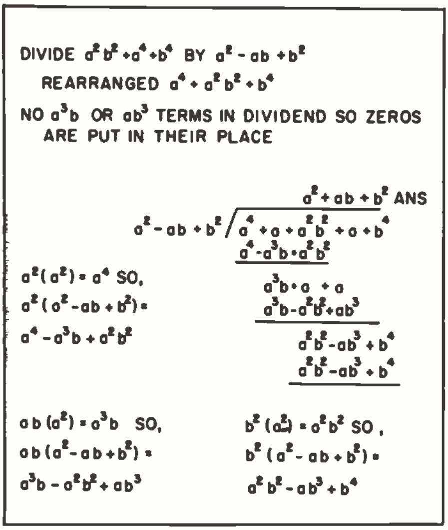

Fig. 9. A polynomial divided by a trinomial.

Some problems in division may not come out exactly even. It is possible to have a remainder in algebraic division, just as we do when working with numbers. An example of such a problem is shown in Fig. 8. Notice that we proceed to work it out just as we would any other problem until we get to a point where the first term of the divisor will not go into the dividend. When we come to this point, we simply stop and carry the remainder as a fraction in our answer, just as we do in ordinary arithmetic.

In Fig. 9, we have worked a problem where the divisor is a trinomial. As you can see, this is really no different from the problems we have been working, where the divisor is a binomial. You shouldn't have any trouble following this example.

Equations

You have now learned how to do arithmetic with letters. Since many of these fundamental operations of algebra were new to you, you had a lot to learn so we did not take the time to see how they could be put to practical use in your work in electronics. Now, however, we have covered most of the elementary processes in algebra and it is time to see how to put these new mathematical tools to work in the solution of circuit problems. This can be done through the use of equations.

An equation is simply a mathematical statement that two quantities are equal to each other. The two equal quantities in an equation are called the "members" of the equation and they are always separated by an equal sign (=). Thus, the mathematical statements that $12 = 12$, $6 \times 2 = 6 \times 2$, $6 \times 2 = 12$, or $6 \times 2 = 3 \times 4$ are all equations, because the quantities on each side of the equal sign are equal to each other. Sometimes, when we want to be specific, we call the quantities on the left of the equal sign the "left member" of the equation and the ones on the right, the "right member."

Although you may already be somewhat familiar with equations and their use, it will be helpful to review some of the more common facts that you will use in working with them. Of course, the most important thing to remember is that an equation is always a statement of equality between the two members, and that in order to use it, we must never upset this equality or balance between the members. Thus, in an equation such as $24 = 24$, if we make any changes in one member, we must be very careful not to upset the balance of the whole equation. For example, we can change $24 = 24$ to $24 \times 1 = 24$, $12 \times 2 = 24$, $6 \times 4 = 24$, $6 \times 4 = 12 \times 2$, $3 \times 2 \times 4 = 6 \times 2 \times 2$, etc., because our changes do not upset the equality of the two members. Likewise, an equation such as $4Ir + 4IR = 4Ir + 4IR$ may be written in any of the following ways:

$$4(Ir + IR) = 4Ir + 4IR$$

$$4I(r + R) = 4Ir + 4IR$$

$$4I(r + R) = 4(Ir + IR)$$

because in any of these cases the equations remain balanced.

We can also do other things to equations without disturbing their equality. For example, we can add or subtract a quantity from one member of an equation as long as we perform the same operation to the other member with the same quantity. Thus, if we have an equation such as $x = x$, we can add the same number to each side without destroying the equation. For example, let's add 2 to each side of the equation $x = x$. This would give:

$$x + 2 = x + 2$$

We can see that this is still an equation, because if we let $x = 4$, and substitute for x, we have:

$$4 + 2 = 4 + 2, \text{ or } 6 = 6,$$

which is still an equation because both members are equal. Likewise, if $x = x$, we can subtract a number from either side, as:

$$x - 3 = x - 3$$

and if $x = 4$, then $x - 3 = x - 3$ becomes

$$4 - 3 = 4 - 3 \text{ or } 1 = 1$$

We can also multiply or divide both members by the same quantity. For example, if $ab = ab$ and we multiply both members by 2, we have: $2ab = 2ab$. Or, dividing by 2, we have $(ab/2) = (ab/2)$. In either case, our equality can be proved by substitution. Thus if $a = 3$ and $b = 4$, substituting in the equation $ab = ab$, $3 \times 4 = 3 \times 4$ or $12 = 12$. And, $2ab = 2ab$, or $2 \times 3 \times 4 = 2 \times 3 \times 4$, which is $24 = 24$. Likewise,

$$\frac{ab}{2} = \frac{ab}{2},$$

or

$$\frac{3 \times 4}{2} = \frac{3 \times 4}{2},$$

or

$$\frac{12}{2} = \frac{12}{2},$$

or

$$6 = 6.$$

In all of these cases our equations remain balanced, because one member always equals the other.

From this, we can make the general statement that we can do anything to one side of an equation as long as we do exactly the same thing to the other side. There is only one exception to this rule, and that is that we can never multiply or divide either member by zero. We will show you why we cannot divide by zero a little later after you have become familiar with working with equations.

These rules for working with equations are very valuable in working with formulas. Formulas are, of course, equations, but they are a special kind of equation. A formula is a rule or a law that is stated as an equation. Thus, both the equations $ab = ab$, and $E = I \times R$ are equations, but only $E = I \times R$ is a formula, because there is a law that makes it a true equation. In other words, $ab = ab$, or $I \times R = I \times R$ are equations because they meet the requirements of any equation automatically. Both members are exactly the same, and therefore equal. However, the fact that $E = I \times R$ is an equation is not apparent, and it wouldn't be recognized as an equation unless we knew that it was a statement of Ohm's Law. Here, both members are equal only by definition.

Since formulas are equations, we can use the rules for equations when working with formulas. Let's see how this can help us with a simple formula such as $P = E \times I$. Suppose we want to use this formula to find the power in a circuit, but we don't know the voltage, E. Instead of knowing the values of E and I, we have the values of I and R. Since, according to Ohm's Law, $E = I \times R$, we can substitute $I \times R$ in place of E in the power formula. Then, instead of $P = E \times I$, we would have $P = I \times R \times I$, or $P = I^2R$. By doing this, we have arranged our formula so that it contains the quantities that we know the values of, but we have not destroyed its equality. We have simply replaced one value, E, with an equal quantity, $I \times R$.

The rules for equations also help us to rearrange formulas so that they indicate directly the quantities we want to find. For example, the formula

$$Z = \sqrt{R^2 + (X_C)^2}$$

tells us how to find the impedance, Z, of a circuit. Suppose, however, we want to find X_C, but do not know the value of C or the frequency of the circuit. However, we have been given the impedance and can measure the resistance. In this case, we can apply the rules for working with equations to rearrange

$$Z = \sqrt{R^2 + (X_C)^2}$$

so that it indicates X_C from Z and R.

We do it like this:

$$Z = \sqrt{R^2 + (X_C)^2}.$$

Then, squaring both members, we have

$$(Z)^2 = \left(\sqrt{R^2 + (X_C)^2}\right)^2$$

which equals

$$Z \times Z = \sqrt{R^2 + (X_C)^2} \times \sqrt{R^2 + (X_C)^2}$$

or

$$Z^2 = R^2 + (X_C)^2$$

Now, subtracting R^2 from both members, we have

$$Z^2 - R^2 = R^2 - R^2 + (X_C{}^2)$$

or

$$Z^2 - R^2 = (X_C)^2$$

This indicates the value of $(X_C)^2$. But we want only X_C itself, so we take the square root of both members:

$$\sqrt{Z^2 - R^2} = \sqrt{(X_C)^2}$$

or

$$\sqrt{Z^2 - R^2} = X_C$$

or

$$X_C = \sqrt{Z^2 - R^2}$$

Now our one basic formula is rearranged to give us X_C directly when Z and R are known.

Likewise, C may be found with the formula $X_C = (1/2\pi fC)$ by rearrangement as follows:

If

$$X_C = \frac{1}{2\pi fC},$$

then

$$X_C \times C = \frac{1}{2\pi fC} \times C$$

or

$$X_C \times C = \frac{1}{2\pi f}.$$

Then,

$$X_C \times C \div X_C = \frac{1}{2\pi f} \div X_C$$

or

$$\frac{X_C \times C}{X_C} = \frac{1}{2\pi f X_C}$$

or

$$C = \frac{1}{2\pi f X_C}$$

Many of our formulas themselves are the result of the use of algebra and the rules for equations. They are found or derived from the knowledge of other facts.

For example, we often have the inductance of a circuit in microhenrys and the capacity in microfarads and want to find the resonant frequency of the circuit. We can do this using the formula

$$f = \frac{159}{\sqrt{LC}}$$

where L is in microhenrys, C is in microfarads, and f is in kilohertz. This formula is developed through the knowledge of other facts. For instance, at resonance we know that:

$$X_L = X_C$$

also $$X_L = 2\pi fL$$

and $$X_C = \frac{1}{2\pi fC}$$

In the formula $X_L = 2\pi fL$, f is in Hertz and L is in henrys; and in $X_C = (1 \div 2\pi fC)$, f is in Hertz and C is in farads.

Since

$$X_L = X_C,$$

We can substitute for X_L and X_C and get

$$2\pi fL = \frac{1}{2\pi fC}$$

Now, multiplying both sides by $2\pi fC$ we get

$$2\pi fL \times 2\pi fC = \frac{2\pi fC}{2\pi fC}$$

or

$$4\pi^2 f^2 LC = 1$$

Now, dividing both sides by $4\pi^2 LC$ we get

$$\frac{4\pi^2 f^2 LC}{4\pi^2 LC} = \frac{1}{4\pi^2 LC}$$

or $$f^2 = \frac{1}{4\pi^2 LC}$$

and taking the square root of both sides

$$\sqrt{f^2} = \frac{1}{4\pi^2 LC}$$

or

$$f = \frac{\sqrt{1}}{\sqrt{4} \times \sqrt{\pi^2} \times \sqrt{LC}} = \frac{1}{2\pi\sqrt{LC}}$$

$2\pi = 6.28$ and dividing 1 by 6.28 gives .159 so we can rewrite the equation as

$$f = \frac{.159}{\sqrt{LC}}$$

where f is in Hertz, L is in henrys and C is in farads.

If we substitute L in microhenrys and C in microfarads in this equation, we must divide each value by 1,000,000 to convert them to henrys and farads. Let's do this in the equation:

$$f = \frac{.159}{\sqrt{\dfrac{L}{1{,}000{,}000} \times \dfrac{C}{1{,}000{,}000}}}$$

which can be written

$$f = \frac{\dfrac{.159}{\sqrt{LC}}}{\sqrt{1{,}000{,}000^2}}$$

which is

$$f = \frac{\dfrac{.159}{\sqrt{LC}}}{1{,}000{,}000}$$

This is the same as

$$f = \frac{.159}{1} \div \frac{\sqrt{LC}}{1,000,000}$$

Now recall that to divide one fraction by another we invert the divisor and multiply. For example,

$$\frac{1}{3} \div \frac{1}{4} = \frac{1}{3} \times \frac{4}{1} = \frac{4}{3}$$

Similarly,

$$\frac{6}{14} \div \frac{1}{2} = \frac{6}{14} \times \frac{2}{1} = \frac{12}{14}$$

and

$$\frac{.159}{1} \div \frac{\sqrt{LC}}{1,000,000} = \frac{.159}{1} \times \frac{1,000,000}{\sqrt{LC}}$$

Therefore,

$$f = \frac{159,000}{\sqrt{LC}}$$

where f is in Hertz, L is in microhenrys and C is in microfarads.

To convert Hertz to kilohertz we divide by 1000. Therefore,

$$f = \frac{159,000}{\sqrt{LC}} \div 1000$$

$$f = \frac{159,000}{\sqrt{LC}} \times \frac{1}{1000}$$

$$f = \frac{159}{\sqrt{LC}}$$

where f is in kilohertz, L in microhenrys, and C in microfarads. Thus, through algebraic manipulation of letters and using the rules for equations, we derive a simple, easy-to-remember formula for finding the resonant frequency.

SHORTCUTS FOR EQUATIONS

Although we can work with any equations with the rules and information that we have already studied, there are some shortcuts which will let us work much faster and more efficiently. They are all derived from the basic rules, so we won't have to learn anything new. We will simply study the rules closely so we can see what the end results of the operations are and learn to apply them directly.

Moving a term from one member of an equation to the other member is an operation that is quite common and is called "transposing." The rule for transposing is:

A term may be transposed from one member of an equation to the other member by changing the sign of the term.

Thus, in an equation such as

$$Z^2 = R^2 + X^2$$

we can transpose the X^2 by simply changing the sign to give

$$Z^2 - X^2 = R^2$$

or transpose the R^2 to give

$$Z^2 - R^2 = X^2$$

or both, to get

$$Z^2 - R^2 - X^2 = 0$$

Using an equation with numbers shows that doing this does not destroy the equality. For example:

If

$$4 + 2 = 6,$$

then

$$4 = 6 - 2,$$

or

$$2 = 6 - 4$$

or

$$0 = 6 - 4 - 2.$$

Likewise, if

$$10 - 4 - 2 = 4,$$

then

$$10 - 4 = 4 + 2$$

or

$$10 - 2 = 4 + 4$$

or

$$10 = 4 + 2 + 4.$$

The basic rule of equations that states that we can add or subtract the same quantity from both members of the equation allows us to transpose. For example, in the equation $Z^2 = R^2 + X^2$, if we subtract X^2 from both members, we have:

$$Z^2 - X^2 = R^2 + X^2 - X^2$$
$$Z^2 - X^2 = R^2$$

Or, in the equation $10 - 4 - 2 = 4$, adding 4 to both members, we have $10 - 4 - 2 + 4 = 4 + 4$ which is equal to $10 - 2 = 4 + 4$. *Thus, transposing terms by changing the sign is simply a shortcut for adding or subtracting quantities to both members.*

Using the same basic rule, we can also make the statement that:

We can cancel out like terms from the members of an equation, if the same term appears in each member, and is preceded by the same sign.

Thus, if we have an equation like $x + y = z + y$, we can cancel the y's out to give $x = z$. Or, an equation with numbers like $4 \times 3 + 2 = 12 + 2$ can be reduced to $4 \times 3 = 12$ by canceling the 2's. As you can see, all we are doing when we cancel is to subtract the same term from both members. Thus, $x + y = z + y$ becomes $x + y - y = z + y - y$ or $x = z$. Likewise, $4 \times 3 + 2 = 12 + 2$ becomes $4 \times 3 + 2 - 2 = 12 + 2 - 2$ or simply

$$4 \times 3 = 12.$$

Another common rule is one that involves the signs of the terms in the equations. Stated simply, it is:

The signs of all the terms of an equation may be changed without changing the equality.

Thus, an equation such as $- x + y = - 4 + 3$ may be rewritten as $x - y = 4 - 3$. In doing this, we are simply multiplying both sides of the equation by the same number, -1. In our example,

$$(- x + y)(- 1) = (- 4 + 3)(- 1)$$

or

$$x - y = 4 - 3.$$

When you studied ratio and proportion, you learned to cross-multiply. Thus, $(x/y) = (a/b)$ could be rewritten as $xb = ya$. Cross-multiplication is also made possible through the rules for working with equations. When we do this, we are really multiplying both members by one term and then multiplying both members again by another term. Thus, $(x/y) = (a/b)$ becomes $xb = ya$, because: If $(x/y) = (a/b)$, then

$$b\frac{x}{y} = \frac{a}{b}b$$

or

$$\frac{xb}{y} = a.$$

Again,

$$\frac{xb}{y}y = (a)y$$

and xb = ya. Thus, cross-multiplication is just a quick way of following the basic rules.

Then, of course, we have the many operations with multiplication and division which help us so much with rearranging our formulas. For example:

$$I = \frac{E}{R} \text{ because } E = I \times R$$

and

$$\frac{E}{R} = \frac{I \times R}{R} \text{ or } \frac{E}{R} = I \text{ or } I = \frac{E}{R}.$$

Likewise,

$$R = \frac{E}{I} \text{ because } E = I \times R$$

and

$$\frac{E}{I} = \frac{IR}{I} = \frac{E}{I} = R.$$

With these rules and shortcuts in mind, and our knowledge of basic algebra, we are ready to practice solving equations.

SOLVING EQUATIONS

The purpose of learning to work with letters and equations is to make it easier to solve the problems in working in electronics. While many of the problems will be straightforward and can be solved by applying basic formulas, others will require more thinking and reasoning before the answer is found. The use of algebra and a good working knowledge of equations will be very helpful in these more difficult solutions. As you have seen, working with letters is not difficult and the rules for operating with equations are both simple and logical. However, to become really proficient with algebra and equations requires a lot of practice.

One of the biggest difficulties in arriving at circuit solutions is not in solving the equations themselves, but in setting up the equations in the first place. This also takes a lot of practice. Although it is difficult, if not impossible, to operate by a strict set of rules for solving problems, there are a few general procedures that are worth following.

First, you should read the problem so carefully that you thoroughly understand everything about it. Then, you should determine exactly what you want to know and represent it with a letter. If there are two or more unknown quantities, you should represent them in terms of the first one. Next, you should try to apply the formulas that will allow you to find the unknown quantity from the known facts. If this is not possible, you should try to set up letter equations that will allow you to state the problem in terms of the unknown quantity. Finally, you should solve the equations for the unknown value by substituting letter and number equivalents that are available. Remember, you will often save yourself a lot of time and effort by working with letters as long as possible before substituting numbers.

Now let's solve some simple equations, and later some problems, to see how we can apply these rules. In the problem

$$3i + 14 + 2i = i + 26$$

solve for i. The first thing to do is to get all like terms together. We can do this by transposing the "i" terms to one side and the numbers to the other side. Thus,

$$3i + 14 + 2i = i + 26$$

becomes

$$3i + 2i - i = 26 - 14$$

Then, collecting terms, we have: $4i = 12$ and then dividing both members by 4 to solve for i gives us

$$\frac{4i}{4} = \frac{12}{4}$$

or $i = 3$.

We can always check this answer by substituting this value of $i = 3$ back into our original equation. Doing this:

given $3i + 14 + 2i = i + 26$

then $3 \times 3 + 14 + 2 \times 3 = 3 + 26$

and $9 + 14 + 6 = 29$ or $29 = 29$

Thus, our answer of $i = 3$ must be correct because our equation is balanced if this value is used to check it.

Solve for y in the equation:

$$3(y - 2) - 10(y - 6) = 5.$$

Here, we follow the rules of order and get rid of the values within the parentheses first. This gives us:

$$3y - 6 - 10y + 60 = 5$$

Transposing:

$$3y - 10y = 5 + 6 - 60$$

Then:

$$-7y = -49$$

Changing signs:

$$7y = 49$$

Solving for y:

$$\frac{7y}{7} = \frac{49}{7}$$

or

$$y = 49 \div 7 = 7$$

Now let's try solving for E in the equation:

$$19 - 5E(4E + 1) = 40 - 10E(2E - 1)$$

Removing parentheses:

$$19 - 20E^2 - 5E = 40 - 20E^2 + 10E$$

Transposing:

$$-5E - 10E = 40 - 19$$

Then:

$$-15E = 21$$

Solving for E:

$$\frac{-15E}{-15} = \frac{21}{-15} \text{ or } E = \frac{21}{-15} = -1.4$$

Notice the cancellation of equal terms in the second step.

Earlier in our discussion of equations, we mentioned that we could never multiply or divide an equation by zero. This is easy enough to remember, but it is not always so easy to realize that we are in danger of doing it. Now that you are more familiar with working with equations, let's examine this important rule more thoroughly by working the following equation. First, let:

$$a = b$$

Multiply by a:

$$a^2 = ab$$

Subtract b^2:

$$a^2 - b^2 = ab - b^2$$

Now,

$$a^2 - b^2 = (a + b)(a - b)$$

and

$$ab - b^2 = b(a - b)$$

Therefore:

$$(a + b)(a - b) = b(a - b)$$

Divide by (a − b):

$$\frac{(a + b)\cancel{(a - b)}}{\cancel{(a - b)}} = \frac{b\cancel{(a - b)}}{\cancel{(a - b)}}$$

Then:

$$a + b = b$$

But,

$$a = b$$

Therefore:

$$2b = b$$

Divide by b:

$$\frac{2b}{b} = \frac{b}{b}$$

and

$$2 = 1.$$

Obviously, 2 cannot equal 1, and somewhere in our manipulation of the equation, we have made a mistake that has destroyed its equality. Although all of our steps seem justified, because we never did anything to one member that we didn't do to the other, we actually have divided by zero at one point. Can you find it? If a = b, then (a − b) must equal zero. Therefore, when we divided both sides of our equation by (a − b), we were dividing by zero, which we can never do.

Setting up Equations. Now let's see what sort of reasoning we have to do to set up an equation for solving a simple problem. For example, consider the following problem: "What value of inductance will produce resonance at 50 Hertz if it is placed in series with a 20 μf capacitor?" Looking at the problem carefully, we see that it deals with resonance and that a resonant frequency and a value of capacitance are given. We are asked for the inductance. Thus, we have:

Given

$$C = 20\,\mu f \quad f = 50 \text{ Hertz}$$

Find L

Since our problem deals with resonance,

we naturally think of our formula for resonance:

$$f = \frac{.159}{\sqrt{LC}}$$

Comparing this with what is given and with what we want to find, we can see that we have the necessary information to use this formula and that L can be found with it, if it is rearranged. Accordingly, we would first rearrange our formula to indicate the value of L.

Doing this:

$$f = \frac{.159}{\sqrt{LC}} \quad \text{or} \quad f^2 = \frac{.159^2}{LC}$$

then

$$Lf^2 = \frac{.159^2}{C}$$

$$L = \frac{.159^2}{f^2 C}$$

Now, we can substitute our values in the formula and solve for L. However, before we do this, we must check our units of measurement to see if the given values can be substituted directly. In this particular problem, we cannot substitute them directly because the formula $f = (.159/\sqrt{LC})$ is in kilohertz when L is in microhenrys and C is in microfarads. Therefore, we must convert 50 Hertz to kilohertz by moving the decimal three places to the left. Thus,

50 Hertz = .05 kHz

Now, using the formula

$$L = \frac{.159^2}{f^2 C}$$

$$= \frac{25{,}281}{.05 \times .05 \times 20}$$

$$= \frac{25{,}281}{.0025 \times 20}$$

$$= \frac{25{,}281}{.05}$$

= 505,620 microhenrys

= .51 henrys (approx.)

While this is a simple problem, it does show the basic reasoning behind the handling of any problem. First, examine the problem. Find a formula, if possible. Arrange the formula to indicate the unknown. Check for proper units of measurement. Substitute and solve for the unknown. Now, let's try the procedure again on a more complex situation.

In the circuit shown in Fig. 10, suppose we are asked to find the resistance of R_4 from the values given. First of all, examination of the problem shows that we are given all the resistances except R_4 and we are also given the supply voltage and the current. Listing these values, we have:

Given:

$E_T = 100V$

$I_T = .2A$

$R_1 = 100\Omega$

$R_2 = 200\Omega$

$R_3 = 800\Omega$

Find: R_4

If we had the total resistance of the circuit, we could set up an equation because we know the total resistance must be equal to R_1 plus the resistance of the parallel branch made up of R_3 in parallel with R_2 and R_4. The resistance of this branch can be expressed using the formula for parallel resistors and treating R_2 and R_4 in series like a single resistance. The resistance of the parallel branch R_p is

$$R_p = \frac{R_3(R_2 + R_4)}{R_3 + (R_2 + R_4)}$$

Thus, the total resistance of the circuit R_T is

$$R_T = R_1 + \frac{R_3(R_2 + R_4)}{R_3 + R_2 + R_4}$$

Now in this equation we do not know the value of R_T or R_4. But we do know the total voltage E_T and the total current I_T so we can find R_T.

$$R_T = \frac{E_T}{I_T}$$

Thus, it looks like we can use the equation expressing R_T in terms of R_1, R_2, R_3, and R_4 to solve for R_4. Indeed we can do this, but look at the term for the resistance of the parallel branch. Notice we have R_4 in both the top and bottom of this expression. We will have to do a great deal of manipulation before we can solve for R_4. Before we start on this task, let's look at the circuit again to see if any easier solution is available.

First, notice that the total current is .2 amp. This means that the current through R_1 is .2 amp so we can easily find the voltage drop across the resistor using:

$$E = I_T R_1$$

$$= .2 \times 100$$

$$= 20 \text{ volts}$$

If we have a source voltage of 100 volts and a voltage drop of 20 volts across R_1, we must have 100 – 20 = 80 volts across the parallel branch. Now let's find the current through R_3 which we can do using

$$I = \frac{E}{R}$$

$$= \frac{80}{800}$$

$$= .1 \text{ amp}$$

If the total current is .2 amp and .1 amp flows through one branch of the parallel circuit, the current in the other branch must also be .1 amp. Therefore we have .1 amp flowing through R_2 and R_4.

We know the voltage across R_2 and R_4 in series is 80 volts. Let's find the voltage across R_2 using:

$$E = IR_2$$

$$= .1 \times 200$$

$$= 20 \text{ volts}$$

This means the voltage across R_4 must be 80 – 20 = 60 volts. Now we know the voltage across R_4, 60 volts, and the current through it, .1 amp, so we can find R_4 using:

$$R = \frac{E}{I}$$

$$= \frac{60}{.1}$$

$$= 600 \text{ ohms}$$

Thus we have solved the problem, using a series of simple steps and avoided some complicated work by taking a second look at the problem.

In a similar fashion, we could solve for E_T if we had the following values given for the circuit in Fig. 10

Given: $R_1 = 350\Omega$

$R_2 = 300\Omega$

$R_3 = 500\Omega$

$R_4 = 600\Omega$

Find E_T if the voltage drop across R_4 is 60V.

First, since you know the voltage across R_4 and the resistance of R_4, find the current through R_4. Once you have this current you can find the voltage across R_2 because the same current flows through R_2 and R_4. When you get the voltage across R_2, you can find the current through R_3 because the voltage across R_3 will be equal to the voltage across R_2 plus the voltage across R_4.

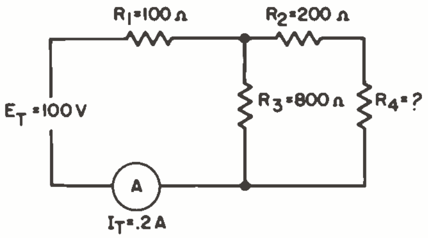

Fig. 10. Circuit used for solving for the resistance of R_4.

Now you can determine the total current flow in the circuit and then find the voltage across R_1. Once you have this voltage you should be able to find the total voltage. Work out this problem using the values given. The answer is 188 volts.

Thus, by applying the simplest formula or equation that we can, and working through the problem a step at a time, we can find the solutions to many different types of problems. As you can see, one of the greatest difficulties is in choosing a basic equation that can be made to use our known quantities. We want to be sure to choose the equation that will lead to the simplest solution. This takes sound reasoning and a lot of practice. Once you learn to do this, your knowledge of algebra and equations will let you solve the problems readily. You will get some more practice in this type of work as you study the "j" operator in the next section.

The J Operator

The "j" operator, or j multiplier as it is sometimes called, is simply a device that allows us to represent a vector mathematically. Through the use of this j operator, we are able to simplify a great deal of work in ac circuits. Instead of having to lay out a vector accurately for each separate value of resistance or reactance, we can simply state them all mathematically and then compute their final value algebraically. This is a great advantage in dealing with the complex arrangements found in tube and transistor circuits as well as any other complex ac circuit.

Being able to compute vectors mathematically means that we can multiply and divide vectors as easily as we can add or subtract them. This in itself is something that we have never been able to do before. In this section of the lesson, we will see exactly what we mean by the term "j" and how it can be used as an operator in ac circuits. We will learn how to do j arithmetic, and then we will apply these new principles to ac circuit calculations.

NUMERICAL REPRESENTATION OF A VECTOR

When you studied vectors you learned that they could be used in electronics to represent the time or phase as well as the magnitude of ac circuit quantities. In constructing vector diagrams, we used two scales at right angles to each other, like those shown in Fig. 11. Our reference vectors were laid out from the center of the scale to the right towards 0° and were used to represent zero time or in-phase components. Those that represented quantities that led the reference vector by 90° were laid out vertically from the center towards 90°. Those that were exactly 180° out of phase were laid out on the horizontal scale, pointing from the center towards the left, or 180°. Those that represented quantities that lagged the reference vector by 90° were drawn down the vertical scale from the center towards 270°.

Thus, any vector that was laid out so that it pointed towards 90° was considered to lead a vector at 0° and lag a vector at 180°. Similarly, a vector pointing down towards 270° was considered to lag a vector at 0° and lead a vector at 180°. Because of this, we arrived at the statement that vectors could be rotated counterclockwise about a common point to indicate phase relationships or the time of an occurrence.

In this way, vector A in Fig. 11 leads 0° but lags 90°. In the same way, vector B leads 90° but lags 180°, vector C leads 180° but lags 270°, and vector D leads 270° and lags 0°.

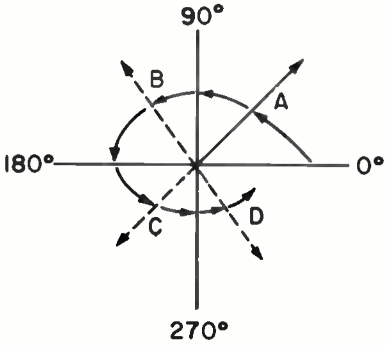

Fig. 11. Rotation of vectors.

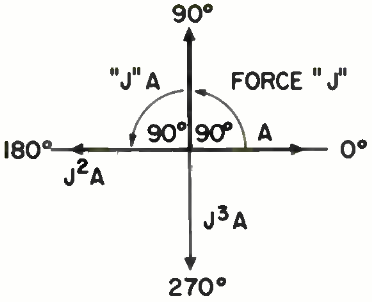

Fig. 12. Using j to rotate a vector.

In your study of algebra, you learned that you could represent any quantity or value by a letter. Therefore, let's consider that a force acts upon vectors to cause them to rotate in this way, and that this force can be represented by a letter value. Further, let's assume that the amount of this force necessary to rotate a vector 90° is represented by the letter j.

Now, let's draw a vector, A, ten units in length, along the reference line from the center toward 0° as shown in Fig. 12. In this position the vector is in phase with the reference and occurs at time zero. If we now multiply the vector by j, which represents a rotating force of 90°, we must consider that the vector will rotate 90° counterclockwise and point towards 90° as shown by vector jA in Fig. 12. Thus, multiplying the base vector A by j has resulted in its being rotated through 90° until it becomes the new vector jA.

Likewise, if we multiply our new vector jA by j, it will rotate another 90° and become vector $j \cdot jA$ or j^2A and will point toward 180° as shown. Multiplying by j again will make our vector rotate another 90° to become $j \cdot j^2A$ or j^3A pointing towards 270°. One more multiplication by j or $j \cdot j^3A$ gives us j^4A and brings the vector back to its starting point.

When we studied signed numbers, we used a horizontal scale similar to the one we use in our reference diagram for vectors. We represented positive numbers as starting from the center at 0 and working toward the right, as shown in Fig. 13. Our negative numbers started at the center and progressed toward the left. In Fig. 13, we have shown the same basic vector reference diagram as we used in Fig. 11 and 12, but we have also included the positive and negative scales along the horizontal line as shown.

Along our reference line, we have drawn vector A to represent an in-phase vector + 5 units long. If we multiply this vector A by j^2, it will rotate 180° and point towards 180° as shown. Now, according to our scale of positive and negative numbers, this new vector j^2A will equal -5. This is as it should be because anything 180° out of phase with $+5$ must be equal to -5 because it is exactly opposite. Just what is minus 5? One explanation is that minus five is plus five times minus one, because $+5 \times (-1) = -5$. If this is the case, then j^2 must be equal to -1, because $j^2 \times (+5) = -5$, just as $-1 \times (+5) = -5$.

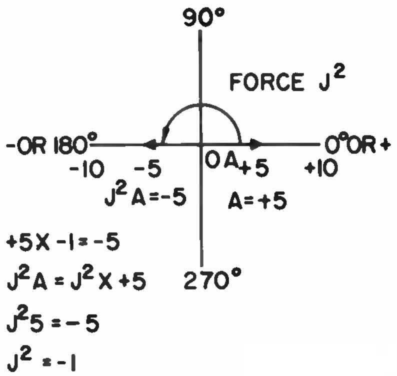

Fig. 13. Diagram of $j^2 = -1$.

Thus, any time that j^2 is used to represent a force for rotating vectors, j^2 will always be equal to -1, and -1 is substituted immediately for j^2. If $j^2 = -1$, then j must be equal to $\sqrt{-1}$. Thus, the value of j is often referred to as being imaginary because there is no number equal to $\sqrt{-1}$ because $1 \times 1 = 1$ and $-1 \times (-1)$ also $= 1$. There is no number you can multiply by itself to get -1! Whenever a j^2 term appears in a problem solution, we eliminate it by substituting -1, but where a j term appears we simply leave the j in the term because there is nothing we can substitute for it. Thus, in the term $6 + j8$, the 6 is called the real or in-phase component and the j8, the imaginary or quadrature component.

Now let's go a step further. If $j^2 = -1$, then $j \cdot j^2$ or j^3 must be equal to $-1 \cdot j$ or $-j$. We have already represented vectors drawn down the vertical line toward 270° as being a reference vector times j^3, so either j^3 or $-j$ times a vector must rotate it so that it points downward toward 270°. If $j \cdot j = j^2$ or -1 and $j \cdot j^2$ or $j^3 = j \cdot -1$ or $-j$, then j^4 representing a full 360° rotation of a vector is equal to $j^3 \cdot j$, or $j^2 \cdot j^2$ or $-1 \times (-1) = +1$. Once again this is as it should be, because any vector rotated completely around the diagram will be back where it started and represents a positive or in-phase value.

Once we understand this use of the letter "j" as an operator for determining the final position of a vector, we can use it in our work in electronics. Any time that we have a quantity multiplied by j, we will immediately know that it is a vector quantity pointing toward 90°. Similarly, if we have a $-j$ or j^3 quantity, we will know that it represents a vector drawn down towards 270°. Any positive quantity without a j or one with a j^4 multiplier can be treated as an in-phase component drawn towards 0°, and any minus quantity or one with a j^2 multiplier will represent a vector drawn out of phase towards 180°.

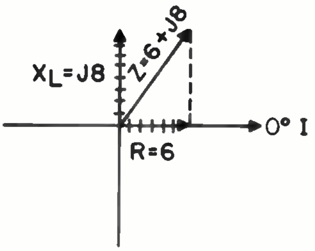

Fig. 14. Diagram of Z = 6 + j8.

Thus, if we have a series circuit consisting of a resistor and a coil, we can represent the impedance vector with a binomial term. For example, suppose the resistor has a resistance of 6Ω and the coil has an inductive reactance of 8Ω. We can say that the impedance of the circuit is equal to (6Ω + j8Ω). As soon as we see the j in the impedance notation, we can visualize a vector diagram like the one shown in Fig. 14. Here the 6Ω has no multiplier so it is drawn along the reference line I and represents the in-phase component. The j in the +j8Ω tells us that this quantity is drawn upward at right angles to the in-phase component, as shown.

Similarly, if we see a notation such as: E = (−100 − j60), we can visualize a

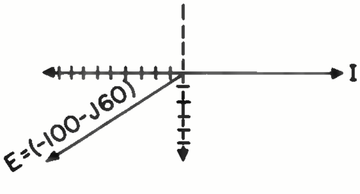

Fig. 15. Diagram of E = (−100 − j60).

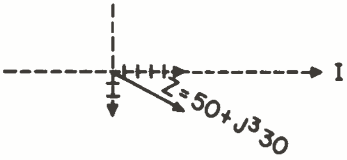

Fig. 16. Diagram of $Z = 50 + j^2 30$.

resultant voltage vector that has an E_R of −100 volts for one component and an E_{X_c} of 60 volts as another component, as shown in Fig. 15. Another vector such as

$$Z = 50 + j^3 30$$

would be immediately recognized, as shown in Fig. 16. In this way, we can represent any vector as a simple binomial term. All we have to do is remember the position values of our various j multipliers.

J ARITHMETIC

Since we are able to represent any vector mathematically as a binomial term through the use of j as a multiplier, we can solve any vector problem through the use of algebra. For example, we learned that the sum of two binomials such as (5a + 66) and (3a − 46) would be

$$5a + 66 + 3a - 46 = 8a + 20.$$

Likewise, the sum of a vector such as (10 + j5) and another equal to

$$(5 - j10)$$

would be

$$(10 + j5) + (5 - j10) = 10 + 5 + j5 - j10,$$

or a new vector equal to 15 − j5. To prove that this mathematical solution is correct we can check it against a measurement solution.

First, let's draw our two vectors, (10 + j5) and (5 − j10) as shown in Fig. 17A. Now, there are two methods which we can use to add vectors. We can break them both down into their components and add the components as we learned to do in our lesson on vectors, and as shown in Fig. 17B. Or, we can add the two vectors head to tail on the same diagram by being careful to place them in their proper position regarding the reference line, and then draw a resultant vector, as shown in Fig. 17C. In either case, the components of the resultant vector are the same and equal 15 − j5, which is exactly what we got mathematically so our mathematical solution must be correct.

To subtract one vector from another, we can also work mathematically with our binomial terms, or we can solve them with diagrams. For example, let's subtract vector B from vector A, as shown in Fig. 18. As you can see from the diagram in Fig. 18A, vector A can be written as 8 +

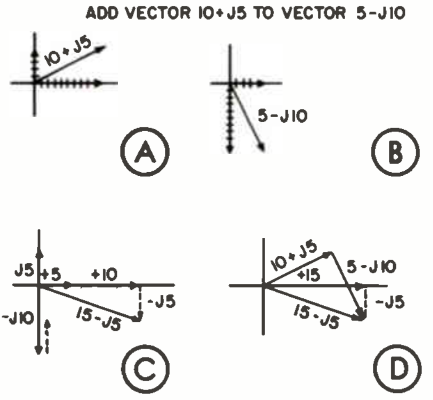

Fig. 17. Adding vectors with diagrams to prove mathematical solution.

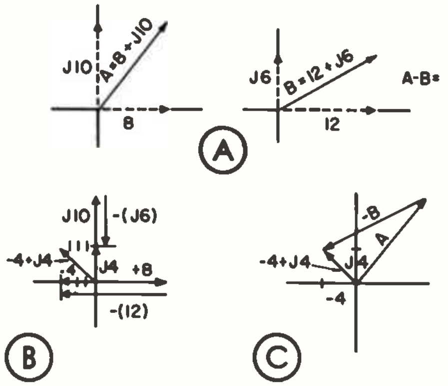

Fig. 18. Subtracting vectors with diagrams.

j10 and vector B can be written as 12 + j6. There are also two ways that we can subtract vectors with a diagram. Let's examine them.

First, there is the resolution method where we break each vector into its two components. Then we take the components of the vector that we are subtracting, reverse their directions and then add them head to tail, as we do in adding vectors. Notice how similar this is to the subtraction of signed numbers. We reverse the direction of the subtrahend (change the signs) and then proceed as in addition.

We have done this in Fig. 18B where the j6 and +12 components of vector B have been reversed in direction and then added vectorially to the j10 and +8 components of vector A. As you can see, this gives us a new vector with components of −4 and j4, or simply −4 + j4. We can also subtract vectors by subtracting them directly, as shown in Fig. 18C. Here we simply reverse the direction of vector B and add it head to tail to vector A, being careful not to change its position in regard to the reference. Then, the result drawn from the tail of A to the head of B is equal to −4 + j4, as it was with the other method.

Subtracting vectors mathematically is much simpler. We simply subtract the binomial notations of the vectors just as we would subtract any binomial terms. For example, vector B from vector A will equal:

$$(8 + j10) - (12 + j6)$$

$$= 8 + j10 - 12 - j6$$

$$= -4 + j4$$

which is the same as we got with our diagrams. This mathematical method of subtracting vectors is especially valuable in complex problems dealing with many vectors at many different angles. For example, consider the vectors A, B, C, and D in Fig. 19. Suppose we want to add vector A to vector B and then subtract vectors C and D from this sum. Mathematically this becomes:

$$(15 + j3) + (6 - j9) - (-8 + j4) - (+9 - j12)$$

$$= 15 + j3 + 6 - j9 + 8 - j4 - 9 + j12$$

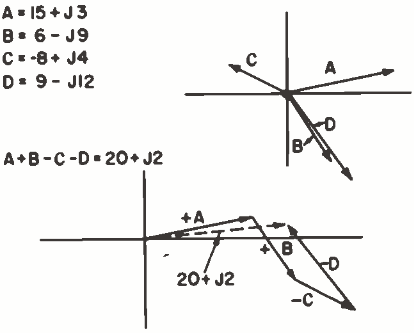

Fig. 19. Addition and subtraction of vectors by diagram.

$$= 15 + 6 + 8 - 9 + j3 + j12 - j9 - j4$$

$$= 29 - 9 + j15 - j13$$

$$= 20 + j2$$

The diagram gives us the same thing, but what a lot of work and confusion it is!

Multiplication and Division. In our work in electronics we may want to multiply or divide two or more vectors. The vectors may represent voltages, currents, or impedances of various values at different phase angles. The j operator will be very handy in this case because there is no purely graphical means of multiplying or dividing vectors with different phase angles. However, as we learned in algebra, it is quite simple to multiply or divide binomials.

Since we studied the multiplication and division of binomials earlier in this lesson, we should not have any trouble with the mathematics. Our only job now is to make sure we understand how we represent our vector resultant. Suppose that we want to multiply vector A by vector B. As shown in Fig. 20A, vector A is equal to (2 + j3) and vector B is equal to (4 + j2). To multiply these two vectors we simply multiply the binomials which gives us:

$$\begin{array}{rrr}
 & 2 + & j3 \\
\times & 4 + & j2 \\
\hline
 & 8 + & j12 \\
 & + & j4 + j^2 6 \\
\hline
 & 8 + & j16 + j^2 6
\end{array}$$

But, remember j^2 is equal to − 1, so $8 + j16 + j^2 6$ becomes

$$8 + j16 + 6(-1)$$

$$= 8 + j16 - 6$$

$$= + 2 + j16.$$

Thus, our resultant vector from this multiplication is equal to a vector of 2 + j16, as shown in Fig. 20B.

Notice that we have not only increased the length of the resultant vector by multiplying, but we have also increased the angle of this vector from the reference line. If we stop and think a moment, we will have to agree that this should happen because we are multiplying a rotating force by a rotating force when we multiply j by j. Further, remember that j alone is enough to rotate a vector 90°, while j^2 rotates it 180°. Looking at this,

$$90^\circ + 90^\circ = 180^\circ \text{ and } j \times j = 180^\circ$$

Thus, multiplying j by j is the same as adding the two 90° angles. Now, if you measure the angle that vector A makes with the reference line and add it to the angle that vector B makes with the reference line, the sum of these two angles will equal the angle of the resultant vector.

In our problem: Since $\phi A = 56^\circ$ and $\phi B = 27^\circ$, then

$$\phi A + \phi B = 56^\circ + 27^\circ = 83^\circ.$$

If we measure the angle of the resultant vector AB, we will find that its angle is exactly 83°. In addition to this relationship between the angles, there is a relationship between the lengths of vector A and vector B in the resultant vector AB. If we determine the length of vectors A and B through measurement or by using the Pythagorean theorem, we will find that A is equal to 3.61 and B is equal to

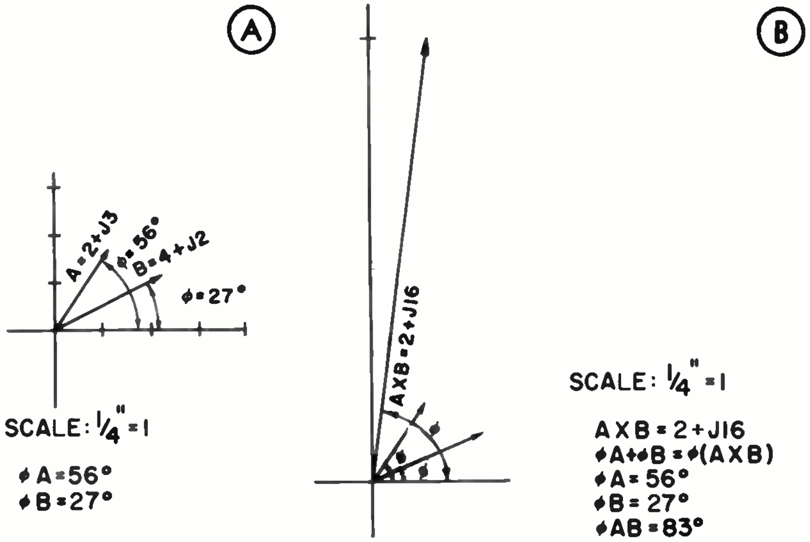

Fig. 20. Multiplying vectors.

4.47. Then if we multiply these actual lengths of A and B we find that A X B = 3.61 X 4.47 = 16.13. Now, either through measurement or by using the Pythagorean theorem, we can also determine the length of our resultant vector AB. It is equal to:

$$\sqrt{2^2 + 16^2}$$

$$= \sqrt{4 + 256}$$

$$= \sqrt{260}$$

$$= 16.13$$

to two decimal places. Thus, our resultant in vector multiplication is a new vector that is equal to the product of the length of all the vectors multiplied and that forms an angle with the reference that is equal to the sum of the angles of all the vectors multiplied. If we stop and think a moment and have understood our previous operations with vectors, we will see that this is what should happen.

In the problem that we just discussed, both of the vectors that we multiplied were made up of positive values. Let's see what happens if we multiply a vector such as 12 + j9 by another vector equal to 7 – j6. Multiplying our binomial, we have:

$$(12 + j9) \times (7 - j6)$$

$$= 84 + j63 - j72 - j^2 54$$

$$= 84 - j9 - 54(-1)$$

$$= 84 + 54 - j9$$

$$= 138 - j9$$

Here, as you can see, we had one vector to the right and above the reference, and another to the right and below the reference. The resultant is a vector that is to the right and below the reference.

Now, suppose we wanted to multiply the following vectors together:

$$(8+j16)\times(5+j2)\times(2+j3)$$

This would give us:

$$\begin{array}{r} 8+j16 \\ 5+\ \ j2 \\ \hline 40+j80 \\ +j16+j^2 32 \\ \hline 40+j96+j^2 32 \end{array}$$

Then:

$$\begin{array}{l} 40+j96+j^2 32 \\ 2+\ j3 \\ \hline 80+j192+j^2 64 \\ +\quad j120+j^2 288+j^3 96 \\ \hline 80+j312+j^2 352+j^3 96 \end{array}$$

Then:

$$\begin{aligned} & 80+j312+j^2 352+j^3 96 \\ &= 80+j312+(352\times -1) \\ &\qquad\qquad +(96\times -j) \\ &= 80-352+j312-j96 \\ &= -272+j216 \end{aligned}$$

Even though all our multipliers were to the right and above the line, our resultant is to the left and above. Notice that the j^2 term was resolved to its value of -1 and that the j^3 term resolved to its equal value of $-j$.

In order to divide vectors, we simply divide our binomial representations of the vectors involved. The easiest way to do this is to set up the division as a fraction and then clear the j term from the denominator. For example, if we wish to divide a vector such as $2+j16$ by a vector equal to $2+j3$, we would set our division up as a fraction:

$$\frac{2+j16}{2+j3}$$

Then, if we multiply both the numerator and the denominator by $2-j3$, we will not change the value of our fraction, but we will get rid of the j term in our denominator. For example, we will have:

$$\frac{(2+j16)(2-j3)}{(2+j3)(2-j3)}$$

$$=\frac{4+j26-j^2 48}{4-j^2 9}$$

$$=\frac{4+j26+48}{4+9}$$

$$=\frac{52+j26}{13}$$

$$=\frac{13(4+j2)}{13}$$

$$=4+j2$$

Thus, $2+j16\div 2+j3=4+j2$. For proof of this, check Fig. 20 again. As you can see $(4+j2)\times(2+j3)$ are the vectors we previously used in this multiplication problem and our product was $2+j16$. Similarly:

$$138-j9\div 12+j9$$

$$=\frac{138-j9}{12+j9}$$

$$=\frac{(138-j9)(12-j9)}{(12+j9)(12-j9)}$$

$$=\frac{1656-j1350+j^2 81}{144-j^2 81}$$

$$=\frac{1656-j1350-81}{144+81}$$

$$= \frac{1575 - j1350}{225}$$

$$= (7 - j6)$$

To prove our answer we simply multiply our quotient (7 – j6) by our divisor (12 + j9) to get our dividend of 138 – j9. Notice that each time we clear our j term from the denominator by multiplying our numerator and denominator by the same number. This number is always a binomial that is exactly the same as the denominator except that the sign of the j term is reversed. Such a term is called a "conjugate" term. You'll notice that each time we get a j^2 term or any even power of j, the j term disappears because $j^2 = -1$. Remember, in algebra we pointed out that $(a - b)(a + b) = a^2 - b^2$. Thus, if we have (a – jb), we can multiply it by (a + jb) to get $a^2 - j^2b^2$ and eliminate the j. Similarly, if we have a + jb, we can multiply it by a – jb to eliminate the j. Thus, we can say that we multiply both the numerator and the denominator by the conjugate of the denominator to clear the j term from the denominator.

When we multiplied two vectors together, we discovered that the product was a new vector equal in length to the product of the vector values at an angle equal to the sum of the angles of the vectors multiplied. In dividing vectors, the opposite relationship exists. If we divide one vector by another and then lay out the dividend vector, the divisor vector, and the quotient vector in a diagram, we will find that:

1. The quotient vector is equal in length to the quotient of the length of the dividend vector divided by the length of the divisor vector.

2. The quotient vector will be at an angle to the reference line that is equal to the difference between the angles of the vectors divided.

Thus, we have two ways that we can multiply or divide vectors. We can multiply or divide the binomial representation of the vectors as we have learned to do in this section, or if we know the vector length we can use it. To multiply, we find the product of the lengths and the sum of the angles. To divide, we find the quotient of the lengths and the difference of the angles.

We mentioned earlier that there was no purely graphical way to multiply and divide vectors. While we can do some of the work graphically, we must always perform some mathematics on the side. Even then, the process of finding the product or quotient in this way is very tedious and involved. Since we already have two methods for finding the products or the quotients mathematically, and since either of these methods is much simpler and faster than the simplest graphical method, it will not be worthwhile for us to study the graphical (plus some math) methods.

In this section of the lesson, you have learned to perform arithmetic operations with vectors. You have learned how to add and subtract vectors, how to multiply and divide by vectors. You will perform all four operations in solving even fairly simple ac circuit problems.

In the next section we will complete the study of the j operator and the binomial representation of vectors, by applying what you have learned to some circuit problems. To test your understanding of this chapter perform the indicated operations in the self-test questions which follow.

Using The J Operator In Circuit Operations

The best way to make sure that you understand representing vectors with binomials by using the j operator is to work with them in circuit calculations. In this way, you will get some practice with j arithmetic as well as some more experience in solving circuit problems. We will start with some simple series ac circuits, and then examine some parallel and series-parallel combinations. If, after we have done this, you feel that you still need more practice, try applying these methods to some of the ac circuits you have worked with in your other lessons.

In analyzing and working the circuit problems in this section, we will use the mathematical solutions and the j operator. However, we will still use vector diagrams to help visualize the circuit quantities and their relationships. But, since we are not going to use the diagrams for our actual calculations, we will not need to draw them to scale. Thus, for every problem, we will have a simple diagram to use in our analysis and a mathematical solution for the diagram. This is by far the best way to work with any ac circuit problem.

Series Circuits. In the circuits shown in Fig. 21 we are to find the current. Let's consider the circuit at A first. Since we have an inductance in the circuit along with a resistance, we know that the voltage will lead the current, or another way of saying the same thing is that the current will lag the voltage. Thus, since we are given the value E = 234V, and we draw it at 0°, as in Fig. 21C, then the current must lag it as shown. To position the current vector in this position, we must have a –j term in the current.

Now let's look at the circuit in Fig. 21B. Here we have a resistance and capacitance in series. We know the current must lead the voltage so we must have a phase relationship like the one shown in Fig. 21D. This means we must have a +j term in the current.

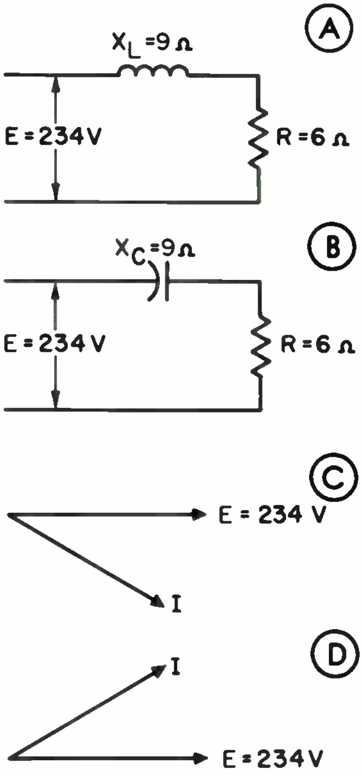

Fig. 21. The vector diagrams at C and D show the phase relationships between the voltage and current in the circuits shown at A and B.

We know that capacitive reactance is the opposite of inductive reactance so one must have a +j sign and the other a –j sign. But which should be + and which should be –? The answer is we must use the signs that make the current come out with the correct sign. Let's see what this means. We know that in an ac circuit

$$I = \frac{E}{Z}$$

In the circuits in Fig. 21 the voltage is 234 volts, the resistance 6 ohms, and the reactance 9 ohms. Thus, in one circuit Z = 6 + j9, and in the other circuit Z = 6 – j9. Now, let's solve the current in both circuits and then we can see whether a +j term represents inductive or capacitive reactance.

$$I = \frac{E}{Z}$$

$$= \frac{234}{6 + j9}$$

$$= \frac{234(6 - j9)}{(6 + j9)(6 - j9)}$$

$$= \frac{1404 - j2106}{36 - j^2 81}$$

$$= \frac{1404 - j2106}{117}$$

$$= 12 - j18$$

Now, since we already know that in the circuit with the inductive reactance we need a –j term in the current, this represents the current in Fig. 21A, and 6 + j9 must represent the impedance of the circuit in Fig. 21A. Therefore, it appears that inductive reactance should be represented by a +j term which means that capacitive reactance will be represented by a –j term. Now let's solve Fig. 21B, using 6 – j9 as the impedance, and see if we get a +j in the current term.

$$I = \frac{E}{Z}$$

$$= \frac{234}{6 - j9}$$

$$= \frac{234(6 + j9)}{(6 - j9)(6 + j9)}$$

$$= \frac{1404 + j2106}{36 - j^2 81}$$

$$= \frac{1404 + j2106}{117}$$

$$= 12 + j18$$

Thus we have a +j term in the current. In fact, notice that the only difference in the two current values is in the sign of the j term which is what we might expect since the reactances are equal.

Remember: *Inductive reactance gets a + sign and capacitive reactance a – sign.* Now, let's do another example.

In the circuit shown in Fig. 22A, we are asked to find the impedance. An examination of the circuit shows that it is a series circuit consisting of resistances, coils, and capacitors. Accordingly, we know that the impedance must be equal to the vector sum of the resistances and reactances. Therefore, in the diagram in Fig. 22B, we have made a simple sketch of the vector relationship of all the

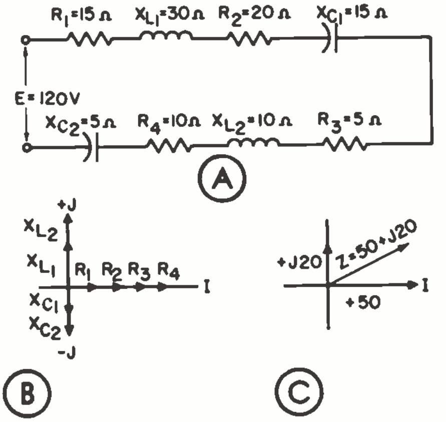

Fig. 22. Series ac circuit and vector representation.

components. Since it is a series circuit and the current is common, we have used a reference line, I, as a base for the diagram. All the resistance vectors are indicated along this reference line to show the total effect of the "in phase" components. Voltages across the resistances will all be in phase with I and hence fall along this reference vector.

The voltage across any coil in the circuit will lead the current by 90° if we neglect its resistance, so X_L vectors are drawn so that they lead the resistance vectors by 90°. This conforms with what we just discovered, that inductive reactance terms are +j terms. The voltage across the capacitors, on the other hand, will lag the current, so the X_C vectors are drawn so that they lag the resistance vectors by 90°. Now, notice that the X_C vectors are $-j$ vectors. The resistance vectors, of course, are in phase and are simply represented as the positive number terms.

Now, from our knowledge of circuit laws, vectors, algebra, and the j operator, we can write the following equation for the circuit impedance:

$$Z = R_1 + R_2 + R_3 + R_4 + jX_{L1} + jX_{L2} - jX_{C1} - jX_{C2} \text{ and,}$$

$$Z = 15 + 20 + 5 + 10 + j30 + j10 - j15 - j5$$

$$Z = 50 + j40 - j20 = 50 + j20$$

Thus, we can draw a resultant vector diagram as shown in Fig. 22C where $Z = 50 + j20$. Since the j term in our resultant vector is only used to indicate the direction of the final reactive component, or the sign of the resultant phase angle, we can drop it while we compute the impedance with our formula $Z = \sqrt{R^2 + X^2}$. Thus, the impedance is:.

$$Z = \sqrt{50^2 + 20^2}$$

$$= \sqrt{2500 + 400}$$

$$= \sqrt{2900}$$

$$= 54\Omega \text{ (approximately)}$$

Therefore, we can write the impedance of our circuit in two ways: As a vector, $Z = 50 + j20$ or from the result of our computation as: $Z = 54\Omega$ (approx).

To show that either of these answers is perfectly correct and acceptable, we can examine the circuit a little further. Suppose that we are told that the current in the circuit is equal to 4 amps and asked to find the voltage. We know that $E = IZ$, so let's substitute both of our answers for Z in this formula and see what we get. First, if $E = I \times Z$, then $E = 4 \times 54$ (approximately) or about 216 volts. Next, if $E = I \times Z$, then

$$E = 4(50 + j20) = (200 + j80) \text{ volts.}$$

Now, since $E_T = \sqrt{E_R{}^2 + E_X{}^2}$ and 200 =

E_R and j80 = E_X, we have, by dropping the j,

$$E_T = \sqrt{200^2 + 80^2}$$

$$= \sqrt{40{,}000 + 6400}$$

$$= \sqrt{46{,}400}$$

$$= 216 \text{ volts (approx.)}$$

Although either the vector representation of the answer or the numerical representation is correct and acceptable, the vector answer is often preferred as it indicates our phase angle and leading voltage. Thus, we would say that our impedance was (50 + j20)Ω and our voltage was (200 + j80)V.

Now, let's look at the circuit in Fig. 23. Here we also have a simple series circuit, and are asked to find the impedance. But, instead of being given all the resistances and the reactances, we are given an assortment of values. However, we still know that Z is equal to the sum of the resistances and the reactances, and we can draw our vector diagram as shown in Fig. 23B. Also, Z will be equal to $E_T \div I$ and E_T will be equal to the sum of the individual voltage vectors, as shown in Fig. 23C. Since we are given the total current, the frequency, some of the individual resistances or reactances, some of the voltage drops, and a value of capacitance, we can find the impedance of the circuit either way. The information given is adequate to give us anything we need to know. For example, using $Z = R \pm jX$, we have: $Z = R \pm jX = R_1 + R_2 + jX_L - j\lambda_{C1} - jX_{C2}$ and Z =

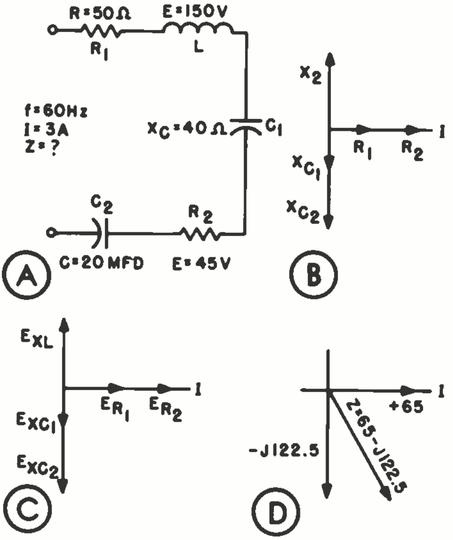

Fig. 23. Series ac circuit with vector diagrams.

$$R_1 + \frac{E_{R2}}{I} + j\,\frac{E_L}{I} - jX_{C1} - j\left(\frac{159000}{fC_2}\right)$$

Therefore,

$$Z = 50 + 15 + j50 - j40 - j\left(\frac{159000}{60 \times 20}\right)$$

and

$$\frac{159000}{60 \times 20} = \frac{1590}{12} = 132.5\Omega$$

and

$$Z = 65 + j50 - j40 - j132.5 = 65 - j122.5$$

as shown in Fig. 23D.

Using the other method, we would have:

$$Z = E_T \div I = (E_{R1} + E_{R2} + jE_{XL} - jE_{XC1} - jE_{XC2}) \div I,$$

then

$$Z = [(IR_1) + E_{R2} + jE_{XL} - j(IX_{C1}) - j(IX_{C2})] \div I$$

Now:

$$j(IX_{C2}) = [jI(159000 \div fC_2)]$$

$$= [jI(159000 \div 1200)]$$

$$= j(132.5I)$$

Thus, Z =

$$\frac{IR_1 + E_{R2} + j(E_{XL}) - j(IX_{C1}) - j(132.5I)}{I}$$

Now,

$$Z = R_1 + \frac{E_{R2}}{I} + \frac{j(E_{XL})}{I} - j(X_{C1}) - j132.5$$

$$= 50 + \frac{45}{3} + \frac{j(150)}{3} - j40 - j132.5$$

$$= 50 + 15 + j50 - j172.5$$

$$= 65 - j122.5$$

which is the same answer we got the other way. By using the Pythagorean theorem, we can further find that:

$$Z = \sqrt{65^2 + 122.5^2}$$

$$= \sqrt{4225 + 15006}$$

$$= \sqrt{19231}$$

$$= 139\Omega \text{ (approximately)}$$

Notice that we always drop the j when we use the Pythagorean theorem, because the j only indicates the position of the impedance vector and there is no way to indicate this in a monomial such as 139. However, we can use the sign of the j operator to indicate the direction by saying "139Ω capacitive."

Parallel Circuits. In our earlier ac circuit calculations, we have worked almost exclusively with series circuits. Although parallel circuits and series-parallel circuits can be solved by using vector measurement solutions alone, the vector diagrams generally become quite complex and difficult to work with. However, now that we have a method of solving ac circuits mathematically, we shall be able to handle these more complex circuits.

The major difference in working with parallel circuits is in the choice of a reference. In your study of dc circuits, you learned that the current divides in the branches of a parallel circuit while the voltage across all the branches is common. This is just the opposite from a series circuit where the current is common and the voltage divides. The same is true for ac circuits, so the general rules for dc circuits will apply to ac circuit solutions. Therefore, in our work with ac parallel circuits, we will use the circuit voltage as a reference instead of the current as we did in most of the series circuits. This difference in the choice of the reference value is very important.

Now, let's look at the simple parallel circuit in Fig. 24. Here, our circuit contains a coil in one leg and a resistor in the other leg. The voltage applied to the circuit is applied equally to each branch. However, the current as shown by an ammeter in each leg is different in each branch. The total current in the circuit is equal to the sum of the current in the branches. What is this total current?

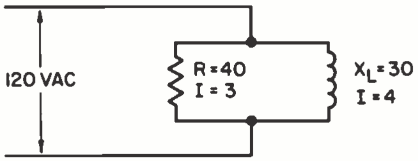

Fig. 24. Simple ac parallel circuit.

Since one branch has an inductive current and the other branch has a resistive current, we cannot add the two currents together numerically. We must add them together vectorially just as we would the voltages in a series circuit. If we draw a vector diagram for this addition, we have to use the voltage as our reference line since the voltage across each branch is the same. Thus, we would lay out our reference line and label it E as shown in Fig. 25A. Next, we want to represent our current vectors for each leg. First, we take a vector representing the current in the resistance branch and draw it along the reference line, E, and label it I_R, as shown in Fig. 25B. We draw this vector along the reference to show that the current through the resistive branch is in phase with the common voltage.

Next, we want to represent the current through our inductive branch as a vector. Now, we know that neglecting the resistance of the coil, this current will lag the voltage by exactly 90°. Since our E reference is along the horizontal and points to the right, we must draw this current vector downward, as shown in Fig. 25C, in order to show this lagging effect. Thus, our I_L vector is a $-j$ value. Therefore, our total current vector for the circuit would be indicated mathematically as

$$I_T = I_R - jI_L,$$

as shown in Fig. 25C.

Now, if we substitute the given values for the two currents shown in Fig. 24, our total current would equal:

$$I_T = I_R - jI_L$$

$$= 3 - j4$$

dropping the j

$$I_T = \sqrt{3^2+4^2}$$

$$= \sqrt{9+16}$$

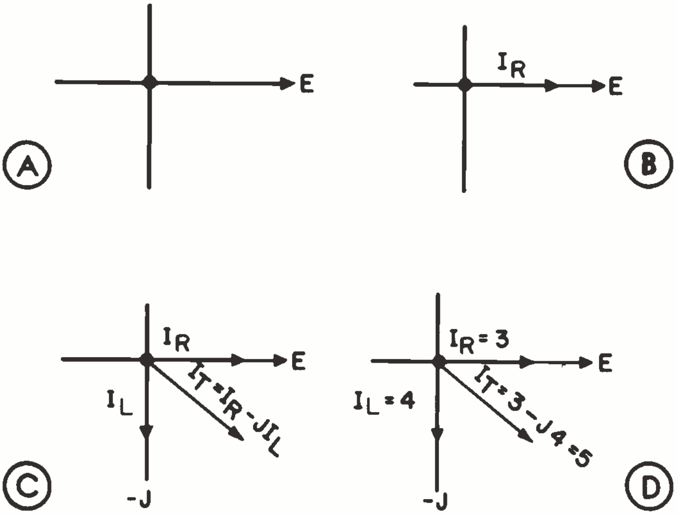

Fig. 25. Parallel circuit solution.

$$= \sqrt{25}$$

$$= 5 \text{ amps}$$

Our j operator was minus, so our total circuit current is 5 amps (lagging) as shown by the vector $I_T = 3 - j4 = 5$, in Fig. 25D.

If we want to find the impedance of this parallel circuit, we can proceed in two ways. The simplest way is to use the total current and the applied voltage in our formula E = IZ and therefore Z = (E/I) or, in our circuit, Z = (120/5) = 24Ω. If we were relying on only vector measurement solutions for parallel circuits, this would be the only way we could find the impedance. The reason for this is that the formula for resistances or impedances in parallel is

$$Z_T = \frac{Z_1 \times Z_2}{Z_1 + Z_2}$$

and we have no purely graphical way of multiplying or dividing the vectors.

However, since we know how to use the j operator, we can multiply or divide these vectors mathematically. Therefore, we can use this formula to find the total impedance. In the circuit shown in Fig. 24, we would have:

$$Z_T = \frac{R(jX_L)}{R + jX_L}$$

$$= \frac{40(j30)}{40 + j30}$$

$$= \frac{j1200(40 - j30)}{(40 + j30)(40 - j30)}$$

$$= \frac{j48000 - j^2 36000}{1600 - j^2 900}$$

$$= \frac{j48000 + 36000}{1600 + 900}$$

$$= \frac{j480 + 360}{25}$$

$$= 14.4 + j19.2$$

and our impedance total written as a vector would be (14.4 + j19.2). Then, applying the Pythagorean theorem to this vector, we would find:

$$Z = \sqrt{(14.4)^2 + (19.2)^2}$$

$$= \sqrt{207.36 + 368.64}$$

$$= \sqrt{576} = 24\Omega$$

This, of course, is the same answer that we got for the impedance by dividing the total voltage by the total current.

While the impedance of any parallel circuit can be found using either method, you can see that it is much simpler and quicker to use the first method. The current can be found by addition of vectors and then a simple division allows us to find the impedance if we know the voltage. The other way requires both the multiplication and division of vectors which can become quite complex. In fact, in complex circuits, it becomes so involved mathematically that it is almost never used.

Because of this complexity, a method of finding impedance has been worked out that involves the addition of current vectors, even though the voltage is not known. For example, consider the circuit in Fig. 26. Here we have a resistor, a coil, and a capacitor in parallel. We are asked to find the impedance and we have the values of X_C, X_L, and R given. Since we have no values of either current or voltage

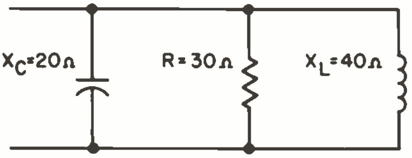

Fig. 26. Parallel circuit with X_C, R_1, and X_L. Find Z.

given, it would seem that we will be forced to use our impedance formulas.

Suppose, however, that we *assume* a circuit voltage of 120 volts. If we do this, then we can find the current that would flow in each branch with this assumed voltage applied to the circuit. It would be:

$$I_C = \frac{E}{X_C} = \frac{120}{20} = 6 \text{ amps}$$

$$I_R = \frac{E}{R} = \frac{120}{30} = 4 \text{ amps, and}$$

$$I_L = \frac{E}{X_L} = \frac{120}{40} = 3 \text{ amps.}$$

Now, we can add these currents using the j operator to find the total current that would flow for the value of assumed voltage we have chosen.

Laying out a vector diagram for reference as shown in Fig. 27, we would use our common reference E as a base. Then our I_L vector would be drawn down toward –j to indicate the current lag through the coil. The vector for I_C would be drawn up toward +j, indicating the leading current through the capacitor. Finally, the I_R vector would be drawn along the reference to indicate the in phase current through the resistance. Now, our problem becomes mathematically:

$$I_T = I_R + jI_C - jI_L$$

$$= 4 + j6 - j3$$

$$= 4 + j3$$

Then,

$$I_T = \sqrt{4^2 + 3^2}$$

and I_T = 5 amps leading (notice the sign of j) with an assumed voltage of 120 volts.

Now, applying our formula Z = (E/I), we have Z = (120/5) = 24Ω. Thus, an assumed voltage forces a total current through the circuit that gives us an impedance of 24Ω. The interesting thing is, that no matter what voltage we assume, the computed current will always be a value such that our impedance for this circuit will work out to 24Ω. Thus, we can assume any voltage for a parallel circuit, compute the total current forced

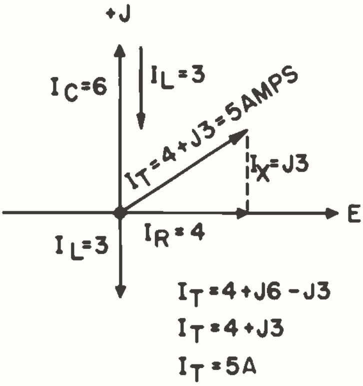

Fig. 27. Vector solution of I for circuit in Fig. 26.

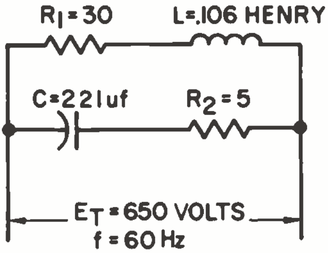

Fig. 28. Series-parallel ac circuit.

through the circuit by this voltage, and then divide to find the impedance. Naturally, in doing this, we always assume a value of voltage that will make our problem as simple as possible. Try assuming a couple of different voltages for the circuit in Fig. 26, and then compute the current and impedance. You will see that 24Ω is always your answer for this circuit.

Series-Parallel Circuits. The next problem is to learn to combine our knowledge of series circuits with our knowledge of parallel circuits for series-parallel combinations. Generally, we do this just as we would for dc circuits. We break our circuit down into simple circuits which we solve one at a time, and then combine our answers. For example, let's consider the circuit shown in Fig. 28.

Here we have a coil in series with a resistor in one branch which is in parallel with another branch containing a resistor and a capacitor. We are given R_1, R_2, L and C, the total voltage, and the frequency. We are asked to find the total current and the total impedance of the circuit. First solve each of the two branches separately, then combine them to find the total current, and then find the total impedance.

The best way is to proceed as follows: Let's call the branch with the coil, branch A, and the one with the capacitor, branch B. Since we want the total current, we would want to find the current in each leg and then combine them. Starting with branch A, we must first find X_L and then find I_A as follows:

$$\begin{aligned}
I_A &= E_A \div Z_A \\
&= E_A \div (R_1 + jX_L) \\
&= E_A \div (R_1 + j2\pi fL) \\
&= 650 \div (30 + j6.28 \times 60 \times .106) \\
&= 650 \div (30 + j40) \\
&= \frac{650\,(30 - j40)}{(30 + j40)\,(30 - j40)} \\
&= \frac{19500 - j26000}{900 - j^2\,1600} \\
&= \frac{195 - j260}{9 + 16} \\
&= \frac{195 - j260}{25} \\
&= 7.8 - j10.4
\end{aligned}$$

Now, notice that I_A is the current through the series circuit of branch A, yet we have it broken up into a j binomial. This probably seems strange since you know that the current is common in a series circuit and the current through the coil is the same as the current through the resistance. Although it is true that we have only one current through the series branch, this current is made up of the combined effects of the resistor and the coil. Therefore, this current is a vector that can be considered to consist of two components just the same as any other vector.

The vector diagrams in Fig. 29 may help you to understand this. In Fig. 29A we have shown the impedance vector 30 + j40 which we found in the first few steps of our equation. Since this is a series circuit, we have used the current as a

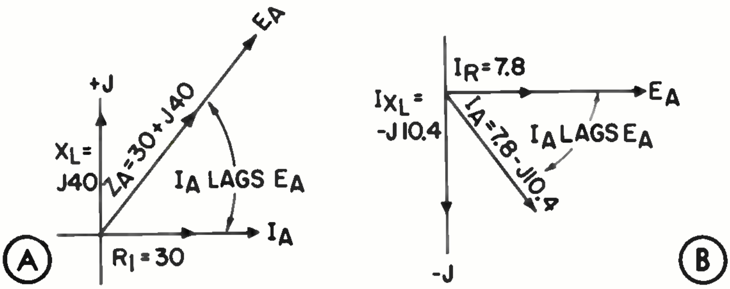

Fig. 29. Vector relationships for branch A. (Not to scale.)

reference for this diagram. Now, if we were to represent the voltage for this series circuit vectorially, it would extend along the same line as the impedance vector, as shown. Thus, the vector diagram in Fig. 29A shows the relationships of the impedance, the current, and the voltage. Notice that the current lags the voltage.

Now, when we get ready to combine branch A and branch B, we will want to use the voltage as a reference because it is common to both branches. When we do this, we would have to show the current for branch A as a vector lagging the voltage, as shown in Fig. 29B. Thus, either Fig. 29A or 29B shows the proper relationship between the current and the voltage. In order to compute with this current vector using the j operator, we would want to break it up into its components. We can do this in the diagram, shown in Fig. 29B, because E is the reference. That is why we simply divided the voltage E_A by the binomial of the impedance vector rather than solving for the monomial impedance. In this way, our current is already broken into its binomial term, ready for use in combining with branch B as soon as we divide the voltage by the impedance.

Now, we follow the same general procedure and solve for the current in branch B as follows:

$$I_B = E_B \div Z_B$$

$$= E_B \div (R_2 - jX_C)$$

$$= E_B \div \left(R_2 - j\frac{159000}{fC}\right)$$

$$= 650 \div \left(5 - j\frac{159{,}000}{60 \times 221}\right)$$

$$= 650 \div (5 - j12)$$

$$= \frac{650\,(5 + j12)}{(5 - j12)\,(5 + j12)}$$

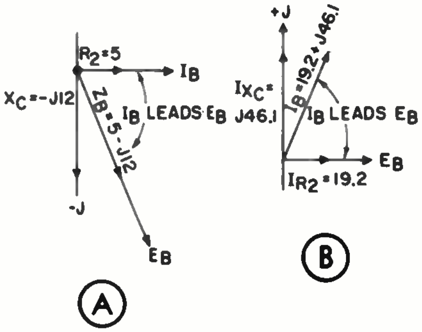

Fig. 30. Vector relationships for branch B. (Not to scale.)

$$= \frac{3250 + j7800}{25 - j^2 144}$$

$$= \frac{3250 + j7800}{25 + 144}$$

$$= \frac{3250 + j7800}{169} = 19.2 + j46.1$$

The vector diagrams for this are shown in Fig. 30 in the same manner as those in Fig. 29. Notice that in the diagram in Fig. 29A, the inductive terms are positive or +j to show that the voltage leads the current reference. However, when we use the voltage as a reference, as in Fig. 29B, the current term must be negative, or –j, in order to show this same lag. Likewise, the sign changes in Fig. 30A and 30B show the same thing except that they are opposite because we are dealing with capacitance or leading current.

Now that we have found the current in the two branches, we simply add them as shown by the vector diagram in Fig. 31 and the following mathematical solution:

$$I_T = I_A + I_B$$

$$= (7.8 - j10.4) + (19.2 + j46.1)$$

$$= 7.8 + 19.2 + j46.1 - j10.4$$

$$= 27 + j35.7$$

$$= \sqrt{27^2 + 35.7^2}$$

$$= \sqrt{729 + 1274.5}$$

$$= \sqrt{2003.5}$$

$$= 44.7 \text{ amps}$$

Now, the impedance is:

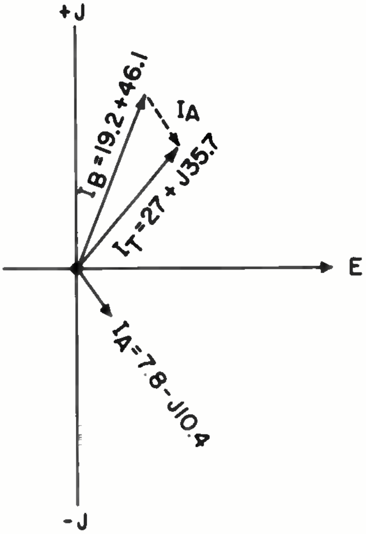

Fig. 31. Vector addition of current in Figs. 25 and 26 (not to scale).

$$Z = \frac{E}{I} = \frac{650}{44.7} = 14.5 \text{ ohms}$$

In solving circuit problems such as this it is wise to set up a complete equation in the beginning. In this way you get straight to the heart of the problem and save yourself from doing a lot of work finding things that you do not need. As an example, we found only the binomial expressions for current and impedance in the circuit we just completed. We did not bother to find the numerical values of the quantities until the last moment. Also, we did not have to find the voltage drops across the individual components. The proper circuit equations will keep you from spending unnecessary time solving for quantities you do not need. Stated as a complete equation, this last circuit would have been:

Given: $E_T = 650V$

$f = 60$ Hertz

$R_1 = 30\Omega$

$R_2 = 5\Omega$

$L = .106\text{h}$

$C = 221\ \mu\text{f}$

find $I_T\ Z_T$
Then,

$$Z_T = \frac{E_T}{I_T}$$

and

$$I_T = I_A + I_B$$

Therefore:

$$Z_T = E_T \div (I_A + I_B)$$

But: $I_A = E_A \div Z_A$

$I_B = E_B \div Z_B$

But: $E_B = E_A = E_T$

Then

$I_A = E_T \div Z_A$

$I_B = E_T \div Z_B$

Therefore:

$$Z_T = \frac{E_T}{\dfrac{E_T}{Z_A} + \dfrac{E_T}{Z_A}}$$

Now: $Z_A = R_1 + jX_L$
$Z_B = R_2 - jX_C$

Therefore:

$$Z_T = \frac{E_T}{\dfrac{E_T}{R_1 + jX_L} + \dfrac{E_T}{R_2 - jX_C}}$$

And: $jX_L = j(2\pi fL)$
$jX_C = j(159000 \div fC)$

Therefore:

$$Z_T = \frac{E_T}{\dfrac{E_T}{R_1 + j2\pi fL} + \dfrac{E_T}{R_2 - j\dfrac{15900}{f_C}}}$$

This is the complete circuit equation and gives us Z_T in terms of our known values. We can now solve for Z_T and apply the Pythagorean theorem to get Z_T as a monomial answer. Ohm's Law will then give us I_T.

In Fig. 32, we have a more complex series-parallel circuit. In this problem, the resistances and reactances are given; you are to find the total circuit impedance.

Examination of the circuit will show that the total impedance "Z_T" is equal to the vectorial sum of R_1 X_{L1} and X_{C1} in series with the combined impedance of the three parallel branches. For con-

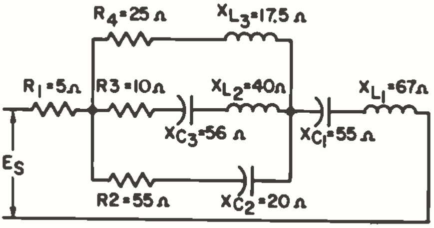

Fig. 32. Series-parallel circuit problem.

venience, we will refer to the combined impedance of the three parallel branches as "Z_b". We can now write the equation for the total circuit impedance:

$$Z_T = (R_1 + jX_{L1} - jX_{C1}) + Z_b$$

We will first find the value of Z_b. Later, we can find the total circuit impedance.

Neither the source voltage E_S nor the voltage drop across any part of the circuit is given. However, we can simplify the work by assuming that a voltage "E_b" exists across the three parallel branches and use this voltage as a reference. Now, we can write the equation:

$$Z_b = \frac{E_b}{I_b}$$

where I_b is the total current flowing in the three parallel branches. Regardless of the assumed voltage E_b, the impedance of the parallel branches will remain the same since the current is proportional to E_b divided by Z_b.

The current I_b is the vectorial sum of the currents flowing through the three individual parallel branches. We will use I_1 to represent the current through R_2 and X_{C2}, I_2 for the current through R_3, X_{C3} and X_{L2}, and I_3 to represent the current through R_4 and X_{L3}. Then, we can write:

$$I_b = I_1 + I_2 + I_3$$

Substituting this in the equation for the impedance of the parallel branches gives us:

$$Z_b = \frac{E_b}{I_1 + I_2 + I_3}$$

The current flowing through each of the parallel branches is equal to the assumed voltage divided by the impedance of the individual branches. The branch currents then are:

$$I_1 = \frac{E_b}{Z_1} \quad I_2 = \frac{E_b}{Z_2} \quad I_3 = \frac{E_b}{Z_3}$$

We can now write the equation for the combined impedance of the parallel branches:

$$Z_b = \frac{E_b}{\dfrac{E_b}{Z_1} + \dfrac{E_b}{Z_2} + \dfrac{E_b}{Z_3}}$$

Let us assume that E_b is equal to 100V (we can assume any value for E_b and still get the same final answer for Z_b) and substitute 100 for E_b in the equation:

$$Z_b = \frac{100}{\dfrac{100}{55 - j20} + \dfrac{100}{10 + j40 - j56} + \dfrac{100}{25 + j17.5}}$$

$$Z_b = \cfrac{100}{\left(\cfrac{100}{55 - j20} \cdot \cfrac{55 + j20}{55 + j20}\right) + \left(\cfrac{100}{10 - j16} \cdot \cfrac{10 + j16}{10 + j16}\right) + \left(\cfrac{100}{25 + j17.5} \cdot \cfrac{25 - j17.5}{25 - j17.5}\right)}$$

$$Z_b = \cfrac{100}{\cfrac{100(55 + j20)}{3025 - j^2 400} + \cfrac{100(10 + j16)}{100 - j^2 256} + \cfrac{100(25 - j17.5)}{625 - j^2 306}}$$

Now, since $j^2 = -1$

$$Z_b = \cfrac{100}{\cfrac{100(55 + j20)}{3025 + 400} + \cfrac{100(10 + j16)}{100 + 256} + \cfrac{100(25 - j17.5)}{625 + 306}}$$

$$Z_b = \cfrac{100}{\cfrac{5500 + j2000}{3425} + \cfrac{1000 + j1600}{356} + \cfrac{2500 - j1750}{931}}$$

$$Z_b = \frac{100}{(1.6 + j.58) + (2.8 + j4.5) + (2.7 - j1.88)}$$

$$Z_b = \frac{100}{7.1 + j3.2}$$

$$Z_b = \frac{100}{7.1 + j3.2} \cdot \frac{7.1 - j3.2}{7.1 - j3.2}$$

$$Z_b = \frac{710 - j320}{60.2}$$

$$Z_b = 11.8 - j5.3\Omega$$

Now solve for the total circuit impedance:

$$Z_T = (5 + j67 - j55) + (11.8 - j5.3)\Omega$$

$$Z_T = 16.8 + j6.7\Omega$$

Then from the Pythagorean theorem, the total circuit impedance is equal to 18.1 ohms.

In this lesson, we have studied two math subjects that will be especially important in your work in electronics — algebra and the j operator. With a knowledge of these two subjects, you will be able to resolve complex ac circuit vectors mathematically. As you can see, this is a far more accurate and less tedious method than solving these problems by laying out and measuring vectors. However, we are still missing one very important factor of ac circuits. We are able to determine whether the current leads or lags the voltage, but we cannot tell what the actual phase angle is by mathematics alone. The only way we can determine the phase angle is to draw our final vector resultant to scale and then measure the angle of lead or lag with a protractor. In our next reference lesson on mathematics, we will learn how to compute the phase angle mathematically and then go on to consider power and resonance in ac circuits in more detail.

$$(X_C - X_L)^2 = Z^2 - R^2$$

$$X_C - X_L = \sqrt{Z^2 - R^2}$$

$$X_C = X_L + \sqrt{Z^2 - R^2}$$

39. 105 volts. First solve for the voltage across R_2.

$E = IR$

$E_{R2} = 2(15)$

$E_{R2} = 30$ volts.

Since R_3 is in parallel with R_2 it must also drop 30 volts. Thus, we can find the current through R_3:

$I = \dfrac{E}{R}$

$I = \dfrac{30}{30}$

I = 1 amp.

Now, the total current in the circuit is equal to the sum of the currents in the two parallel branches or 3 amps. This means that 3 amps of current is flowing through R_1. Therefore, R_1 drops (25 ohms × 3 amps) = 75 volts. Thus, the total applied voltage is 75 volts plus 30 volts equals 105 volts.

40. 95 volts. First find the current through R_4. $I = \dfrac{E}{R} = \dfrac{5}{5} = 1$ amp. Then find the voltage dropped by R_3. $E = IR = 1(20) = 20$ volts. Thus, the voltage across R_2 must be 5 volts + 20 volts = 25 volts. Consequently, the current through R_2 is: $I = E/R$; $I = 25/10 = 2.5$ amps. This means that the total current through R_1 is 1 amp + 2.5 amps = 3.5 amps. Now, find the voltage dropped across R_1: $E = IR$; $E = 3.5(20)$; $E = 70$ volts. Thus $E_T = 70$ volts + 25 volts = 95 volts.

$$= \frac{225 + j275}{25} = \frac{25(9 + j11)}{25}$$

$$= 9 + j11$$

59. $$\frac{44 - j168}{7 - j9} = \frac{44 - j168\,(7 + j9)}{(7 - j9)\,(7 + j9)}$$

$$= \frac{308 - j780 - j^2 1512}{49 - j^2 81}$$

$$= \frac{1820 - j780}{130} = \frac{130\,(14 - j6)}{130}$$

$$= 14 - j6$$

60. $$\frac{255}{6 + j7} = \frac{255\,(6 - j7)}{(6 + j7)\,(6 - j7)}$$

$$= \frac{1530 - j1785}{36 + 49}$$

$$= \frac{1530 - j1785}{85} = \frac{85\,(18 - j21)}{85}$$

$$= 18 - j21$$

61. (4 + j2) ohms. There are two ways to work this problem. One method is to substitute the given impedance values into the formula for two impedances in parallel, $Z_T = \frac{Z_1 Z_2}{Z_1 + Z_2}$. Another method is to assume an applied voltage; solve for the current in each leg; solve for the total current; and finally solve for the total impedance. Although the latter method sounds involved, it is usually the easier of the two. The solution using the second method is given below. An applied voltage of 100 volts is assumed. You could have assumed any other voltage and arrived at the same answer.

$$I_1 = \frac{E}{Z}$$

$$I_1 = \frac{100}{3 + j4} = \frac{100\,(3 - j4)}{3 + j4\,(3 - j4)}$$

$$= \frac{100\,(3 - j4)}{9 - j^2 16} = \frac{100\,(3 - j4)}{25}$$

$$= 12 - j16$$

$$I_2 = \frac{E}{Z}$$

$$I_2 = \frac{100}{8 - j6} = \frac{100\,(8 + j6)}{(8 - j6)\,(8 + j6)}$$

$$= \frac{100\,(8 + j6)}{64 - j^2 36} = \frac{100\,(8 + j6)}{100}$$

$$= 8 + j6$$

$$I_T = I_1 + I_2$$

$= (12 - j16) + (8 + j6)$

$= 20 - j10$

$$Z = \frac{E}{I_T} = \frac{100}{20 - j10} = \frac{100}{10\,(2 - j1)}$$

$$= \frac{10}{2 - j1} = \frac{10\,(2 + j1)}{(2 - j1)\,(2 + j1)}$$

$$= \frac{10\,(2 + j1)}{5} = 4 + j2$$

62. 2 amps. First convert the impedance from j operator form to ohms.

$Z = \sqrt{R^2 + X^2}$

$Z = \sqrt{40^2 + 30^2}$

$Z = \sqrt{1600 + 900}$

$Z = \sqrt{2500}$

$Z = 50$ ohms

Now find the current.

$$I = \frac{E}{Z} = \frac{100}{50} = 2 \text{ amps}$$

63. $(40 - j25)$ ohms.

$$Z = R_1 + R_2 + R_3 - jX_{C1} - jX_{C2} + jX_{L1} + jX_{L2}$$

$$Z = 12 + 17 + 11 - j75 - j50 + j40 + j60$$

$Z = 40 - j125 + j100$

$Z = 40 - j25$

64. $(18 + j10)$ ohms.

$Z_T = Z_1 + Z_2 + Z_3 + Z_4 + Z_5$

$$Z_T = (1 + j6) + (3 - j2) + (4 - j7) + (3 + j14) + (7 - j1)$$

$Z_T = (18 + j10)$

65. $I_T = 25$ amps.

$EX_L = 250$ volts.

$EX_C = 250$ volts.

Series-resonant circuit. This is a series resonant circuit since $X_C = X_L$. This means that the 10 ohms of capacitive reactance is exactly canceled by the 10 ohms of inductive reactance. Therefore, the only opposition to current flow is the 4-ohm resistor. Thus, $I_T = \frac{E}{Z} = \frac{100}{4} =$ 25 amps. And $EX_L = I(X_L) = 25 \times 10 = 250$ volts. Also, $EX_C = I(X_C) = 25(10) = 250$ volts.

66. $(3.9 + j2)$ amps or approximately 4.4 amps.

$I_T = I_R + jI_C - jI_L$

$$I_R = \frac{E}{R} = \frac{117}{30} = 3.9 \text{ amps}$$

$$I_C = \frac{E}{X_C} - \frac{117}{39} = 3 \text{ amps}$$

$$I_L = \frac{E}{X_L} = \frac{117}{117} = 1 \text{ amp}$$

$I_T = 3.9 + j3 - j1$

$I_T = (3.9 + j2)$ amps

$$I_T = \sqrt{(3.9)^2 + (3 - 1)^2}$$

$$I_T = \sqrt{(3.9)^2 + (2)^2}$$

$$I_T = \sqrt{15.21 + 4}$$

$$I_T = \sqrt{19.21}$$

I_T = 4.4 amps

67. 3.33 ohms.

First assume an applied voltage. Any value will work but 48 volts is particularly convenient.

$$I_T = I_{R1} + I_{R2} + I_{R3} - jI_L$$

I_{R1} = 48/16 = 3 amps

I_{R2} = 48/16 = 3 amps

I_{R3} = 48/8 = 6 amps

I_L = 48/6 = 8 amps

$$I_T = (12 - j8)$$

$$Z = \frac{E}{I_T}$$

$$Z = \frac{48}{12 - j8} = \frac{48}{4\,(3 - j2)}$$

$$= \frac{12\,(3 + j2)}{(3 - j2)\,(3 + j2)}$$

$$= \frac{36 + J24}{13} = 2.77 + j1.84$$

$$= \sqrt{(2.77)^2 + (1.84)^2} = 3.33 \text{ ohms}$$

68. (8 – j6) amps or 10 amps.

$$I = \frac{E}{Z}$$

$$I = \frac{E}{R + jX_L - jX_C}$$

$$I = \frac{E}{R + j\,2\pi fL - j\,\frac{1}{2\pi fC}}$$

$$I = \frac{E}{12 + j\,(6.28)\,(120)\,(.1) - j\,\frac{.159}{120\,(.000\,02)}}$$

$$I = \frac{150}{12 + j75 - j66}$$

$$I = \frac{150}{12 + j9}$$

$$I = \frac{150}{3\,(4 + j3)} = \frac{50}{4 + j3}$$

$$I = \frac{50\,(4 - j3)}{(4 + j3)\,(4 - j3)}$$

$$= \frac{50\,(4 - j3)}{16 - j^2 9} = \frac{50\,(4 - j3)}{25}$$

$$I = 8 - j6$$

$$I = \sqrt{(8)^2 - (j6)^2}$$

I = 10 amps

69. 1 amp.

$$I_C = \frac{E_C}{X_C};\ E_C = E_L;\ E_L = I_L\,(X_L);$$

E_C = 40 volts

$$I_C = \frac{40}{40} = 1 \text{ amp}$$

70. 55 amps.

At resonance $X_L = X_C$ and the two cancel each other. Thus, the only opposition to current flow is the 2-ohm resistor. I = E/Z; I = 110/2; I = 55 amps.

71. 510 ohms.

$$Z_T = \frac{Z_1 \times Z_2}{Z_1 + Z_2}$$

$$Z1 = 0 - j100$$

$$Z2 = 20 + j100$$

$$Z_T = \frac{-j100\,(20 + j100)}{-j100 + (20 + j100)}$$

$$Z_T = \frac{-j2000 - j^2\,10{,}000}{20}$$

$$= \frac{10{,}000 - j2000}{20}$$

$$Z_T = 500 - j100$$

$$Z_T = \sqrt{500^2 + 100^2}$$

$$Z_T = \sqrt{260{,}000}$$

$$Z_T = 510\Omega$$

Lesson Questions

Be sure to number your Answer Sheet X202.

Place your Student Number on *every* Answer Sheet.

Most students want to know their grade as soon as possible, so they mail their set of answers immediately. Others, knowing they will finish the next lesson within a few days, send in two sets of answers at a time. Either practice is acceptable to us. However, don't hold your answers too long; you may lose them. Don't hold answers to send in more than two sets at a time or you may run out of lessons before new ones can reach you.

1. Add the following:
   (1) $(3a^2 + 2b^2 + 6c + 3d^2)$ plus $(2a^2 - b^2 + c^2 - 4d^2)$
   (2) $(ax^3 + bx^2y + cxy^2 + y^3)$ plus $2ax^3 + ax^2y + 6cxy^2 - 4y^3$.

2. Perform the following subtractions:
   (1) From $6a - 3b + 2c + d$ take $2a - 4b - c + 3d$
   (2) From $12ax^2 - 6by^2 - 4cz^2$ take $6ax^2 + 2by^2 - 5cz^2$

3. Multiply:
   (1) $(a^2 - b^2 + 3c)$ times $(a + b)$ (2) $(3x^2 + y)$ times $(3x^2 - y)$

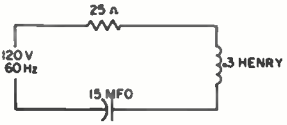
4. Divide:
   (1) $(4a^2 - 8ab + 4b^2) \div (2a-2b)$
   (2) $(18a^5 + 33a^4b + 6a^3b^2 - 11a^2b^3 + 20ab^4 + 32b^5) \div (3a + 4b)$

5. (1) Add $(4 + j17) + (3 - j2)$ (2) Subtract $(16 - j2) - (4 + j6)$

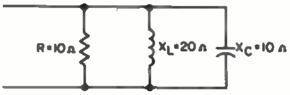
6. (1) Multiply $(6 + j9)(7 + j3)$ (2) Divide $(10 + j62) \div (8 + j2)$

7. If a resistance of 62 ohms is connected in series with a coil with a reactance of 42 ohms and a capacitor with a reactance of 100 ohms, what is the impedance of the circuit expressed in j-operator form?

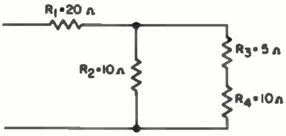
8. Find the current in the series circuit shown at the right. Give your answer in j-operator form.



9. Find the impedance of the circuit shown at the right. Give your answer in j-operator form.



10. Find the source voltage in the circuit shown at the right if the voltage across R_4 is 10 volts.



SUCCESS

The word "SUCCESS" means different things to different people. But the definition of "Success" which appeals to me most is this one, written by Mrs. A. J. Stanley.

"He has achieved success who has lived well, laughed often and loved much; who has gained the respect of intelligent men and the love of little children; who has filled his niche and accomplished his task; who has left the world better than he found it, whether by an improved poppy, a perfect poem, or a rescued soul; who has never lacked appreciation of earth's beauty or failed to express it; who has looked for the best in others and given the best he had; whose life was an inspiration; whose memory is a benediction."

Those of us who can even come close to achieving success of this kind will truly be contented, happy men.

MATHEMATICS IN PRACTICAL ELECTRONICS

This text begins with a summary of shortcuts, some of which you have been using in your earlier lessons. Related to this summary is a discussion of significant figures. You will learn when it does not pay to be too exact and yet have reliable practical results.

You have learned many ways of dealing with the problems involved in making ac circuit computations. You know how to lay out the resultant vectors and measure the angles of lead or lag to determine their values. Although this is satisfactory for many problems and circuits, you will find it awkward when working with precision timing circuits, filter networks, and frequency control circuits that are so important in electronics work.

Many of these difficulties can be overcome by applying the principles of trigonometry to vector solutions. In this way we are able to account for the angles formed by vectors, as well as the length of the vectors, without having to rely on any construction or measurement. Although you may never have used trigonometry, or "trig" as it is usually called, it is a very valuable mathematical tool. It is not difficult to learn or use; in fact, it is simpler than many of the processes you have already learned.

By studying trigonometry, you will not only learn another method of computing with vectors, but you will also learn more about vector principles. You will see why a sine wave of alternating current is called a "sine wave" and learn why ac vectors are often called "phasors." In addition, you will learn to work with power in ac circuits and study some of the factors concerning the importance of "power factor." This knowledge of trigonometry will be of value to you throughout your career in electronics. For example, this knowledge of trigonometry is essential when working with computer equipment.

In this lesson you will also learn how to construct and use different types of graphs that will enable you to present complex information clearly and precisely. The importance of graphs cannot be overemphasized, because the technical texts and references which you will constantly need in your work use this form of presentation. In many ways, this is the most important lesson on mathematics since you will be using and reviewing all previous material and "polishing up" the rough edges.

Computing Shortcuts

Many simple calculations in electronics can become quite tedious because of the size of the numbers involved. Take the case of finding the plate current of a tube by measuring the voltage drop across the plate load resistor. Assuming there is a 7.0-volt drop across a 22,000-ohm resistor, what is the current? Ohm's Law tells us that we divide the voltage by the resistance to get the current. This is simple enough, but look at the arithmetic involved:

$$\begin{array}{r}
.00031818\\
22000\overline{)7.00000000}\\
\underline{6\,6000}\\
40000\\
\underline{22000}\\
180000\\
\underline{176000}\\
40000\\
\underline{22000}\\
180000\\
\underline{176000}\\
4000
\end{array}$$

There are five digits in the divisor, nine in the dividend, and eight in the quotient. No matter how many places there are in the quotient, there will still be a remainder with either four or five digits in it.

Practically speaking, a lot of needless work was done in performing this division. This operation could have been simpler. For one thing, the quotient was carried three decimal places too many. The second simplification is to get rid of those three zeros in the divisor. When these things are done, your division looks like this:

$$\begin{array}{r}
.31\\
22\overline{)7.00}\\
\underline{6\,6}\\
40\\
\underline{22}\\
18
\end{array}$$

Admittedly, the quotients obtained by these two divisions have their decimal points in different places. However, the method that was used to get rid of the three zeros in the second divisor also shows us how to shift the decimal point in the second quotient.

How to take the unnecessary work out of practical calculations will be the subject of this section of the lesson. There are two parts of this section: One is concerned with the number of digits that should be used in any arithmetic operation; the other is how to get rid of zeros whose only purpose is to locate the decimal point.

The rules that you will learn in this section are not only labor-saving tricks, they greatly reduce the possibility of mistakes. Everyone makes mistakes in arithmetic. The more marks you have to make on a piece of paper, the more likely you are to make a mistake. By using no more figures than are absolutely necessary, you can reduce the likelihood of an incorrect answer.

EXPONENTIAL NUMBERS

Many of the numbers used in science represent either very large or very small quantities. The field of electronics is no exception. In many cases, the majority of the digits in the numbers are zeros. These zeros serve only to locate the decimal point. They are necessary but very inconvenient to work with.

Mathematicians working in the different fields of science have developed another way of writing these numbers. The method is simply to express the number as the product of two factors. One factor, called the *digit factor*, contains the significant digits (this term is explained later in this section). The other factor, called the ***exponential factor***, is a whole numbered power of 10 which properly locates the decimal point. This method of writing large and small numbers is sometimes called the scientific method of expressing numbers.

As examples, let's use the resistance and current values in the sample division earlier in this section. The resistance was 22,000 ohms. Using the two-factor method, this number is expressed as 2.2×10^4. The current is .000318. This is written using exponential numbers: 3.18×10^{-4}. To show that these new figures are correct, we multiply them. 10^4 is 10,000; multiply this by 2.2 and we get 22,000. 10^{-4} is .0001; multiply this by 3.18 and we get .000318.

Conversion from one system to the other is very simple and involves only determining the correct power of 10. One rule tells the whole story: The power of 10 is given by the number of places the decimal point must be moved to obtain the digit factor. Moving the decimal point to the left gives a positive exponent; moving the decimal point to the right gives a negative exponent. For convenience, the digit factor is usually written with only one digit to the left of the decimal point.

Here are some examples: Convert 473,000 to exponential form. The decimal point in the digit factor will come between the 4 and the 7; this is five places to the left, giving an exponent of +5. The digit factor is then 4.73 and the exponential factor is 10^5. The complete expression is 4.73×10^5. Convert 6,720,000. The decimal point moves six places to the left, giving 6.72×10^6. Convert .000706. The decimal point moves to the right four places making the exponent −4. The complete expression is 7.06×10^{-4}. Convert .0000000123. The decimal point moves eight places to the right giving 1.23×10^{-8}.

Converting the number back is just as easy: Move the decimal point as many places as the power of 10 shown by the exponent. If the exponent is positive, move the decimal point to the right; if the exponent is negative, move the decimal point to the left. After this conversion, every place must be shown. If the decimal point is moved more places than are occupied by digits in the digit factor, fill in the blank places with zeros.

To convert 3.14×10^{-2}, we must move the decimal point to the left two places. There is only one place in the digit factor to the left of the decimal point so that we must add a zero to the left of the 3. This results in .0314. To convert 3.14×10^2, the decimal point must move two places to the right. This time there are digits in the digit factor for each place moved over and no zeros are added. 3.14×10^2 is equal to 314.

As simple as this system is for general use, it is even easier to make conversions in electronics. Many times it is not even necessary to count the number of decimal places. The method of giving the values of voltage and current, and of components has the digits all counted. You seldom see 1,500,000 ohms written out in full; instead, it is written 1.5M or 1.5 meg. Either way it means 1.5 million. One million is equal to 10^6, so as soon as you see the expression megohm, you know that the exponential factor is 10^6.

There are a number of other common methods of indicating size in the name of a unit. For instance, 1 kilohertz is 1000 or 10^3 Hertz; 1K ohm means 1 kilohm or 10^3 ohms. The prefix "kil" or "kilo" immediately tells you that the exponential factor is 10^3. Similarly, 1 milliampere is 1/1000 of an ampere; 1 millihenry is 1/1000 of a henry; 1 millivolt is 1/1000 of a volt, etc. 1/1000 is $1/10^3$ or 10^{-3}. The prefix "milli" is just another way of writing 10^{-3}. In the same way, "micro" means 1/1,000,000 or 10^{-6}. "Micro-micro" means one millionth of a millionth or 10^{-12}. Basic units such as volts, amperes, henrys, etc. have an exponential factor of 10^0 or 1.

Multiplication and Division. Exponential numbers are at their best for multiplication and division. It is in these operations that they save the most work. These operations are actually performed in two parts. The indicated operation is performed on the digit factors and then on the exponential factors. As an example, suppose a calculation called for multiplying .0022 X 670 X 3.14. Converting and grouping digits gives $(2.2 \times 6.70 \times 3.14) \times (10^{-3} \times 10^2 \times 10^0)$. First multiply the digit factors together and you get 46.2836. Next, multiply the exponential factors by adding the exponents algebraically; $-3 + 2 + 0 = -1$. Combining the two factors you get 46.2836×10^{-1}. This can be simplified by moving the decimal point in the digit factor one place to the left giving $4.62836 \times 10^1 \times 10^{-1}$. Now the two exponents cancel, leaving 4.62836 as the final answer.

Division is just as easy. For example, divide .0572 by .0026. Converting and grouping gives

$$(5.72 \div 2.6) \times (10^{-2} \div 10^{-3})$$
$$5.72 \div 2.6 = 2.2$$

The division of the exponential factor is performed by subtracting the exponent of the divisor (−3) from the exponent in the dividend (−2).

$$-2 - (-3) = -2 + 3 = 1$$

The complete quotient of this division is 2.2×10^1 or 22. The same basic procedures are followed for operations with combined multiplications and divisions. As an example, take

$$(22{,}000 \div 80) \times (.032 \div 308) \times 7$$

Fig. 1 shows how this is set up and solved.

Power and Roots. Raising a number to a power is a special form of multiplication; taking a root is a special form of division. As in multiplication and division, we must perform the indicated

$$\begin{aligned} 22000 &= 2.2 \times 10^4 \\ 80 &= 8.0 \times 10^1 \\ 032 &= 3.2 \times 10^{-2} \\ 308 &= 3.08 \times 10^2 \\ 7 &= 7 \times 10^0 \end{aligned}$$

$$\left(\frac{2.2}{8.0} \times \frac{3.2}{3.08} \times 7\right) \left(\frac{10^4}{10^1} \times \frac{10^{-2}}{10^2} \times 10^0\right)$$

$$= \frac{2.2 \times 3.2 \times 7}{8.0 \times 3.08} \times \frac{10^4 \times 10^{-2} \times 10^0}{10^1 \times 10^2}$$

$$= \frac{49.28}{24.64} \times \frac{10^2}{10^3} = 2 \times 10^{-1} = .2$$

Fig. 1. Solving combined multiplication-division problems using exponential numbers.

operation on the digit factor and treat the exponential factor separately. An exponential number is raised to a power by multiplying the exponents. You can see that this will give the correct answer by considering the following:

$$10 \times 10 = 10^2$$
$$10 \times 10 \times 10 = 10^3$$

and therefore

$$10^2 \times 10^2 \times 10^2 = (10^2)^3$$

But we know that

$$10^2 \times 10^2 \times 10^2 = 10^{2+2+2} = 10^6$$
$$(10^2)^3 = 10^{(2)(3)} = 10^6$$

Extracting the root is the reverse of raising to a power. A root of an exponential number is taken by dividing the exponent by the digit indicating the root, 2 for square root, 3 for cube root, etc. Suppose you want the square root of 10^6. Dividing the exponent 6 by 2 gives 10^3. We know that $10^3 \times 10^3 = 10^6$ which shows that dividing the exponent by the root gives the correct result.

We know from arithmetic that $6 \div 2$ is the same as $6 \times \frac{1}{2}$. Thus, $\sqrt{10^6}$ may be written as $(10^6)^{\frac{1}{2}}$. Fractional exponents indicate that roots must be taken. When this method of indicating the roots is used, square root is handled as the 1/2 power, cube root as the 1/3 power, and so on. The square root of 10^6 could be written as $10^{6/2}$. The square root of 10^3 would be written as $10^{3/2}$.

At the beginning of this section, you learned that the exponent of 10 in an exponential number must be a whole number. This can lead to a slight complication when taking roots. Consider taking the square of 8.1×10^3. We would write this as $\sqrt{8.1 \times 10^{3/2}}$. But our exponential number system does not allow fractional or decimal exponents. In order to extract the square root of 8.1×10^3, we must have an exponent divisible by 2. We get this by increasing or decreasing the exponent and moving the decimal point in the digit factor accordingly.

$$8.1 \times 10^3$$
$$= 81 \times 10^2$$
$$= .81 \times 10^4$$

The square root of 81×10^2 is 9×10; the square root of $.81 \times 10^4$ is $.9 \times 10^2$. Both of these roots convert to 90 in the decimal system. 8.1×10^3 converts to 8100, the square root of which is 90 and you can see that we have obtained the correct result. To extract the cube root, the exponent of 10 must be divisible by 3; the exponent for a fourth root must be divisible by 4, etc.

Addition and Subtraction. There is nothing to be gained by converting decimal numbers into exponential numbers for addition and subtraction. However, addition and subtraction may occur as part of a calculation when exponential numbers are used to simplify multiplication and division. When addition and subtraction are indicated, you must remember that you can only add and subtract exponential numbers having the same power of 10. The reason for this is simple. For example, 160 + 16 = 176. But we can write 160 as 1.6×10^2 and 16 as 1.6×10. If we simply add 1.6 + 1.6, we get 3.2 which is not the correct answer for 160 + 16 regardless of whether we multiply it by 10 or 10^2. If we first change the numbers so that we have the same power of 10, then we will get the correct answer. For example, $160 = 16.0 \times 10$, and $16 = 1.6 \times 10$. Then,

$$16 \times 10 + 1.6 \times 10 = 17.6 \times 10 = 176$$

As you can see, the use of exponential numbers greatly simplifies multiplication and division when working with large numbers having many zeros adjacent to the decimal point and on either side of it. Still greater simplification can be obtained when some of the digits in a number like 4.62836 can be dropped. This is possible when we are working with measured values. In most practical work, it is seldom necessary to use more than four digits in any factor. The rules for dropping digits from a number which has been obtained by a measurement are the next subject that we take up.

SIGNIFICANT FIGURES

When you took arithmetic in grade school, the teacher probably listed numbers like 67,530, 4156, 873, and told you to "round them off" to the nearest thousand or hundred or ten. You did this sort of thing for homework two or three nights and that was the end of it. The next and last time you did this was on a test. Well, that time wasn't wasted; studying significant figures is just learning when to round off and how much.

The term "significant" is used here to mean: "having a meaning." In working with significant figures, you retain only those figures which have meaning and drop all others by "rounding off." The use of significant figures applies only to numbers which are connected in some way with measurements.

The figures that you used when studying mathematics were considered exact. 1 was 1, and 2 was 2. Each digit meant exactly what is said; not almost or approximately, or a little more or less. This is not true of numbers that are obtained by measurement. There is always a certain amount of estimating or guesswork in taking any measurement. The first step in using significant figures is to properly record the results of the measurement. This means putting down meaningful figures in a manner that shows how exact the measurement is.

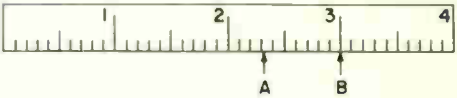

Fig. 2. Scale for showing use of significant figures in recording a measurement.

Fig. 2 shows a scale with two arrows at the bottom edge. The scale is used to show the position of pointers represented by the arrows. The scale is divided into four major units and each of these units is subdivided into ten parts. Suppose we want to read the position of arrow **A**. Arrow **A** lies between two and three units so the first figure is 2. Since the arrow is slightly past the third mark following the 2, the second figure is .3. Two figures are all that can be read directly from the scale marks. We estimate the third digit by mentally dividing the space between the scale marks into ten parts. Then we must decide which of these ten parts the arrow is nearest. 3 is the third digit for arrow **A**.

Perhaps you disagree with the reading of 2.33. Maybe you think the reading should be 2.32 or 2.34. Perhaps it should. The last digit is an estimate, not an exact figure. Because it is an estimate, different observers will record different values for this digit. However, if each observer reads the scale carefully, the readings should span only three digits; in this case, .02, .03, and .04. This is what you are saying when you record any measurement. Only the right-hand digit is an estimate and the error in reading is not more than ±1 in the right-hand figure.

Perhaps you think the arrow is exactly one-quarter of the way between 2.3 and 2.4; in other words, the reading should be 2.3 $\frac{1}{4}$. However, a mixed decimal and fraction is awkward to use. Since $\frac{1}{4}$ = .25, why not record the reading as 2.325? This, however, gives misleading information. To anyone using this figure, it means that you could tell the difference between 2.324, 2.325, and 2.326. Obviously you cannot, so 2.325 should not be recorded. You could, however, record 2.3 $\frac{1}{4}$. This indicates that you could tell the difference between 2.3, 2.3 $\frac{1}{4}$, and 2.3 $\frac{1}{2}$. It also says that no attempt was made to read the scale any closer than one-quarter of the smallest division. But instead of using a mixed decimal and fraction, it is better to estimate so that you will have only 3 digits.

The arrow B appears to be exactly on the "3" line. If it is recorded as 3, it indicates only that the reading is nearer to 3 than to 2 or 4. If it is recorded as 3.0, it means nearer to 3 than to 2.9 or 3.1. The correct way to record this is as 3.00. The two zeros to the right of the decimal point say that the scale can be read to 1/100 of a unit. 3.000 would be wrong because you cannot read the scale to thousandths. Even when a pointer falls directly on a scale mark, you cannot assume a more precise reading than at any other point on the scale.

Each of the readings, 2.33 and 3.00, has three digits. Therefore, we say that they have three significant figures. If we had read the scale only to the nearest scale mark, the readings would have been 2.3 and 3.0 with two significant figures each.

Zeros in a decimal number may or may not be significant, depending on where they are in the number. The decimal number .00678 has only three significant figures. The two zeros between the decimal point and the 6 are not considered significant.

.0067800 has five significant figures. The two zeros between the decimal point and the 6 are not significant, but the two zeros following the 8 are. If these last two digits had not been significant, they should not have been written; since they were written, you must assume that the measurement could be made to five figures.

Numbers like 22,000 create a problem. The "2's" are significant, but what about the zeros? As the number is written you cannot tell how many significant figures it has. Unless there is some note with the data, you must assume only two significant figures. However, if this were written as an exponential number, there would be no uncertainty. 2.2×10^4 has two significant figures. 2.20×10^4 has three significant figures. This is another advantage of exponential numbers; only significant figures appear in the digit factor.

Rules for Significant Figures. For convenience the rules for using significant figures will be listed by number. Then, examples of the application of the rules will be shown. In the examples, the rules that apply will be shown by number.

1. Only one uncertain figure should be recorded in giving the numerical value of any measured quantity. The uncertainty of the last figure will be ±1 unless otherwise stated.
2. When adding and subtracting with significant figures, keep only as many

decimals as are given in the number having the fewest decimals.

3. When multiplying and dividing, retain enough figures in each factor so that no factor has a greater uncertainty than the factor with the least number of significant digits.

4. When dropping nonsignificant digits by rounding off, increase the most right-hand retained figure by 1, if the figure to its right is 5 or greater.

5. Products and quotients should be rounded off so that the uncertainty is the same as that of the factor with the least number of significant figures.

Now some examples: Add 14.16 + .0078 + 1.234. The least number of decimal places is 2, so the last two numbers must be rounded off to two decimal places (Rule 2). .0078 becomes .01, and 1.234 becomes 1.23 (Rule 4). The sum is 15.40 (not 15.4). Since there are two decimal places in the numbers added, there must be two decimal places in their sum. (Common sense.)

Multiply 14.16 X .0078 X 1.234. The decimal number .0078 has the least number of significant figures (two), and an uncertainty of one part in 78. The other two factors must be rounded off. 14.16 rounded off to three figures becomes 14.2 (Rule 4) with an uncertainty of one part in 142. Rounded off to two figures it becomes 14 with an uncertainty of one part in 14. This uncertainty is much greater than one part in 78, so three significant figures must be used (Rule 3). 1.234 rounds off to 1.23 with an uncertainty of one part in 123. The product of 14.2 X .0078 is .11076; we round this off to .111 (Rule 5, Rule 4). .111 X 1.23 = .13653 which when rounded off becomes .137 (Rule 5, Rule 4).

What effect does this rounding off have on the accuracy of the calculation? None. If we had not rounded off any of the figures, the final product would have been .136292832. If we had not rounded off .11076, the final answer would have been .1362348. Both of these numbers round off to .136. Our answer was .137, just one unit greater. Since the last digit has an uncertainty of ±1, we can say the three answers were practically identical. By rounding off we have saved a lot of needless work without any loss of accuracy.

Multiply 19.7 X 9.81. Both numbers have the same number of significant figures. However, the larger number can be rounded without loss of accuracy. 19.7 has an uncertainty of one part in 197 or about .5%. 9.81 has an uncertainty of one part in 981 or about 1/10%. Rounding off 9.81 gives 9.8 with an uncertainty of one part in 98 or about 1%. This is much closer to the uncertainty of 19.7. The product without rounding off is 193.257; if 9.81 is rounded off to 9.8, the product is 193.06. Rounded to three figures, the answers are the same. It is apparent that Rule 4 can be modified at times to say that the percentage uncertainty of two factors should be nearly the same. It is hard to state this as a fixed rule and give exact values of how much the uncertainties can differ, but it does show how the use of common sense fits in with significant figures.

It is seldom necessary to use more than three significant figures in electronics. Except for precision parts, tolerances range from ±1% to ±20%; a good service meter has an accuracy of ±2% for voltage and current and ±5% for resistance. Keep the accuracy of your instruments and the tolerances of your parts in mind when performing calculations. Do not carry a lot of meaningless digits. Three significant figures are accurate enough for all but the most exacting laboratory work. Two significant digits are enough when using ±20% parts.

SELF-TEST QUESTIONS

1. Express the following in exponential form:
   - (a) 1,100,000
   - (b) 7200
   - (c) 0.00015
   - (d) 0.64
2. Convert the following exponential numbers to standard form:
   - (a) 326×10^{-12}
   - (b) 1.22×10^{6}
   - (c) 7.7×10^{-4}
   - (d) 9×10^{0}
3. Perform the following division and give the answer to three significant figures.

$$\frac{1}{6.28 \times 1550 \times 10^{3} \times 452 \times 10^{-7}}$$

4. Divide:

   $.0058 \times .000983$ by $.0000071$

5. Applying the rules for significant figures, add the following numbers:

$$\begin{array}{l} 7.92 \\ 3.0094 \\ 6.101 \\ \underline{0.0076} \end{array}$$

Trigonometry

Trigonometry is the study of the mathematical relationships that exist between the sides and angles of triangles. The word trigonometry itself is derived from two Greek words which mean the measurement of angles. The origin and earliest uses of trigonometry were for measuring distances and objects by using triangles. Today surveyors and construction engineers use trigonometry for this same purpose. However, the science of trigonometry has been developed to such a point that it is now commonly used for many other purposes.

As an electronics technician your most important use for trigonometry will be in the solution of the triangles formed by vector diagrams to determine phase relationships. Before you can actually learn to use trigonometry in this way, you must first learn some of the basic fundamentals and principles of angles, triangles, and coordinate systems.

ANGLES

When two straight lines meet at a point, an angle is formed. Thus, when the two lines OX and OY meet at the point 0 as shown in Fig. 3A, an angle is formed between the two lines. Similarly, the two lines OA and OB meeting at the point 0 in Fig. 3B also form an angle. The point 0, where the lines meet, is called the ***vertex*** of the angle, and the lines themselves are known as the sides of the angle. The angle in Fig. 3A is called "angle XOY" to show that it is the angle formed by lines OX and OY. Likewise, the angle in Fig. 3B is "angle AOB."

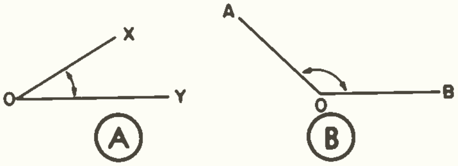

Fig. 3. Angles are formed when two straight lines meet.

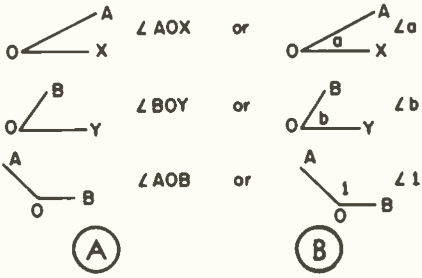

Fig. 4. Naming angles.

To save time and space, the symbol "$\angle$" is used in mathematics to represent the word "angle." Thus, the angles in Fig. 4A could be designated as $\angle$ AOX, $\angle$ BOY, and $\angle$ AOB. In working with a large number of angles, it is often awkward to describe angles in this way. Instead, we insert a letter or a number in the vertex of the angles, as shown in Fig. 4B and simply call them "$\angle$ a", "$\angle$ b", or "$\angle$ 1" as shown. Many times special designations are used to describe angles. For example, we often use the Greek letter theta, θ, in electronics to designate the phase angle. This would be written $\angle \theta$, and if we are working with several different phase angles we would indicate them with appropriate subscripts such as $\angle \theta_2$, $\angle \theta_3$, or perhaps $\angle \theta_a$ and $\angle \theta_b$.

The size or the magnitude of an angle is a measure of the space or distance between the sides and is determined by the difference in ***direction*** of the sides. Notice that it is only the difference in direction of the two sides that determines the size of an angle. The lengths of the sides do not in any way affect the size of the angle itself. You can easily see that either shortening or lengthening the sides of the angles shown in the figures will not change the size of the angles.

In working with the size or measurement of angles, as in measuring anything else, some standard unit of measurement must be chosen. Although it is easy to see that an angle is either smaller or larger or nearly the same size as another angle, this is not enough definition for the precision required in mathematics or electronics. Although there are three generally accepted units of measurements for angles, we will be concerned with only two of them: the degree (°), and the radian. To understand these two units of measurement, let's examine angles more closely, especially their relationship to circular measure.

An angle should be thought of as being generated by a line that starts at a certain initial position and rotates about the vertex of the angle until it stops at its final position. This is shown in Fig. 5. Consider the two straight lines: the short, heavy line OX and the lighter, longer line OY.

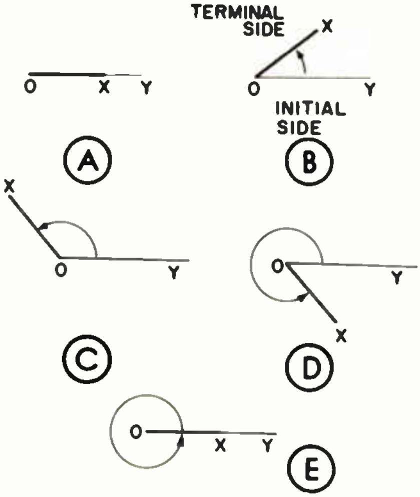

Fig. 5. Generation of angles.

In Fig. 5A, line OX is drawn on top of line OY and no angle is formed. However, in Fig. 5B, an angle is formed because the line OX is rotated counterclockwise from its initial position on line OY. Thus, the various angles XOY in Figs. 5B, 5C, and 5D are formed by the rotation of line OX from its initial position. The side of the angle that represents the original or initial position of the rotating side is known as the ***initial side***. The final position of the rotating side determines the size of the angle and is known as the ***terminal side***.

If the terminal side of the angle is rotated one complete revolution before it is stopped, the two lines are back at their original position, as shown in Fig. 5E. Thus, an angle is said to be formed by a line rotating about a point from one position to another. The unit of measure called the degree is based upon this formation by rotation. By definition, there are 360° in one complete revolution or 1° equals 1/360 of a complete revolution.

As we progress with our study of angles, triangles, and trigonometry, we will find that the degree is often a large unit of measurement. For this reason, the degree can be divided into smaller units called ***minutes***, written (′), and the minute can be further divided into units called ***seconds*** written (″). There are 60 minutes in one degree, and 60 seconds in each minute. Thus, the size of a certain angle might be written as 35° 46′ 57″ to tell us that the angle is 46 minutes and 57 seconds more than 35/360 of a revolution of the terminal side. Although these minutes and seconds may seem to be ridicuously small units, we will soon see that they can be very important. Remember, there are 360° in one revolution; 60 minutes in each degree (360 X 60 or 21,600 minutes in a revolution); and 60 seconds in each minute (60 X 60 or 3600 seconds in a degree and 60 X 60 X 360 or 1,296,000 seconds in a revolution).

In trigonometry, we often use the decimal system instead of minutes and seconds. For example, instead of saying that an angle is 36° 30′, we can write it as 36.5° because 30′ is half of 60′ and 1/2 equals .5. When using decimals, however, we must remember that there are 60 parts to a degree. For example, 36.25° is 36-1/4° which is 36 and 1/4 of 60, or 36° and 15′. Likewise, in converting 36° 12′ to decimals, we have 36-12/60° = 36-1/5° = 36.2°. It is very easy to make errors in converting from decimals to minutes or seconds.

Let's again use Fig. 5 to examine the other unit of angular measure: the radian. As the line OX rotates about the vertex to form the various angles, it must pass through every possible position from an angle of 0° (or no angle at all, as shown in Fig. 5A) to an angle of 360° (or one complete revolution, as shown in Fig. 5E). If we assume that the line OX never changes in length as it is rotating through this one revolution and place a pencil at the point X, we would find that a complete circle is drawn, as shown in Fig. 6.

Thus, we can say that since there are 360° in one revolution of side OX there are 360° in the circle. Also, since the *length* of OX has no bearing on the number of degrees in the revolution or in the size of the angles that could be formed by any one partial revolution, we can say that there are 360° in every circle, no matter how small or large it may be. Changing the length of OX would change the radius of the circle and its area, but not the number of degrees in it.

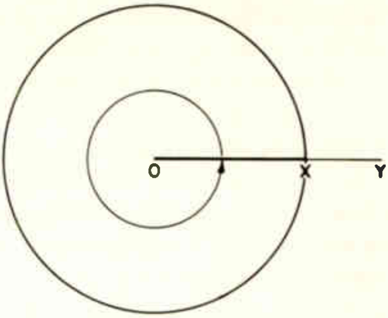

Fig. 6. Point X describes a complete circle in one complete revolution of terminal side OX.

If we were to mark off each degree on the circumference of the circle shown in Fig. 6, the degree marks would be very close together. In fact, they would be so close together that it might be difficult to show any space between them at all. In such a small circle, the difference between a degree or two would be insignificant as far as the linear distance between the marks is concerned.

However, suppose that we were considering a circle as large as the earth. At the equator, where it is about 25,000 miles around the earth, there would be nearly 70 miles between the degree marks and each degree would be extremely important. In fact, even a difference of a minute (1/60°) would be nearly 1.2 miles. Thus, a degree can be a very small unit or a very large unit, depending on where and how it is used. Consequently, the minute and second subdivisions can be quite important.

Although we don't often stop to realize it, a straight line is really a 180° angle and is therefore the most common angle. We can show that there are 180° in any straight line by rotating the terminal

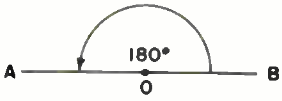

Fig. 7. Straight line is 180° angle.

side OA of any angle such as ∠ AOB in Fig. 7 until the line AB is straight. When the line AB is a straight line, the ∠ AOB equals one half a revolution of the rotating side, which is 180°.

Even though the straight line is the most common angle, the right angle is the most important. We are already familiar with the fact that there are 90° in a right angle and that there is a system of angular measurement based on right angles. The Pythagorean relationships of angles in a triangle having a right angle make it easy to solve electronics problems using trigonometry.

When two straight lines intersect each other so that four right angles are formed, the lines are said to be perpendicular to each other or mutually perpendicular. In Fig. 8, the two lines X′X and Y′Y are mutually perpendicular because angles 1, 2, 3, and 4 are all equal to 90° and are right angles. This is, of course, the basis of our coordinate systems which are used in making graphs, surveying, navigating, etc. We will learn more about this a little later.

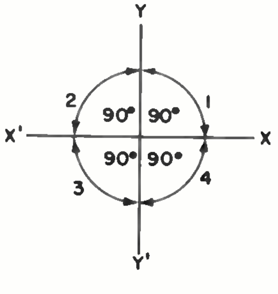

Fig. 8. Right angles formed when two lines are mutually perpendicular.

Any angle that is less than 90° is called an acute angle and any angle larger than 90° is called an obtuse angle. Two acute angles whose sum is equal to a right angle or 90° are called complementary angles. Either one of such acute angles may be called the complement of the other. Two angles whose sum is two right angles (180° or a straight line) are called supplementary angles.

Angles, of course, may be added, subtracted, multiplied, or divided, using the rules of arithmetic or algebra. We even have positive and negative angles to consider sometimes. A positive angle is generated when the terminal side is rotated counterclockwise to form the angle. If the angle is formed by the terminal side rotating clockwise it is called a negative angle.

RADIANS

The radian is a unit of measure that is based upon the length of an "arc" of a circle as compared with the radius of the circle. An "arc" is simply a part or section of the curved line that forms the circumference of a circle. An arc can be any length, but it must be a section of a true circle in order to be called an arc. Otherwise it would simply be called a curved line, or curve. An arc that is exactly equal in length to the radius of the circle of which the arc is a part is said to be a radian. A more formal way of saying it is that a radian is an angle that, when placed with its vertex at the center of a circle, intercepts an arc equal in length to the radius of the circle. Thus, if the ∠ XOY in the circle shown in Fig. 9A is to be equal to one radian, the length of the arc XY measured along the circumference of the circle must be equal to the

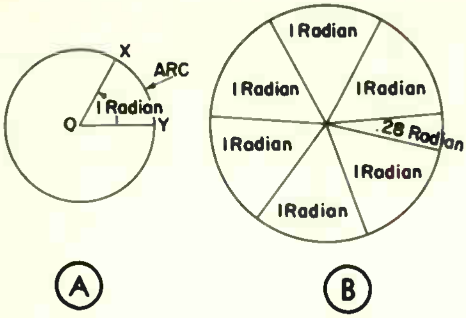

Fig. 9. Radian measure.

radius of the circle or the sides OX or OY of the angle.

If we lay out and mark off a circle using angles that are each equal to 1 radian, as shown in Fig. 9B, we will find that there are 6.28 radians in a circle. This must hold true for any circle regardless of its size since the length of arc intercepted by an angle of 1 radian must change directly as the radius of the circle changes. We are already familiar with the Greek letter π which we use in working with the area of circles. We know that it is a constant equal to 3.14. Therefore, we usually say that there are 2π radians in every circle since $6.28 \div 3.14 = 2$.

Many times you will want to change from radian measure to degrees, etc. Therefore, you should know how many degrees there are in a radian and how to convert from one to the other. Since there are 360° in every circle and 2π radians in every circle, 2π radians = 360°. From this:

$$\begin{aligned} 2\pi \text{ radians} &= 360^\circ \\ \pi \text{ radians} &= 180^\circ \\ 1 \text{ radian} &= 180/\pi \\ &= 57.32/57.3^\circ \end{aligned}$$

or approximately 57.3°. Accordingly, to change radians to degrees we would multiply the number of radians indicated by 57.3. Since 57.3 or $180/\pi$ is the multiplier when changing radians to degrees we would multiply the number of degrees by $\pi/180$ or .01745 in order to change them to radians.

Now let's consider triangles.

TRIANGLES

A triangle is a three-sided, closed plane figure. It is probably quite obvious what we mean by a closed, three-sided figure. However, if you have not studied geometry you may wonder what we mean by a

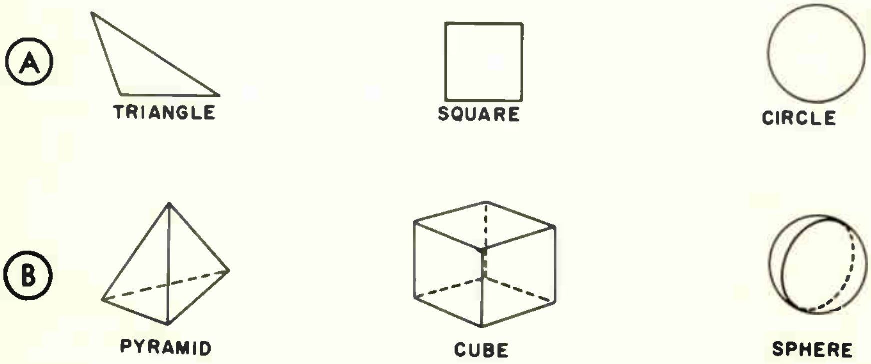

Fig. 10. (A) Plane figures. (B) Solid figures.

"plane" figure. A plane figure is simply a figure that has height and width, but no depth. Thus, a triangle, a square, a circle, or any other figure that is drawn flat on a piece of paper is a plane figure. A pyramid, a cube, or a sphere are all what we call "solid" figures, whether they actually exist or whether they are drawn with their depth indicated. Thus, the figures in Fig. 10A are plane figures and those in Fig. 10B are solid figures. The study of trigonometry includes both plane and solid figures, but in your work you will only need to be familiar with trigonometry for plane figures unless you enter some very specialized field work.

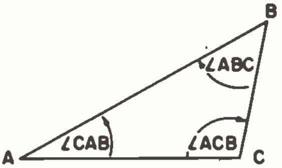

Fig. 11. A triangle has three angles and three sides.

Since a triangle has three sides, it must also contain three angles, as shown in Fig. 11. A triangle is named for reference purposes by naming the three vertexes of the three angles in order around the triangle. Thus, the triangle in Fig. 11 would be called triangle ABC. It might also be called triangle CBA, triangle BCA, triangle CAB, triangle BAC, or triangle ACB, depending on which vertex we start with and in which direction we go around. The mathematical symbol for a triangle is "Δ." Thus, the triangle in Fig. 11 could be written ΔABC.

The sum of the three angles in a triangle is always 180°. It can never be any more or any less no matter how large or small the triangle may be. This is very important in your work in trigonometry since you can always find the value of the third angle of any triangle if you know the other two.

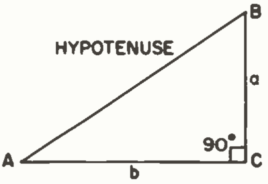

Fig. 12. A right triangle contains one right angle.

If one of the angles of a triangle is a right angle, the triangle is called a ***right triangle***. Accordingly, since a right triangle always has one 90° angle, the other two angles must be acute angles whose sum is also 90°. This relationship allows us to find one acute angle of a right triangle if we know the other acute angle. A right triangle is shown in Fig. 12. The fact that it is a right triangle is shown by drawing a small square at the vertex. The side of a right triangle that is opposite the right angle has been given the special name ***hypotenuse***. When a right triangle is in standard position as shown in Fig. 12, side a is called the ***altitude*** and side b the ***base***.

Two triangles are said to be ***similar*** when their corresponding angles are equal. In other words, similar triangles are triangles that are identical in shape, but not necessarily in size. Thus, although the corresponding angles of similar triangles are equal, the sides are not equal. However, there is a special relationship between the sides of similar triangles that forms the basis of trigonometry.

The corresponding sides of similar triangles are always proportional.

For example, the triangle in Fig. 13A is similar to the triangle in Fig. 13B,

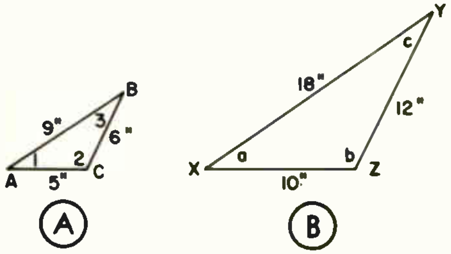

Fig. 13. Similar triangles have corresponding angles equal.

because ∠ 1 = ∠ a, ∠ 2 = ∠ b, and ∠ 3 = ∠ c. If we establish a ratio between any two sides of one of the similar triangles, we will find that it is equal to the ratio established between the corresponding sides of the other similar triangle. Thus, the ratio of side AC to side CB of ΔABC is:

$$\frac{AC}{CB} = \frac{5''}{6''}$$

The ratio of the corresponding sides of ΔXYZ would be:

$$\frac{XZ}{ZY} = \frac{10''}{12''} = \frac{5''}{6''}$$

Accordingly, we can establish a proportion from the two ratios as:

$$\frac{AC}{CB} = \frac{XZ}{ZY}$$

Also,

$$\frac{AB}{CB} = \frac{XY}{ZY} \text{ since } \frac{9''}{6''} = \frac{18''}{12''}$$

and

$$\frac{AC}{AB} = \frac{XZ}{XY} \text{ since } \frac{5''}{9''} = \frac{10''}{18''}$$

Remember that this proportionality between corresponding sides always exists when two or more triangles are similar.

Since we know that there are 180° in all triangles, we can determine if triangles are similar by knowing only two of the angles. If two angles of one triangle equal two angles of another triangle, the third angle must also be equal to each other and the triangles will be similar.

In the case of right triangles, the right angle of one is always equal to the right angle of another. Consequently, if one of the acute angles of one right triangle equals an acute angle of another right triangle, the two right triangles must be similar.

Suppose we have two similar right triangles such as the ones shown in Fig. 14. In these triangles, angle 1 and angle a are both equal to 30°. Any other right triangle that has one of its acute angles equal to 30° will be similar to these right triangles. If we examine the ratios of any two sides of these similar right triangles, we will discover a very important fact.

The ratio of the side opposite the 30° angle to the hypotenuse of any right triangle containing a 30° angle is always equal to .5. For example, the ratio of the side opposite the 30° angle, BC, to the

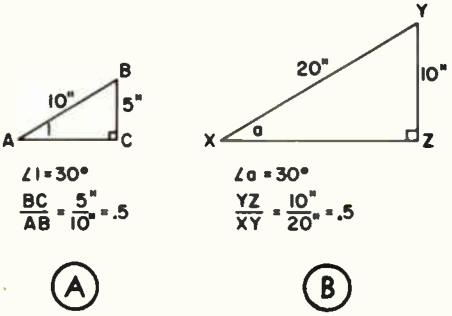

Fig. 14. Right triangles are similar if one acute angle equals the corresponding acute angle.

hypotenuse, AB, of ΔABC in Fig. 14 is equal to:

$$\frac{BC}{AB} = \frac{5''}{10''} = .5$$

Likewise, the same ratio exists for the corresponding sides of ΔXYZ because:

$$\frac{YZ}{XY} = \frac{10''}{20''} = .5$$

Since any other right triangle containing an acute angle of 30° must be similar to these, the ratio of the side opposite the 30° angle to the hypotenuse must always be equal to .5 for any right triangle that contains a 30° angle. Mathematically, this can be written as:

$$\frac{\text{side opp } 30^\circ}{\text{hypotenuse}} = .5$$

By applying this equation, we can determine any one of the factors if one of the others is known.

If we have a right triangle where one side equals 12.5 and the hypotenuse equals 25, we can tell that the angle opposite the 12.5 side must be equal to 30° whether it is given to us or not. If one of the acute angles is 30°, the other must be 60° because $30^\circ + 60^\circ + 90^\circ = 180^\circ$. Or, if we know that the hypotenuse of a right triangle equals 50 and one of the angles equals 60°, we can find the value of one of the sides because:

$$180^\circ - 90^\circ - 60^\circ = 30^\circ$$

and

$$\frac{\text{side opp } 30^\circ}{\text{hypotenuse}} = .5$$

and

$$\frac{\text{side opp } 30^\circ}{50} = .5$$

and

$$\text{side opp } 30^\circ = 25$$

Now, if we were to construct a right triangle containing a 29° angle and compute the same ratio for it, we would find that it would equal .4848. Thus, any time a ratio of the side opposite the angle to the hypotenuse works out to .4848, we know that the angle would be 29° because the ratios of corresponding sides of similar triangles are always equal. By continuing in this way we could work out the ratios for all possible angles that can exist in a right triangle and use these ratios to compute other unknown facts about their triangles.

This is trigonometry in its most basic form. Mathematicians have worked out ratios for all the angles it is possible to have in a right triangle and listed them in tables. These ratios are called the ***trigonometric functions*** of angles and can be used for computing unknown facts about similar right triangles. Since the functions are computed for all the angles that can exist, any right triangle you may work with will be similar to one for which the functions are listed.

TRIGONOMETRIC FUNCTIONS

We have seen that certain ratios can be established between two of the sides of a right triangle and that these same ratios will exist between the corresponding sides of any similar right triangle, no matter how large or how small it may be. These ratios are called the trigonometric functions of the angles to which they are related. If you examine any right triangle carefully, you will see that there are six of these ratios or "functions" that can be established for each of the acute angles of the triangle. These six functions have been given special names that you must learn and thoroughly understand in order to make any practical use of trigonometry.

Let's look at the typical right triangle shown in Fig. 15 and consider the angle θ at the lower left. Notice that the three sides of this right triangle have been given special names.

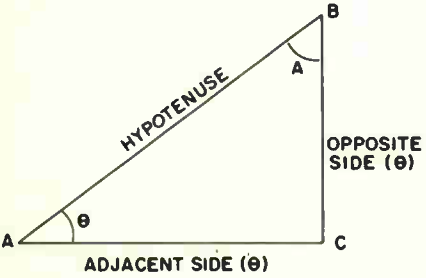

Fig. 15. Right triangle showing names of sides with respect to $\angle\theta$.

The side, BC, opposite the angle θ is called the ***opposite side***. The side, AC, of angle θ is called the ***adjacent side***. The side, AB, opposite the right angle is called the ***hypotenuse***. The hypotenuse and the adjacent side form the angle θ. Using these special names, the six separate ratios or functions that can be established for the acute angle θ are:

1. $\frac{BC}{AB}$ or $\frac{\text{opposite side}}{\text{hypotenuse}}$ is the function called the ***sine*** of the angle θ.

2. $\frac{AC}{AB}$ or $\frac{\text{adjacent side}}{\text{hypotenuse}}$ is the function called the ***cosine*** of the angle θ.

3. $\frac{BC}{AC}$ or $\frac{\text{opposite side}}{\text{adjacent side}}$ is the function called the ***tangent*** of the angle θ.

4. $\frac{AC}{BC}$ or $\frac{\text{adjacent side}}{\text{opposite side}}$ is the function called the ***cotangent*** of the angle θ.

5. $\frac{AB}{AC}$ or $\frac{\text{hypotenuse}}{\text{adjacent side}}$ is the function called the ***secant*** of the angle θ.

6. $\frac{AB}{BC}$ or $\frac{\text{hypotenuse}}{\text{opposite side}}$ is the function called the ***cosecant*** of the angle θ.

The first three of these functions are the most commonly used in electronics. If you examine them carefully, you will see that the cotangent is simply the reciprocal of the tangent, the secant is the reciprocal of the cosine, and the cosecant is the reciprocal of the sine. Since all the sides of the triangle are taken into consideration in the first three functions (sine, cosine, and tangent), the reciprocal relationships expressed by the cotangent, secant, and cosecant do not tell us anything really new. They just express it in a different way to provide certain conveniences for persons who work extensively with trigonometry. Since you will probably not be using trigonometry enough to make it worthwhile, you do not have to memorize the last three functions. However, it is important that the first three functions be memorized.

These trigonometric functions are usually abbreviated as follows:

$$\sin\theta = \frac{\text{opp}}{\text{hyp}}$$

$$\cos\theta = \frac{\text{adj}}{\text{hyp}}$$

$$\tan\theta = \frac{\text{opp}}{\text{adj}}$$

$$\csc\theta = \frac{\text{hyp}}{\text{opp}}$$

$$\sec\theta = \frac{\text{hyp}}{\text{adj}}$$

$$\cot\theta = \frac{\text{adj}}{\text{opp}}$$

In addition to the angle θ in the triangle shown in Fig. 15, we also have another acute angle. This is ∠ A at the top of the triangle and it is the "complement" of the angle θ because ∠ θ + ∠ A must equal 90° in a right triangle. Angle A also has six separate ratios or functions which can be established between its sides. These six functions of angle A are stated just the same as those for ∠ θ. In other words:

$$\sin A = \frac{\text{opp}}{\text{hyp}}$$

$$\cos A = \frac{\text{adj}}{\text{hyp}}$$

$$\tan A = \frac{\text{opp}}{\text{adj}}, \text{etc.}$$

However, notice that the side *opposite* angle A is the side that was adjacent to angle θ. Likewise, the side adjacent to angle A is the side that was opposite angle θ. Thus, although the trigonometric functions of sin, cos, tan, etc., are stated the same for either of the acute angles, the sides actually referred to in these functions as "opposite" and "adjacent" are different.

For this reason, even though we can simply say:

$$\sin = \frac{\text{opp}}{\text{hyp}}$$

$$\cos = \frac{\text{adj}}{\text{hyp}}$$

$$\tan = \frac{\text{opp}}{\text{adj}}$$

as a general statement of the trigonometric functions, we must express the specific angle as:

$$\sin\theta = \frac{\text{opp}}{\text{hyp}}$$

or

$$\cos A = \frac{\text{adj}}{\text{hyp}}$$

in order for our expression to have any specific meaning for a particular triangle. In fact, as you can see from studying the sides and angles of Fig. 15

$$\sin\theta = \frac{\text{opp}}{\text{hyp}} = \frac{BC}{AB}$$

but BC is adjacent to angle A, so

$$\frac{BC}{AB} = \frac{\text{adj}}{\text{hyp}}$$

or the cosine of angle A. Thus,

$$\sin\theta = \frac{BC}{AB} = \cos A$$

and sin θ equals cos A.

The following relationships between the functions of one acute angle and its complement can be worked out by referring to Fig. 15.

Angle (θ)	Sides Used	Complement (A)
$\sin\theta$	$= \frac{\text{opp}}{\text{hyp}} = \frac{BC}{AB} = \frac{\text{adj}}{\text{hyp}} =$	$\cos A$
$\cos\theta$	$= \frac{\text{adj}}{\text{hyp}} = \frac{AC}{AB} = \frac{\text{opp}}{\text{hyp}} =$	$\sin A$
$\tan\theta$	$= \frac{\text{opp}}{\text{adj}} = \frac{BC}{AC} = \frac{\text{adj}}{\text{opp}} =$	$\cot A$
$\cot\theta$	$= \frac{\text{adj}}{\text{opp}} = \frac{AC}{BC} = \frac{\text{opp}}{\text{adj}} =$	$\tan A$
$\sec\theta$	$= \frac{\text{hyp}}{\text{adj}} = \frac{AB}{AC} = \frac{\text{hyp}}{\text{opp}} =$	$\csc A$
$\csc\theta$	$= \frac{\text{hyp}}{\text{opp}} = \frac{AB}{BC} = \frac{\text{hyp}}{\text{adj}} =$	$\sec A$

Tables of Functions. We mentioned earlier that mathematicians have worked out trigonometric functions or ratios of the sides of triangles for all possible angles and listed them in tables. They are called Tables of Functions. Some of them are very detailed, such as those used in navigation where the functions are listed in minutes and seconds for all the angles. This is necessary for this type of work because, as we have seen, even a few minutes can mean several miles when we are considering the whole earth.

However, such detailed tables require a thick book which would not be practical for most of your work in electronics. Usually, accuracy to one degree, or possibly a few tenths of a degree, will be close enough. A typical Table of Functions that is simple and efficient is shown in Fig. 16. This table lists the sine, tangent, cotangent and cosine for angles from 0° through 90° in a convenient form.

The angles from 0° to 45° are listed in steps of 1° in the column marked "Degrees" at the left of the table. In the next column, the sine of all the angles from 0° to 45° are listed, then the tangent, the cotangent, and the cosine of the angles in the indicated columns. You should be familiar enough with tables of this sort to find the indicated functions of the angles from 0° through 45° without any trouble. For example, to find any of the functions for an angle, say 36°, we read down the degree column until we come to 36. Then, reading to the right, the sine of 36° is .5878, the tangent is .7265, the cotangent is 1.3764, and the cosine is .8090.

We know that the sine of an angle is equal to the cosine of its complement. That is, in Fig. 15, the sine θ equals:

$$\frac{BC}{AB} = \cos A$$

Therefore, if the sine of 36° is equal to .5878, as shown in the table, this same value of .5878 must be equal to the cosine of 54° which is the complement of 36° (36° + 54° = 90°). Likewise, the cosine of 36°, which according to the table is .8090, must be equal to the sine of 54°. Thus, if we know the functions of the angles from 0° to 45°, we automatically know the functions of all the angles from 0° to 90° if we remember the relationships of the functions of complementary angles.

Most tables are made so that they can be read up as well as down, like the one in Fig. 16. Notice that the functions are

Fig. 16. Table of functions.

listed again at the bottom of the table, but in the reverse order. In addition, at the extreme right we have another heading marked "Degrees." This we read from the bottom, 45°, to the top, 90°, in conjunction with the function headings at the bottom. Thus, to find the cosine of 63°, we read up the right-hand degree column to 63, then across to the extreme left to the column which is marked "cosine" at the bottom. This shows us that cosine 63° is .4540; cotangent 63° is .5095; tangent 63° is 1.9626; and sine 63° is .8910.

Thus, sine 63° is .8910 which is the cosine of its complement 27°. By studying the table, you will notice some important relationships between the various functions. The sine of 0° is .0000, but the cosine is 1.0000, while the sine of 90° is 1.0000 and the cosine is .0000. Thus, the sines of angles start from 0° and .0000 and work up to a maximum of 1.0000 at 90°. The cosine works out exactly the opposite; it has a value of 1 at 0° and decreases until it is .0000 at 90°. The value of the sine or the cosine of an angle can never be more than 1. The tangent also starts at 0° and .0000, but the tangent functions have no upper limit. At 89° it is 57.290, but as you can see, it is increasing in value rapidly as it approaches this upper limit. From 89° it increases to some infinite (unmeasurable) value at 90°.

Interpolation. Although accuracy to one degree is usually satisfactory, you may want to be accurate to a fraction of a degree. You can get this additional accuracy from the Table of Functions even though it shows only whole degree steps. We do this by a process known as interpolation. Suppose we want to find the sine of an angle of 36.5°. Since it is between 36° and 37°, we know that its sine must be more than the sine of 36° and less than the sine of 37°. Therefore, we look up the sine of both 36° and 37° and proceed as follows:

First, we subtract to find the difference between the values of the sines of the two angles. Thus:

$$\begin{array}{r} \text{sine } 37^\circ = .6018 \\ -\ \text{sine } 36^\circ = .5878 \\ \hline \text{difference} \quad .0140 \end{array}$$

The angle that we are trying to find the sine for is 36.5°, which is an increase of .5° over 36°. Therefore the sine of 36.5° must be the sine of 36° plus .5 of the difference between 36° and 37°.

$$.5 \times .0140 = .00700$$

Then, .5878 (sine 36°) plus .007 equals .5948, which is the sine of 36.5°.

To make sure that we understand this, let's try another example. What is the sine of 28° 15′? First,

$$\begin{array}{r} \text{sine } 29^\circ = .4848 \\ -\ \text{sine } 28^\circ = .4695 \\ \hline \text{difference} \quad .0153 \end{array}$$

Now, 28° 15′ is 15/60 or .25 more than sine 28°. Therefore:

$$.25 \times .0153 = .003825$$

and

$$.4695 + .003825 = .473325$$

which is the sine of 28° 15′. To interpolate sine functions, find the difference between the functions of the next smaller and the next larger angle. Then, multiply this difference by the amount of increase and add the product to the function of the smaller angle. The same procedure is used to interpolate tangent functions.

Interpolation of cosine and cotangent functions starts the same: Find the difference between the next smaller and next larger functions and multiply this difference by the amount of increase. Now, since the values of cosine and cotangent become smaller as the angle becomes larger, you must ***subtract*** the product from the value of the function of the smaller angle.

You have learned to find the value of a function of an angle by interpolation when it lies between two angles. A similar process is used to find an angle when the value of a function does not appear in the table.

For example, suppose we want to find the angle θ whose tangent is .5978. The Table of Functions does not show a tangent for .5978. But the tangent of 31° is .6009 and the tangent of 30° is .5774. Therefore, the angle θ lies somewhere between 30° and 31° since its tangent lies between the tangents of 30° and 31°.

First find the difference of the tangent values:

$$\begin{array}{r} \tan 31^\circ = .6009 \\ -\ \tan 30^\circ = .5774 \\ \hline \text{difference} = .0235 \end{array}$$

Therefore, an increase of 1° between 30° and 31° makes an increase of .0235 in tangent value.

Next, subtract the tangent of the smaller angle (30°) from the tangent of angle θ:

$$\begin{array}{r} \tan \theta = .5978 \\ -\ \tan 30^\circ = .5774 \\ \hline \text{difference} = .0204 \end{array}$$

The tangent shows an increase of .0204 from the tangent of 30°, therefore the angle which lies between 30° and 31° is determined by the fraction:

$$\frac{.0204}{.0235}$$

or .868 when expressed as a decimal. The angle θ whose tangent is .5978 must be 30.868°. Working to the nearest one tenth of a degree will usually be accurate enough. Therefore angle θ is equal to 30.9°.

Interpolation applies to all functions and all angles not shown in a table of functions.

Coordinate Systems

We have become use to expressing a vector as a binominal term by using the j operator. Now that we have learned a little about trigonometry, we can also express a vector as a numerical value and an angle. For example, suppose we have the simple circuit shown in Fig. 17. The coil has an inductive reactance of 15 ohms and is in series with a 15-ohm resistance. Neglecting the resistance of the coil itself, what is the impedance and the phase angle of the circuit?

We already know two ways to solve such a problem. The first method is to construct a very accurate vector diagram using the resistive and reactive components and then measure the resultant impedance vector and the phase angle. Although this can be done for simple circuits, the drawings can become complex and difficult to work with if the circuits are the least bit complicated. However, the greatest disadvantage in this method is that the accuracy depends on drawing neatly and precisely. Since most of us are not draftsmen or artists, it may be difficult to make a completely accurate drawing to scale and this gives a large margin for error when using this method.

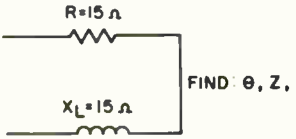

Fig. 17. Simple ac circuits.

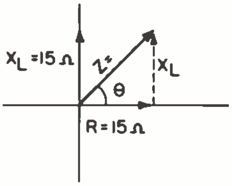
The other method is to use the j operator and express the vector mathematically using a binomial number. This eliminates the need for many of the accurate diagrams because we can work with vectors mathematically to combine them into a final binomial representation of the resultant. Then, by using the Pythagorean Theorem, we can find the numerical value of the binomial representation which gives the length of the final vector. However, we still must construct a diagram and actually measure the angle of lead or lag to find the phase angle.

Using trigonometry to solve vector diagrams will eliminate the need for any construction or measurement in finding the phase angle as well as the impedance. It is also easier than finding the square roots of numbers as we do when using the Pythagorean Theorem. Now, let's use trigonometry to solve the circuit shown in Fig. 17.

The best way to begin is to lay out a simple sketch of the vectors involved. Since we are not going to make any



FIND θ, Z

$$\mathrm{TAN}\,\theta = \frac{\mathrm{Opp}}{\mathrm{Adj}} = \frac{X_L}{R} = \frac{15}{15} = 1.0000$$

$$\theta = 45^\circ$$

$$\mathrm{SIN}\,\theta = \frac{\mathrm{Opp}}{\mathrm{Hyp}} = \frac{X_L}{Z}$$

$$Z = \frac{X_L}{\mathrm{SIN}\,45^\circ} = \frac{15}{.7071} = 21.2\,\Omega$$

Fig. 18. Trigonometric solution to circuit in Fig. 17.

measurements, this can be a rough diagram as shown in Fig. 18. Here the resistance component becomes a vector that forms the base of a triangle. The reactance component becomes a vector that represents the altitude of a triangle. Since the phase angle between a pure resistance and a pure inductance is exactly 90°, these two vectors form a 90° angle. Therefore, the resultant impedance vector which we draw from the tail of the resistance vector to the head of the reactance vector becomes the hypotenuse of a right triangle. We want to know the value of the length of this impedance vector and the size of the phase angle θ that is formed by it.

Looking at this triangle in terms of what we know about it as compared to what we want to know, we see that we know the value of the side opposite the angle θ and the value of the side adjacent to the angle θ. Now, we consider the trigonometric functions that we have just learned to see which one of them fits the unknown angle θ in terms of the known values. If we go down the list of functions, the first one we come to that uses the opposite and adjacent sides is the tangent. This states that

$$\tan\theta = \frac{\text{opp}}{\text{adj}}$$

If we use this function as an equation, and substitute the known values, we have:

$$\tan\theta = \frac{\text{opp}}{\text{adj}} = \frac{X_L}{R} = \frac{15}{15} = 1.0000$$

This tells us that the tangent of the angle θ is equal to 1.0000 when the opposite side and the adjacent side are both equal to 15.

Now, we turn to the Table of Functions in Fig. 16 and look down the column headed "Tangent" until we come to 1.0000. Then, looking to the left, we find that this number is the tangent of an angle of 45°. Thus, the phase angle θ in our diagram must equal 45°, because our equation states that $\tan\theta = 1.0000$ and our Table of Functions shows us that only 45° has a tangent equal to 1.0000.

Now that we have found our phase angle, we will want to find the value of our impedance vector. We can do this quite easily now that we know the value of θ because:

$$\sin\theta = \frac{\text{opp}}{\text{hyp}} = \frac{X_L}{Z}$$

Stated in terms of Z, this becomes:

$$Z = \frac{X_L}{\sin\theta} = \frac{15}{\sin 45^\circ}$$

Then, from the Table of Functions,

$$\sin 45^\circ = .7071 \text{ and } Z = \frac{15}{.7071}$$

Performing the mathematics:

$$Z = 15 \div .7071 = 21.2$$

Thus, using two steps of simple algebra and arithmetic and the Table of Functions, we can find both the phase angle (45°) and the impedance (21.2Ω) for the circuit shown in Fig. 17. By using the trigonometric functions of angles in this way, we can find the value of either of the acute angles of a right triangle if two of the sides are known, or the value of the two unknown sides if one of the sides and an acute angle are known.

Thus, we can say that the impedance is $21.2 \underline{/+45^\circ}\Omega$. As you recall from an earlier lesson, the impedance can also be expressed as a binomial: $(15 + j15)\Omega$. That is, the impedance can be expressed as a number and an angle or as a binomial. Either expression gives us a number picture of the vector and allows us to construct an accurate diagram of both the resultant vector and its components. They also allow us to compute with the vectors mathematically.

These two methods of noting vectors mathematically are given special names. The first, using a binomial such as 15 + j15 ohms is termed a ***rectangular*** or ***Cartesian*** coordinate. The second, using a number and an angle such as $21.2 \underline{/+45^\circ}$ ohms is called a ***polar*** coordinate. Notice that in the polar form we give the angle a positive value to show that we are measuring it in a counterclockwise direction from the reference to vector Z.

We give the angle a negative sign when measuring clockwise from the reference to the vector Z. The angle is usually given the same sign as the corresponding j term when we use rectangular coordinates. Thus vector $Z = 20 + j20$ ohms would be written in polar form as $Z = 28.3 \underline{/+45^\circ}$ ohms.

Both of these methods of describing a vector or locating a point are commonly used. Measurements and computations are made either way, depending on the information desired. Often, when mechanical or electronic computers are used, conversions from rectangular coordinates to polar coordinates and back again are made constantly, depending on the nature of the information supplied, the type of information needed, and the equipment in the computer. Although we have actually learned nearly everything about these two systems of describing a vector, our work in electronics is such that we have used them constantly without knowing some of the basic concepts of these systems of coordinates. Now is a good time to catch up on some of these basic considerations.

RECTANGULAR COORDINATES

A coordinate system is simply a standard frame of reference for describing some particular value, condition, or place. Unless we have these standard references, even everyday occurrences would be difficult to explain or describe. For example, the common directions of north, south, east and west have no meaning unless we know what they are north, south, east or west from. Describing the voltage-current relationship of a circuit as 120 volts lagging a current of 1 ampere by 30° has no meaning unless we are familiar with a standard condition to compare it with. For this reason, standard reference frames have been established for universal use so that everyone will have the same means for describing a situation so that everyone else can understand it.

Originally, the rectangular coordinate system was devised for giving directions in a standard manner. Since this system is so simple and so widely understood, it

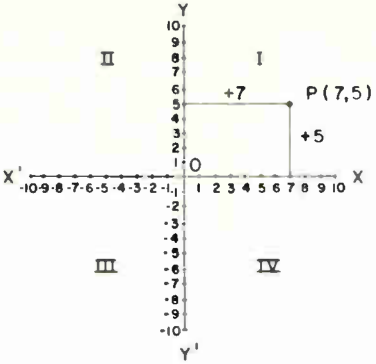


Fig. 19. Coordinate reference frame.

has been adopted for locating values and describing conditions throughout the fields of science and mathematics.

To begin with, let's call a rectangular coordinate system a device for associating points with pairs of numbers. The standard reference for this system consists of two mutually perpendicular lines, as shown in Fig. 19. One line is always horizontal and is labeled X′X as shown. Therefore, the other line labeled Y′Y is always vertical as shown, and the lines intersect at the point 0. We have used this device constantly in our work with vectors and it is nothing new except that we have never used these particular letters for the axes.

Now the two lines are called the coordinate axes and are said to be made up of the X axis (line X′X) and the Y axis (line Y′Y). The point 0 is called the origin. We can lay off scales along these axes to suit our particular purpose, but the scale from the origin, 0, to the right along the X axis is always positive, while the scale is always negative from the origin, 0, to the left along the X axis. Likewise, the scale from the origin, 0, up toward Y is always positive and the scale down from the origin, 0, to Y′ is always negative.

This reference frame consisting of the two coordinate axes serves as a means of locating any point in the plane of the axes by referring to two numbers. The two numbers completely express the position or distance of the point from the origin of the coordinate axes. For example, consider the point P in Fig. 19.

We can completely describe its position so that anyone familiar with this system can immediately locate it by saying it lies +5 from the X axis and +7 from the Y axis. The distance of the point from the Y axis, measured along the X axis is called the ***abscissa*** of the point. The distance of the point from the X axis measured by the scale on the Y axis is called the ***ordinate*** of the point. These two numbers, each with their proper algebraic sign, are called the ***coordinates*** of the point. In writing the coordinates of a point, the abscissa is written first and the ordinate second. Thus, we would write the coordinates of the point P in Fig. 19 as "the coordinates of P are (7, 5)."

The coordinate axes divide the area into four sections or quadrants as they are called. These quadrants are numbered in Fig. 19 by the Roman numerals I, II, III, IV. Notice that a point must have two positive coordinates to lie in the first quadrant and two negative coordinates to lie in the third quadrant. A point in the second quadrant must have a negative abscissa and a positive ordinate, while a point in the fourth quadrant has a positive abscissa and a negative ordinate.

This system of referring to a point by its coordinate is sometimes called the "Cartesian" coordinate system in honor of the French mathematician Descartes. It is also called the rectangular coordinate system because a rectangular figure is drawn when the points are completely located.

In electronics work, we use this standard coordinate reference frame constantly, but we usually use some other method of labeling the coordinate axes. However, regardless of the symbols we may use, the quadrant designations always remain the same, the signs of the scales are always the same, and we always consider the positive section of the X axis as the starting point or reference line. When the frame is assigned a degree system of reference, 0° is always at X, 90° at Y, 180° at X′, and 270° at Y′. Although most of our work will lie in the first and fourth quadrants, which is all we need to represent vectors consisting of coordinates using positive resistance, +jX and –jX, we will have some occasion to get into the second and third quadrants when we consider polyphase systems and "negative" resistances later in the course.

POLAR COORDINATES

As we have seen in studying ac circuits and trigonometry, degrees can be used to designate the points in the standard coordinate reference frame as shown in Fig. 20. Thus, we can locate a point P accurately and clearly by saying it is 10 units from the "0" of the graph and a line connecting the point "P" with "0" forms an angle of 45° with the positive X axis, as shown in Fig. 20. This would be written $10\underline{/+45^\circ}$ to show the length of a line from the origin, 0, to the point as 10 units; and the displacement of the line from 0° (measured counterclockwise) as $\underline{/+45^\circ}$. Thus, saying point P is $10\underline{/+45^\circ}$ would describe the location of the point in terms of polar coordinates. We call this the polar coordinate system because of its use in reference to the poles of the earth for navigation and surveying. Remember, a negative sign is used for angles generated or measured from 0° in a clockwise direction.

CONVERTING POLAR AND RECTANGULAR COORDINATES

Point P in Fig. 20 can be completely described or located by using either polar coordinates or rectangular coordinates. Therefore, we may want to convert polar coordinates to rectangular coordinates and vice versa. This can easily be done by using the fundamentals of trigonometry.

For example, suppose we wish to refer to the point P in Fig. 21 in rectangular

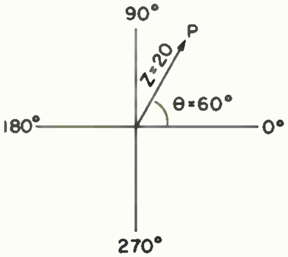

Fig. 21. Converting polar coordinates to rectangular coordinates.

coordinates so that it can be combined with other points that are also expressed as rectangular coordinates. When point P is expressed in polar form as an impedance vector and a phase angle it is written as $Z = 20\underline{/+60^\circ}$. To convert this impedance vector to its rectangular coordinates, we would express it as a resistance ± reactance.

The resistance component is always the adjacent side of $\angle\theta$ and the reactive component is always the opposite side of $\angle\theta$, representing the ±j term. Accordingly:

$$\cos\theta = \frac{\text{adj}}{\text{hyp}}$$

or

$$\text{adj} = \text{hyp} \times \cos\theta$$

Substituting:

$$R = Z\cos\theta$$

Likewise:

$$\sin\theta = \frac{\text{opp}}{\text{hyp}}$$

or

$$\text{opp} = \text{hyp} \times \sin\theta$$

Substituting:

$$X = Z\sin\theta$$

Then, since

$$Z = R \pm jX$$

we can substitute:

$$Z = Z\cos\theta \pm j(Z\sin\theta)$$

or

$$Z = Z(\cos\theta \pm j\sin\theta)$$

By applying this equation, we can convert polar coordinates to rectangular coordinates.

In Fig. 21, we would have:

$$Z = Z(\cos\theta \pm j\sin\theta)$$

Substituting:

$$Z = 20(\cos 60 + j\sin 60)$$

From our table:

$$Z = 20(.5 + j.866)$$

and:

$$Z = 10 + j17.32$$

would express

$$Z = 20\underline{/+60^\circ}$$

in rectangular coordinates.

For example, to convert the rectangular coordinates of an impedance, $Z = 250 - j100$ ohms to polar coordinates we have in three steps:

$$\tan\theta = \frac{\text{opp}}{\text{adj}}$$

Substituting:

$$\tan\theta = \frac{-jX}{R}$$

$$= \frac{-100}{250} = -.4$$

and from our tables:

$$\theta = -21.8^\circ$$

(θ is negative because jX is negative.)

Then:

$$\sin\theta = \frac{\text{opp}}{\text{hyp}}$$

or:

$$\text{hyp} = \frac{\text{opp}}{\sin\theta}$$

Substituting:

$$Z = \frac{-jX}{\sin\theta} = \frac{100}{\sin 21.8^\circ}$$

$$= \frac{100}{.3714} = 269\Omega$$

Accordingly, in polar coordinates:

$$Z = 269\underline{/-21.8^\circ\Omega}$$

Notice that once we found θ, and since all the necessary values are available, we could have used:

$$\cos\theta = \frac{\text{adj}}{\text{hyp}}$$

instead of:

$$\sin\theta = \frac{\text{opp}}{\text{hyp}}$$

However, our answer would still have worked out to the same value of $269/-21.8^\circ\Omega$.

MULTIPLICATION AND DIVISION USING POLAR COORDINATES

You will recall from your study of operator j that complex quantitites can be multiplied and divided to form other complex quantities. For example, if both the current and impedance were known in an ac circuit, we can find the voltage by multiplying the current by the impedance:

$$E = I \times Z$$

To do this, we would use the following procedure (keeping in mind significant figures). Assume:

$$I = 1.72 + j.38 \text{ amperes}$$
$$Z = 246 - j12 \text{ ohms}$$
$$E = I \times Z$$

$$\begin{array}{rrrr}
 & (1.72 & + j.38) & \\
\times & (24.6 & - j\,12) & \\
\hline
 & 42.3 & + j9.35 & \\
 & & -j20.6 & + \;4.56 \\
\hline
 & 42.3 & -j11.3 & + \;4.56
\end{array}$$

$$= 46.9 - j11.3$$

$$E = 46.9 - j11.3 \text{ volts}$$

We can perform the same calculations using the polar form for the current and impedance. To do this we first convert the current and impedance expressions to polar form:

$$I = 1.72 + j.38 = 1.76\underline{/+12.5}$$
$$Z = 24.6 - j12 = 27.4\underline{/-26^\circ}$$

The rules for multiplication in polar form are:

1. *Multiply* the magnitudes.
2. *Add* the angles.

Using the figures for I and Z already determined, we obtain:

$$E = 1.76 \times 27.4\underline{/(+12.5) + (-26)}$$
$$E = 48.3\underline{/-13.5^\circ}$$

To check our calculation, we can convert $48.3\underline{/-13.5^\circ}$ to get rectangular form and we get $E = 46.9 - j11.3$ volts.

We can also divide using the polar form for complex numbers. You will recall that to divide complex numbers in rectangular form we multiply numerator and denominator by the conjugate of the denominator to remove the j term from the denominator. This is a long and complicated operation which can be simplified by using the polar form. The rules for division are:

1. ***Divide*** the magnitude of the numerator by the magnitude of the denominator.
2. ***Subtract*** the angle of the denominator from the angle of the numerator.

As an example, suppose we have $E = 123\underline{/20^\circ}$ and $I = 1.4\underline{/-46^\circ}$. To find the impedance we divide E by I:

$$Z = \frac{E}{I} = \frac{123\underline{/20^\circ}}{1.4\underline{/-46^\circ}} = 87.9\underline{/(20^\circ) - (-46^\circ)}$$

$$Z = 87.9\underline{/66^\circ} \text{ ohms}$$

As an exercise, convert E and I to rectangular form and perform the calculation using conjugates. Then see if your result is equal to $35.8 + j80.3$ ohms.

PHASORS AND SINE WAVES

In the lessons on alternating currents, you learned that an alternating current is sinusoidal in nature. In other words, the various values of current and voltage generated by an alternating current source describe what is called a sine wave which repeats itself periodically. However, we have not yet discussed what a sine wave is nor why ac current values produce it.

Additionally, in your first introduction to vectors, we mentioned that the vectors used in ac circuit calculations were not considered vectors by electronic engineers. In a most accurate technical sense, they are *phasors*. This is because vectors usually express force as magnitude and direction, while phasors represent sine wave values with respect to time or phase.

Since many of you learned to work with vectors in high school or college physics, and since vectors and phasors are treated the same in circuit computations, we will continue to call them vectors.

However, many modern engineering texts refer to electrical vectors as phasors and we should know why they are phasors. This is a good time to examine both the sine wave and electrical vectors in greater detail.

Angles Greater Than 90°. In studying trigonometry, we have considered the functions of angles only up to 90°. We can, however, have angles of any magnitude, depending on where the terminal side of an angle stops and on how many complete revolutions it makes in generating the angles. In our study of sine waves, we will need to consider the functions of all possible angles up to 360°.

To begin with, let's consider the sine of the acute angle θ shown in Fig. 22A. Since $\angle\theta$ is equal to 30°, the sine of θ is equal to the ratio of the length of the opposite side over the hypotenuse which always works out to .5.

Now let's consider the angle θ shown in Fig. 22B. Angle θ is equal to 150° which is larger than 90° and so cannot be one of the angles in a right triangle. We know that the trigonometric functions are based on the sides and angles of right triangles. Yet, $\angle\theta = 150^\circ$ is considered to have a sine function, even though it cannot be part of a right triangle. In fact, the sine of 150° is .5, just the same as the sine of 30°.

To see how this is determined, we must consider what is known as the "associated acute angle" of the angle θ. First of all, an angle is said to be in *standard position*

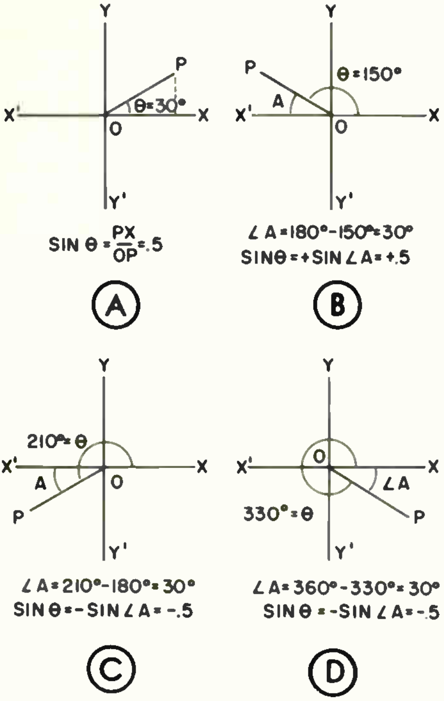

Fig. 22. Sines of angles greater than 90°.

when its *initial* side coincides with the *positive* side of the *X axis* of the standard coordinate reference frame, regardless of where its terminal side may be. Thus, the $\angle \theta = 150^\circ$ in Fig. 22B is in the standard position. Now, the ***associated acute angle*** of any angle θ larger than 90° is the acute angle which the terminal side of the angle makes with the X axis when the angle θ is in the standard position. Since $\angle \theta$ (Fig. 22B) is by definition in standard position, $\angle A$ is its associated acute angle. $\angle A$ is the supplement of $\angle \theta$, and therefore $\angle A = 180^\circ - \angle \theta (150^\circ)$ or 30°.

In Fig. 22C we have another angle θ which is equal to 210°. Its associated acute angle is $\angle A$ because, by definition, the associated acute angle is the acute angle formed between the terminal side and the X axis. Since θ equals 210°, and since the $\angle X'OX$ is equal to 180°, the $\angle A$ in Fig. 22C must be equal to $210^\circ - 180^\circ$ or $\angle A = 30^\circ$ again.

In Fig. 22D, we show still another angle θ. This time $\angle \theta = 330^\circ$ and its associated acute angle, $\angle A$, must equal $360^\circ - 330^\circ$ or 30° once again.

Remember, the associated acute angle always lies between the terminal side of $\angle \theta$ and the X axis as shown in Fig. 22. Notice that from this definition, $\angle \theta$ in Fig. 22A is really its own associated acute angle.

There is a trigonometric statement that says:

The function of any angle greater than 90° is equal to plus or minus the function of its associated acute angle.

This simply means that a 150° angle has the same sine as its associated acute angle, which is $\angle A$. Since $\angle A$ is 30°, the sine of the 150° angle is the same as the sine of the 30° angle. Likewise, the sine of 210° is equal to the sine of 30° except that it is negative, and the sine of 330° is also equal to the sine of 30° except that it is negative.

To determine the sine of any angle greater than 90°, find the value of the function of its associated acute angle. Then affix a plus or minus sign, depending on the quadrant in which the terminal side of the angle lies.

As you have probably guessed, all the other functions can also exist for any angle greater than 90°. The rule for the sine function applies to the other functions as well.

In Fig. 23A, the cosine of $\angle \theta = 252^\circ$ is equal to minus the cosine of 72° or $-.3090$ because 72° is the associated acute angle of 252° and the terminal side lies in the third quadrant. Likewise, the tangent of $\angle \theta = 305^\circ$ is equal to minus

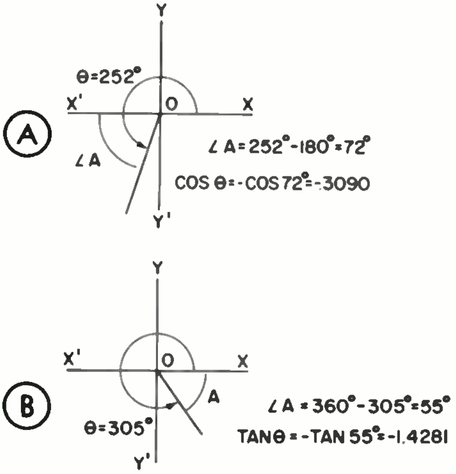

Fig. 23. All functions exist for all angles.

the tangent of 55° or −1.4281, as shown in Fig. 23B.

Now let's consider the sign of the functions in the different quadrants.

SIGNS OF FUNCTIONS IN QUADRANTS

In the first quadrant, all six functions are positive. In the second quadrant, the sine and cosecant are positive, all other functions are negative. In the third quadrant the tangent and its reciprocal (the cotangent) are positive and the other functions are negative. In the fourth quadrant, the cosine and secant are positive and the other four functions are negative.

To see why the functions have these signs, look at Fig. 24. First consider that the X–X′ axis and the Y–Y′ axis divide the figure into four quadrants. A line drawn from the Y–Y′ axis along or parallel to the X axis is considered positive if it is drawn to the right, and negative if it is drawn to the left. Similarly, a line drawn from the X–X′ axis along or parallel to the Y axis is positive if it is drawn upward and negative if it is drawn below the X–X′ axis.

Now look at angle θ in Fig. 24A. Side a is positive because it is drawn above the X–X′ axis, and side b is also positive because it is drawn to the right of the Y–Y′ axis. *The hypotenuse of the triangle is always considered positive* and therefore the functions are as follows:

$$\sin\theta = \frac{+a}{+c}$$

$$\cos\theta = \frac{+b}{+c}$$

$$\tan\theta = \frac{+a}{+b}$$

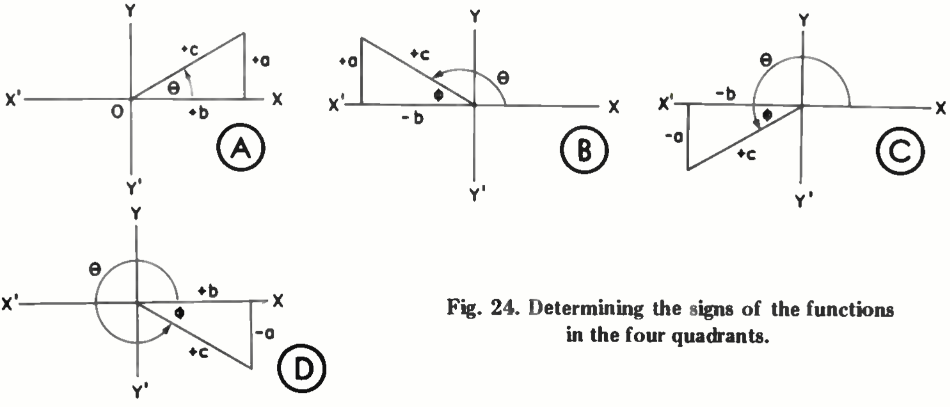

Fig. 24. Determining the signs of the functions in the four quadrants.

$$\cot\theta = \frac{+b}{+a}$$

$$\sec\theta = \frac{+c}{+b}$$

$$\csc\theta = \frac{+c}{+a}$$

In each case we have a plus term divided by another plus term, so the result in each case is positive.

Now look at Fig. 24B and consider the second quadrant. Again we are interested in angle θ. The functions are equal to the functions of the associated acute angle which we have labeled Φ (Greek capital letter Phi). The hypotenuse c is always positive. Side a which is parallel to the Y axis and drawn above the X–X′ axis is positive. Side b which is parallel to the X axis is drawn to the left of the Y–Y′ axis and is therefore negative. So now the functions are as follows:

$$\sin\theta = \sin\Phi = \frac{+a}{+c}$$

$$\cos\theta = -\cos\Phi = \frac{-b}{+c}$$

$$\tan\theta = -\tan\Phi = \frac{+a}{-b}$$

$$\cot\theta = -\cot\Phi = \frac{-b}{+a}$$

$$\sec\theta = -\sec\Phi = \frac{+c}{-b}$$

$$\csc\theta = \csc\Phi = \frac{+c}{+a}$$

From this you can see that the sin and csc will be positive because you have a plus term divided by another plus term and the other four functions will be negative because in each of these expressions there is one plus term and one negative term.

Now look at θ in the third quadrant shown in Fig. 24C. The hypotenuse c is positive, but now both a and b are negative. Therefore:

$$\sin\theta = -\sin\Phi = \frac{-a}{+c}$$

$$\cos\theta = -\cos\Phi = \frac{-b}{+c}$$

$$\tan\theta = \tan\Phi = \frac{-a}{-b}$$

$$\cot\theta = \cot\Phi = \frac{-b}{-a}$$

$$\sec\theta = -\sec\Phi = \frac{+c}{-b}$$

$$\csc\theta = -\csc\Phi = \frac{+c}{-a}$$

In the case of the tan and cot functions you have a minus term divided by a minus term which gives you a plus result so the tangent and cotangent are positive in the third quadrant and all other terms are negative.

Now look at θ in the fourth quadrant as shown in Fig. 24D. Again c is positive. Side b will also be positive, but side a is negative. Therefore:

$$\sin\theta = -\sin\Phi = \frac{-a}{+c}$$

$$\cos\theta = \cos\Phi = \frac{+b}{+c}$$

$$\tan\theta = -\tan\Phi = \frac{-a}{+b}$$

$$\cot\theta = -\cot\Phi = \frac{+b}{-a}$$

$$\sec\theta = \sec\Phi = \frac{+c}{+b}$$

$$\csc\theta = -\csc\Phi = \frac{+c}{-a}$$

Thus cos and sec are positive and the other four functions are negative in the fourth quadrant.

The Sine Wave. Now that we can determine the sine of any angle up to 360°, we are ready to continue with the definition of a sine curve. A sine curve is merely a graph of all the sines of all the angles up to 360° that repeats itself periodically. Since there are an infinite number of angles that can be formed between 0° and 360° (if all the possible stopping points of the terminal side are considered), there are also an infinite number of sine functions to plot a curve. Therefore, we simply choose angles in 15° steps from 0° to 360° and plot their functions. We then round off the sine functions of these angles to two decimal places because this is as accurate as we can be if we are to keep the graph to a reasonable size.

Now let's examine and list the sine functions of the angles, starting with $\angle\theta = 0°$. When θ equals zero, there is no angle or opposite side, so when $\angle\theta$ equals 0°, the opposite side must also be zero. Therefore, since $\sin\theta$ equals the ratio of opp/hyp, and $\sin\theta$ equals the ratio of 0/hyp, when $\angle\theta$ equals 0°, $\sin\theta$ must also equal 0. Therefore, our list of functions begins with:

$$\theta = 0°; \quad \sin\theta = 0$$

We have seen that the ratio of opp/hyp is always equal to the sine of $\angle\theta$ as listed in the tables, no matter what the relative lengths of the sides of the right triangle may be. Therefore, you can use the tables directly to make a list of the sine functions of all the angles you wish to use.

The next step is to lay out a graph as shown in Fig. 25. Here the base line is laid out on the X axis and is marked in 15° steps from 0° to 360°. The numbers 0 to 1.0 are laid out vertically in steps of

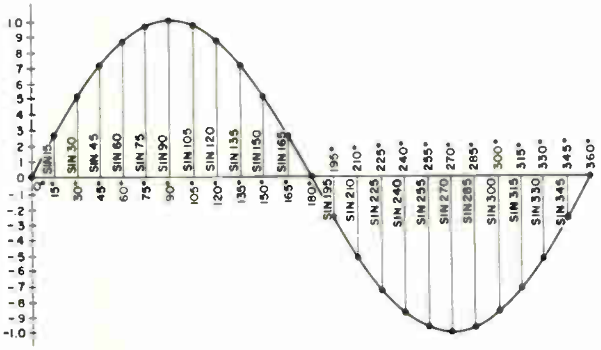

Fig. 25. Graphical plot of the sines of angles in 15° steps from 0° to 360°.

.1 in the positive direction along the Y axis. The numbers from 0 to −1.0 are laid out in steps of −.1 in the negative direction along the Y axis. At each 15° step along the X axis, the appropriate value of the sine of the angle is indicated in terms of the numbers located on the Y axis. Thus, we have a graph of ***various values*** of the Y values of the sines of all the angles indicated along the X axis. This is generally called a graph of Y = sin X.

When these points are joined with a smooth curve, a curve is formed which represents the sines of all the angles between 0° and 360°. This is called a sine curve or sine wave. We can consider the terminal side of angles generated to form a sine curve as a rotating vector, as shown in Fig. 26. This rotating vector generates the angles and consequently the functions of the angles indicated by the sine curve. If sine θ equals

$$\frac{\text{opp}}{\text{hyp}}$$

and hyp (rotating vector) equals 1 unit, then sin θ equals

$$\frac{\text{opp}}{1} = \text{opp}$$

Thus, if this vector equals 1″, 1′, 1 volt, or any other value, the sine functions generated will be equal to the length of the perpendiculars, which will also equal the actual value of the sine functions as listed in the tables.

Notice that as the vector starts from 0°, the function is 0; as it passes through 90° the maximum function is generated. At 180° the function is again 0; at 270° in the negative direction it is maximum; and at 360° it is back again to no function. Also notice that the value of the function changes most rapidly when the vector is rotating through 0°, 180°, and 360°. This rotating vector can be compared to the rotation of the armature of a basic ac generator as shown in Fig. 27.

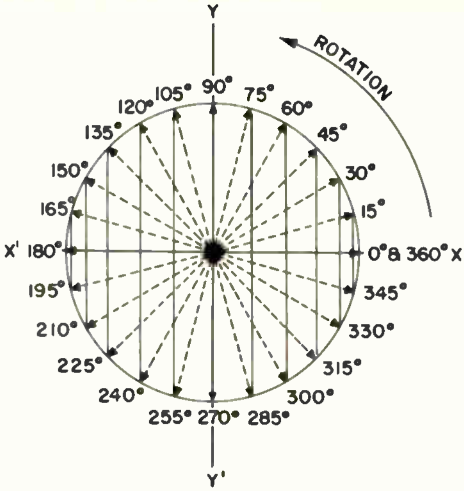

Fig. 26. Diagram of rotating vector generating sine functions shown in the sine curve of Fig. 25.

As the armature moves parallel to the lines of force as shown in Fig. 27A, no voltage will be generated. As it moves at right angles to the lines of force as in Fig. 27B, the maximum number of lines of force will be cut and the maximum voltage will be generated. While it is

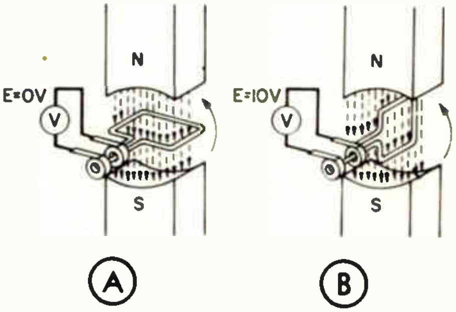

Fig. 27. Generator armature can be compared to rotating vector in Fig. 26.

moving from its position shown in Fig. 27A to that shown in Fig. 27B, the voltage generated will increase from zero to maximum in proportion to the sine of its instantaneous angular position. Thus, if we consider the maximum voltage as 10 volts at 90° of rotation as shown in Fig. 27B, and zero voltage as 0 volts at 0° of rotation as shown in Fig. 27A, the instantaneous value of voltage at a rotation of 15° would be 2.7 volts. It would be 5 volts at 30°, 7.1 volts at 45°, etc. If we were to measure all these instantaneous voltages at each 15° step of angular rotation of the basic armature in a standard magnetic field from 0° through 360°, we would obtain a sine wave graph similar to the one in Fig. 25. This is why an ac voltage is said to vary sinusoidally, and is called a sine wave.

If the armature continues to rotate again and again at the same speed, the sine wave voltage will repeat itself indefinitely. We will get a complete 0° – 360° sine wave during each complete revolution or period, so the sine wave is a periodic repetition of the same functions.

Phase Relationships. We have seen how the voltage generated by the rotating armature describes a sine wave just as the sine functions of the rotating vector describe the sine curve of the angles it passes through. Now suppose we have two generators represented by rotating vectors, as shown in Fig. 28. They are exactly the same except that when one armature is passing through 90° the other is passing through 0°. The sine wave outputs of the two generators are superimposed on each other as shown by the solid and dotted sine waves in Fig. 29.

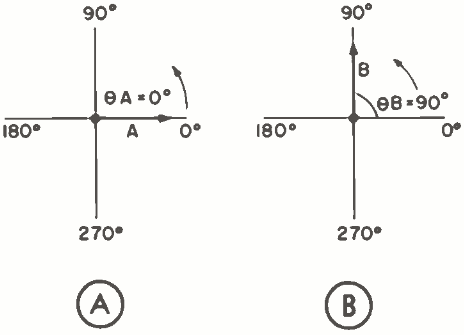

Fig. 28. Two generators represented by rotating vectors. (A) shows instantaneous value of sin θ to be zero. (B) shows instantaneous value of sin θ to be maximum at the same instant.

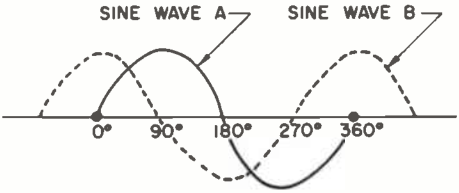

Fig. 29. Sine waves generated by two identical phasors operating 90° apart.

As you can see, these voltage sine waves are generated 90° out-of-phase with each other just as the vectors are 90° out-of-phase. Thus, the rotating vectors represent the relative phase of the two sine waves and are called phasors. By applying the principles of trigonometry to the angle generated by one of the phasors, we can determine the instantaneous value of voltage generated for any position of the phasor if we know its value at $\sin \theta = 1$.

Thus, if at $\sin \theta = 1$, or 90°, the phasor produces a voltage of 120 volts, then at $\angle \theta = 30$, the instantaneous value of voltage generated will equal

$$\sin \theta = \frac{\text{opp}}{\text{hyp}}$$

And, hyp equals phasor length at $\sin \theta = 1$, therefore hyp equals 120. Then,

$$\sin \theta = \frac{\text{opp}}{120}$$

and θ equals 30°, therefore

$$\sin 30^\circ \text{ or } .5 = \frac{\text{opp}}{120}$$

and opp equals $120 \times .5 = 60$ volts of instantaneous voltage. In this way phasors can be used to represent the instantaneous values of all the sine wave voltages occurring across circuit components at any instant.

Phasors can be expressed in rectangular coordinates as well as polar coordinates All the principles of the parallelogram measurement method for solving vector diagrams can be applied to phasors. Similarly, the j operator and trigonometry can be used in the solution of phasor problems. Consequently, we shall continue to call our phasors "vectors" in this course. Remember, however, that although a phasor can perhaps be considered a special type of vector as is done in most older texts, a vector cannot be considered a phasor.

SELF-TEST QUESTIONS

16. A 15-ohm resistor is connected in series with a 15-ohm capacitive reactance. What is the impedance of the circuit? Express your answer in both polar and binomial form.
17. R_1, R_2, C_1, C_2, L_1 and L_2 are connected in series. $R_1 = 10$ ohms, $R_2 = 30$ ohms, $X_{C1} = 9$ ohms, $X_{C2} = 16$ ohms, $X_{L1} = 20$ ohms, $X_{L2} = 35$ ohms. What is the impedance? Express your answer in both polar and binomial form.

Trigonometry in AC Circuits

In an earlier part of this lesson we saw how trigonometry is used in simple series circuit calculations. In this section we will apply what we have learned about vector diagrams, the j operator, algebra, and trigonometry to more complicated ac circuits. Before discussing series parallel circuits, let's take a look at a series circuit and get familiar with voltage computations.

Resistance in Coils. Until now we have neglected the resistance that exists in the windings of coils in our ac circuit calculations. Although we can do this without being too far off, occasionally we will want to be more accurate. This does not present any particular problem where both the resistance and either the inductance or inductive reactance of the coil are given. However, in many circuits, this information is not easy to obtain. Although, it is easy to measure the resistance of a coil with an ohmmeter, the inductance cannot be found as easily unless we have a special meter.

However, through the use of trigonometry and standard measuring instruments, it is quite easy to determine the inductance of a coil and separate the inductive reactance from the resistance. For example, consider the circuit shown in Fig. 30. Here we have a coil, a capacitor, and a resistor in series with each other. If we measure the voltage drops across each of these units as shown, and then compute the total voltage of the circuit, we will find that the total voltage computed does not agree with the total voltage indicated by the measurement. Let's see why this difficulty occurs and how to overcome it.

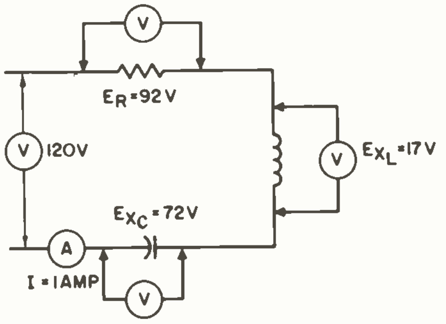

Fig. 30. Typical series circuit voltage measurements.

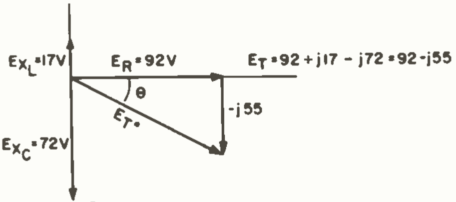

$$\text{TAN } \theta = \frac{\text{Opp}}{\text{Adj}} = \frac{55}{92} = .5978 = \text{TAN } 30.868^\circ \text{ or } 30.9^\circ$$

$$\theta = 30.9^\circ$$

$$\text{SIN } \theta = \frac{\text{Opp}}{\text{Hyp}} = \frac{55}{E_T}$$

$$E_T = \frac{55}{\text{SIN } 30.9^\circ} = \frac{55}{5135} = 107.1 \text{ VOLTS}$$

Fig. 31. Computation of total voltage without considering coil resistance.

First, computing the total voltage, E_T, without considering any possible resistance that the coil might have, we get the results shown in Fig. 31. Drawing our rough vector diagram as shown, we have E_{X_L} of 17V as the inductive vector component, E_{X_C} of 72V as the capacitive vector component, and E_R of 92V as the resistive vector component. Mathematically, this gives us: 92 + j17 – j72, or 92 – j55 as our final vector stated as a binomial. Thus, E_T is the hypotenuse of a right triangle with a base of 92V and an altitude of 55V. Then, using trigonometry, we find that the phase angle θ equals:

$$\tan\theta = \frac{\text{opp}}{\text{adj}} = \frac{55}{92} = .5978$$

Therefore:

$$\theta = \text{angle whose tangent is } .5978$$

By using our Table of Functions and interpolating we find that the angle θ equals 30.9°.

Now that we have the angle θ, we can find the value of E_T through the function:

$$\sin\theta = \frac{\text{opp}}{\text{hyp}} \text{ or hyp} = \frac{\text{opp}}{\sin\theta}$$

or $$E_T = \frac{55}{\sin 30.9^\circ}$$

Since our table lists the functions in one-degree steps we must interpolate to find the sine of 30.9°. Doing this, we find:

$$\sin 30.9^\circ = .5135$$

Substituting:

$$E_T = \frac{55}{\sin 30.9^\circ}$$

$$= \frac{55}{.5135} = 107.1 \text{ volts}$$

Thus, by computing, we find that E_T = 107.1 volts, even though the measured value for E_T in the circuit of Fig. 30 is 120 volts. The reason for this difference is that the Q of the coil is low; therefore, the ratio of the resistance of its winding to its inductance is large. This means that the voltage E_{X_L}, which we assumed to be purely inductive, does not lead the current in the circuit by a full 90°. Consequently, our E_{X_L} of 17 volts is really voltage made up of $E_{R_L} + jE_{X_L}$ and cannot be written $+j17$ and added directly to our $-j72$. It must be broken down into its two components, $E_{R_L} + jE_{X_L}$. Thus, the vector diagram of our circuit must be drawn as shown in Fig. 32, and our voltage vector E_T must be found from:

$$E_T = E_R + E_{T X_L} - jE_{X_C}$$

and

$$E_T = E_R + (E_{R_L} + jE_{X_L}) - jE_{X_C}$$

$$= 92 + E_{R_L} + jE_{X_L} - j72$$

In order to work out a solution to this problem, we must know the values of both E_{R_L} and E_{X_L}. Neither the value of the resistance of the coil nor the value of its inductance is given. However, the chances are that if we have a meter or meters capable of reading the voltages of the circuit and the current through the circuit, as shown in Fig. 30, we will also

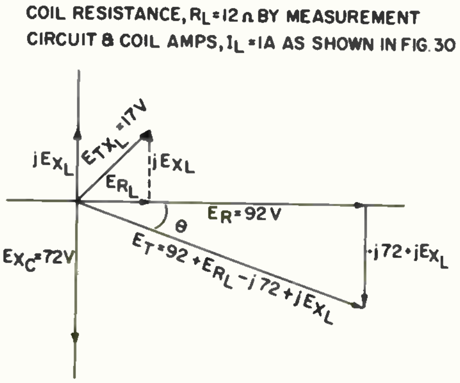

Fig. 32. Vector diagram of circuit in Fig. 30 considering coil resistance.

have an ohmmeter. With the ohmmeter we can determine the resistance of the coil, and then by computing we can find E_{R_L} and E_{X_L}.

For example, suppose we measure the resistance of the coil and find it to be 12 ohms. Our circuit ammeter shows us that the current through the circuit is 1 amp. Thus,

$$\begin{aligned} E_{R_L} &= I \times R_L \\ &= 1 \times 12 \\ &= 12 \text{ volts} \end{aligned}$$

This gives us one of our components of E_{X_L}, so our equation for E_T becomes:

$$\begin{aligned} E_T &= 92 + E_{R_L} + jE_{X_L} - j72 \\ &= 92 + 12 + jE_{X_L} - j72 \end{aligned}$$

Now, all we have left to determine is the value of jE_{X_L}.

This is where trigonometry really helps. We have the total coil voltage drop and have been able to compute the resistance component of this total drop. Therefore, we have the value of both the hypotenuse and the base of a right triangle as shown in Fig. 33A, and can compute the value of jE_{X_L}. First we list our values as:

Given: $E_{TX_L} = 17\text{V}$

$I_L = 1\text{A}$

$R_L = 12$ ohms

$$\begin{aligned} E_{R_L} &= I_L \times R_L \\ &= 1 \times 12 \\ &= 12\text{V} \end{aligned}$$

Find: E_{X_L}

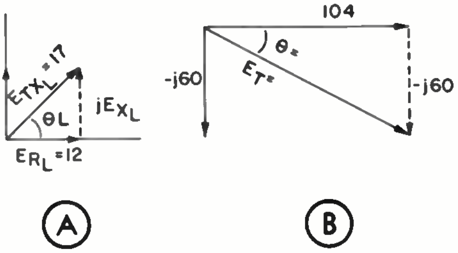

Fig. 33. Trigonometric solution of vector diagram of Fig. 32.

Now, sketching the vector diagram with 17 as the hypotenuse and 12 as the base of a right triangle, as shown in Fig. 33A, allows us to use our trigonometry. First we want to find the phase angle θ_L. To do this, we use the cosine function which is:

$$\cos\theta = \frac{\text{adj}}{\text{hyp}} = \frac{E_{R_L}}{E_{TX_L}} = \frac{12}{17} = .7057$$

In checking our Table of Functions we find that there is no cosine given as exactly .7057. Although we could interpolate to find the exact value for θ, our cosine of .7057 is so close to .7071, which is the cosine of 45°, that we can use the approximate value of 45° as the angle θ_L.

Now that we know that θ_L is equal to 45°, we can proceed to find the value of jE_{X_L} (the opposite side) by using one of the other functions. For example,

$$\tan\theta_L = \frac{\text{opp}}{\text{adj}}$$

and:

$$\text{opp} = \text{adj} \times \tan \theta_L$$

Substituting:

$$jE_{X_L} = E_{R_L} \times \tan 45^\circ$$

$$jE_{X_L} = 12 \times 1.0000 = 12$$

Thus, jE_{X_L}, which is the reactive component of the total coil voltage, is also equal to 12 volts. Notice that we could also have used the sine since

$$\sin \theta_L = \frac{\text{opp}}{\text{hyp}}$$

and therefore

$$\text{opp} = \sin \theta_L \times \text{hyp}$$

or

$$jE_{X_L} = \sin 45^\circ \times E_{TX_L}$$

$$= .7071 \times 17 = 12 \text{ (approx.)}$$

The function used is a matter of personal choice or convenience as long as the necessary values are known.

Notice what we have done. We took a voltage drop across a coil and broke it up into its resistive and reactive components. We could not measure these components because they do not exist separately; they exist together as a total. The fact that this vector sum is not exactly in phase with the current tells us that it must have both of the components. In order to ***compute*** the circuit values accurately, we must have the values of the components, not their vector sum. Since the resistance of a coil, the current through the coil, and the total voltage across the coil are all easy to measure with instruments, we have used these values, together with trigonometry, to obtain the two components of total coil voltage.

If we have the inductance or the inductive reactance of the coil, we can also use them to compute the value of the components. However, in practical circuits the value of the inductance or inductive reactance is often not known. Since these values can only be measured with instruments, which are usually not available in the average shop, we have shown you a method to use to solve the problem.

Since we now have all the values required to find E_T as shown in Fig. 32, we can continue with our computation as shown in Fig. 33B. We have already established the fact that:

$$E_T = E_R + E_{TX_L} - jE_{X_C}$$

By substitution:

$$E_T = E_R + (E_{R_L} + jE_{X_L}) - jE_{X_C}$$

and:

$$E_T = 92 + 12 + j12 - j72$$

Then:

$$E_T = 104 - j60$$

and we can draw the vector diagram as shown in Fig. 33B and compute the value of E_T and θ by using trigonometry. First:

$$\tan \theta = \frac{\text{opp}}{\text{adj}} = \frac{60}{104} = .5769$$

and

$$\theta = 30^\circ \text{ (approx.)}$$

Then:

$$\sin\theta = \frac{\text{opp}}{\text{hyp}}$$

and

$$\text{hyp} = \frac{\text{opp}}{\sin\theta} = \frac{60}{.5} = 120\text{V}$$

This is the value of E_T that we obtained by measurement in Fig. 30 and is therefore correct.

We have used a very low Q coil to demonstrate the importance of considering the resistive component of voltage in a coil.

$$Q = \frac{12}{12} = 1$$

Although such a low Q coil will not be found often in practical circuits, it is still important to know how to handle these effects when they do occur. You are probably wondering about the resistance of capacitors and if it too has to be considered. It does not. Although all capacitors do have some resistance, it is never large enough to be noticed in a practical capacitor.

SERIES-PARALLEL CIRCUITS

Now let's look at a more complicated circuit, such as the one shown in Fig. 34. This is a series-parallel circuit with the various values given. We are asked to find the total impedance Z_T, the total current I_T, and the final phase angle θ_T.

First, we want to find the impedance of the three parallel branches, a, b, and c, which we can do as follows:

$$Z_a = R + jX_L = 25 + j17.5 \text{ ohms}$$

$$\tan\theta_a = \frac{\text{opp}}{\text{adj}} = \frac{X_{La}}{R_a} = \frac{17.5}{25} = .700$$

$$\theta_a = 35^\circ$$

Then:

$$\sin\theta_a = \frac{\text{opp}}{\text{hyp}} = \frac{X_{La}}{Z_a}$$

or

$$Z_a = \frac{X_{La}}{\sin\theta_a} = \frac{17.5}{\sin 35^\circ}$$

$$= \frac{17.5}{.574} = 30.5 \text{ ohms}$$

Thus:

$$Z_a = 30.5\underline{/35^\circ} \text{ ohms}$$

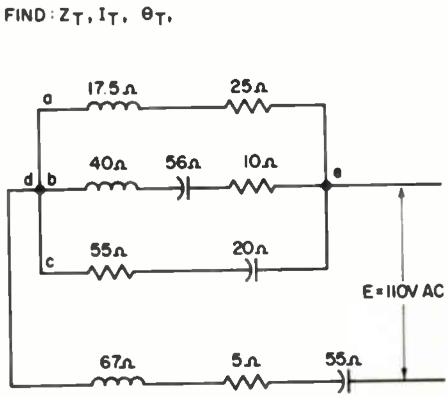

Fig. 34. Series-parallel ac circuit.

Next:

$$Z_b = R + jX_L - jX_c$$

$$= 10 + j40 - j56$$

$$= 10 - j16$$

$$\tan \theta_b = \frac{\text{opp}}{\text{adj}} = \frac{X_b}{R_b}$$

$$= \frac{-16}{10} = -1.6$$

$$\theta_b = -58^\circ$$

Then:

$$\sin \theta_b = \frac{\text{opp}}{\text{hyp}} = \frac{X_b}{Z_b}$$

or

$$Z_b = \frac{X_b}{\sin \theta_b} = \frac{-16}{\sin -58^\circ}$$

$$= \frac{-16}{-.848} = 18.9$$

Thus:

$$Z_b = 18.9\angle{-58^\circ} \text{ ohms}$$

Next:

$$Z_c = R - jX_c = 55 - j20$$

$$\tan \theta_c = \frac{\text{opp}}{\text{adj}} = \frac{-20}{55} = -.364$$

$$\theta_c = -20^\circ$$

Then:

$$\sin \theta_c = \frac{\text{opp}}{\text{hyp}} = \frac{X_c}{Z_c}$$

or

$$Z_c = \frac{X_c}{\sin \theta_c} = \frac{-20}{\sin -20}$$

$$= \frac{-20}{-.342} = 58.5$$

Thus:

$$Z_c = 58.5\angle{-20^\circ} \text{ ohms}$$

Now assume a voltage between d and e and find I for each branch as follows:

$$I_a = \frac{E_{de}}{Z_a} = \frac{100\angle{0^\circ}}{30.5\angle{35^\circ}} = 3.28\angle{-35^\circ} \text{ amps}$$

$$I_b = \frac{E_{de}}{Z_b} = \frac{100\angle{0^\circ}}{18.9\angle{-58^\circ}} = 5.3\angle{58^\circ} \text{ amps}$$

$$I_c = \frac{E_{de}}{Z_c} = \frac{100\angle{0^\circ}}{58.5\angle{-20^\circ}} = 1.71\angle{20^\circ} \text{ amps}$$

Now convert branch currents I_a, I_b, and I_c from polar to rectangular coordinates for easy addition as follows:

$$\begin{aligned} I_a &= I_a (\cos \theta_a + j \sin \theta_a) \\ &= 3.28 (\cos -35^\circ + j \sin -35^\circ) \\ &= 3.28 (.8192 - j.5736) \\ &= 2.69 - j1.88 \text{ amps} \end{aligned}$$

Since -35° lies in the fourth quadrant, cos -35° is positive and sin -35° is negative. This explains why the resistive term is positive and the reactive term is negative.)

$$\begin{aligned}I_b &= I_b(\cos\theta_b + j\sin\theta_b)\\ &= 5.3(\cos 58^\circ + j\sin 58^\circ)\\ &= 5.3(.5299 + j.8480)\\ &= 2.81 + j4.5 \text{ amps}\end{aligned}$$

$$\begin{aligned}I_c &= I_c(\cos\theta_c + j\sin\theta_c)\\ &= 1.71(\cos 20^\circ + j\sin 20^\circ)\\ &= 1.71(.9397 + j.3420)\\ &= 1.61 + j.585 \text{ amps}\end{aligned}$$

Now,

$$I_{de} = I_a + I_b + I_c$$

and:

$$\begin{array}{l} I_a = 2.69 - j1.88\\ I_b = 2.81 + j4.5\\ \underline{I_c = 1.61 + j.585}\end{array}$$

thus,

$$I_{de} = 7.11 + j3.205$$

Now

$$\tan\theta_{de} = \frac{\text{opp}}{\text{adj}} = \frac{I_{de_x}}{I_{de_r}}$$

$$= \frac{3.2}{7.11} = .45$$

$$\theta_{de} = 24.2^\circ$$

And I_{de} in polar form:

$$\sin\theta_{de} = \frac{\text{opp}}{\text{hyp}} = \frac{I_{de_x}}{I_{de}} \text{ or } I_{de} = \frac{I_{de_x}}{\sin\theta_{de}}$$

Then:

$$I_{de} = \frac{I_{de_x}}{\sin\theta_{de}} = \frac{3.2}{\sin 24.2^\circ}$$

$$= \frac{3.2}{.4099} = 7.8$$

Thus:

$$I_{de} = 7.8\underline{/24.2^\circ} \text{ amps}$$

And:

$$Z_{de} = \frac{E_{de}}{I_{de}} = \frac{100\underline{/0^\circ}}{7.8\underline{/24.2^\circ}}$$

$$= 12.8\underline{/-24.2^\circ} \text{ ohms}$$

Converting Z_{de} to rectangular coordinates:

$$\begin{aligned}Z_{de} &= Z_{de}(\cos\theta_{de} + j\sin\theta_{de})\\ &= 12.8(\cos -24.2 + j\sin -24.2^\circ)\\ &= 12.8(.9121 - j.4099)\\ &= 11.7 - j5.25 \text{ ohms}\end{aligned}$$

Now combining:

$$\begin{aligned}Z_T &= Z_{de} + j67 - j55 + 5\\ Z_T &= 11.7 + 5 - j5.25 + j67 - j55\\ Z_T &= 16.7 + j6.75 \text{ ohms}\end{aligned}$$

Then:

$$\tan\theta_T = \frac{\text{opp}}{\text{adj}} = \frac{6.75}{16.7} = .404$$

$$\theta_T = 22^\circ$$

Converting Z_T to polar form:

$$\sin\theta_T = \frac{\text{opp}}{\text{hyp}} = \frac{X_T}{Z_T}$$

or

$$Z_T = \frac{X_T}{\sin\theta_T} = \frac{6.75}{\sin 22^\circ} = \frac{6.75}{.3746} = 18$$

$$Z_T = 18\underline{/22^\circ} \text{ ohms}$$

Then:

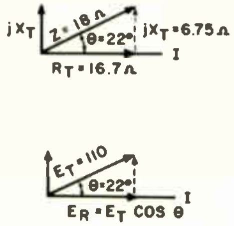
$$I_T = \frac{E_T}{Z_T} = \frac{110\underline{/0^\circ}}{18\underline{/22^\circ}}$$

$$= 6.11\underline{/-22^\circ} \text{ amps}$$

With this as a typical example of using trigonometry in ac circuits, try some of the problems you solved using the j-operator and the Pythagorean Theorem in your previous lessons.

Power in AC Circuits. Up until now we have not considered power in ac circuits because we have not had a simple method of finding it. In a purely resistive circuit, where the current and voltage are in phase, the power is equal to the voltage times the current as it is in a dc circuit. In a purely reactive circuit where there is no resistance whatsoever, power is alternately stored up by the reactive elements and then returned to the line. Such a circuit can exist only in theory, of course, because practical circuits always have some resistance. However, oscillatory tank circuits, which you have studied, do come fairly close to being resistance-free and, consequently, small properly timed surges of current can keep them going indefinitely.

Thus, we can say that the resistive elements of a circuit consume the only power expended. Let's see what this means in terms of the circuit we have just studied. If we construct the resultant vector diagram of the circuit from $\theta_T = 22^\circ$, $Z_T = 18\Omega$, we have a vector $Z_T = 18\underline{/22^\circ}$ as shown in Fig. 35. The reactive component of this impedance is jX_T as shown, and the resistive component is equal to R_T as shown. The resistive component is equal to 16.7 ohms, while the reactive component is 6.75 ohms, as we discovered while solving for Z_T.



$P = EI \cos\theta$

$P_a = EI$

$P.F. = \cos\theta$

Fig. 35. Vector representation of power factor.

Now, if the resistive component is all that consumes power, the power must be equal to $E_R \times I$ since only the resistive component of voltage forces current through the resistance to consume power. However, in the circuit we have just solved, we are not given the value of E_R, nor did we find it in any of our computations. However, if we lay out a vector representing the conditions of our circuit, we have a vector of the total voltage E_T of 110V leading the current vector, which we have taken as our reference vector, by 22°. We can find E_R now by using:

$$\cos\theta = \frac{\text{adj}}{\text{hyp}} = \frac{E_R}{E_T}$$

and

$$E_R = E_T \cos\theta$$

Now, if $P = E_R \times I$ equals the power expended and $E_R = E_T \cos\theta$, by substitution:

$$P = (E_T \cos\theta)I$$

or

$$P = EI \cos\theta$$

Then, substituting values:

$$\begin{aligned} P &= 110 \times 6.11 \times \cos 22^\circ \\ &= 110 \times 6.11 \times .9272 \\ &= 623 \text{ watts} \end{aligned}$$

This is the power actually consumed by the circuit.

Now, in ac circuits we have another value of power which is called the apparent power. This is simply the product of E_T and I_T without considering their relative instantaneous values at any particular moment. Thus, in the circuit we have just solved, the apparent power is simply 110 × 6.11 or 672.1W. The apparent power in a circuit is designated as P_a to separate it from the true power P which does take into consideration the relative instantaneous values of E and I through multiplication by $\cos\theta$.

Now, we have another situation in ac power that must be considered. This is the power factor PF which is the ratio of the true power P to the apparent power P_a. Mathematically, this is stated:

$$PF = \frac{P}{P_a}$$

then

$$PF = \frac{EI\cos\theta}{EI} = \cos\theta$$

and the power factor can be found from $PF = \cos\theta$. In the circuit we have just computed, PF = .927 lagging because the current lags the voltage by 22°. Power factor is also expressed as a percentage, 92.7%.

There are other formulas for power factor in ac circuits, but these are the most common. Since the formula $P = I^2R$ uses only resistance and current, it will also give us the true power. Here we are not multiplying the effective values of current by an effective value of voltage without considering their relative instantaneous values. We are simply squaring the effective value of current and multiplying it by the total resistive component of Z. Thus, $P = I^2R$ gives us: $6.11^2 \times 16.7 = 623$ watts which is true power.

We can also write another formula for power factor. If

$$PF = \frac{P}{P_a}$$

and

$$P = I^2R$$

and

$$P_a = EI$$

Then:

$$PF = \frac{I^2R}{EI} = \frac{IR}{E}$$

But

$$E = IZ$$

so

$$PF = \frac{IR}{IZ} = \frac{R}{Z}$$

Therefore

$$PF = \frac{R}{Z}$$

However, this is just another way of saying $\cos\theta$, because

$$\cos\theta = \frac{adj}{hyp} = \frac{R}{Z}$$

It also should be noted that true power P equals PF × P_a because

$$PF = \frac{R}{Z} \text{ or } \cos\theta$$

and

$$P_a = EI$$

and our first formula for power was $P = EI \cos \theta$. Any of the relationships may be used, and if you remember that:

$$P_a = EI$$

and

$$P = EI \times PF$$

$$PF = \cos \theta$$

you can use algebra and trigonometry to work out the other formulas.

Although you will not become an expert in the science of trigonometry from what you have learned in this lesson, you have covered most of the basic fundamentals and their application in electronics. You will be able to handle nearly every problem when you understand the elementary principles of trigonometry. Like any other math, trig requires a lot of practice to become familiar with it. You should practice solving the right triangles of circuits in other lessons to obtain this practice.

Now answer the following Self-Test Questions which are an overall review of trigonometry. They will give you further practice in solving ac circuit problems.

Graphs

A graph is a picture that shows the effect of changes in one variable on a second variable. Graphs are very common in electronics literature since they provide a simple means of describing circuit operations, illustrating equations and formulas, showing relationships when no formulas exist, and displaying results of experiments.

Graphs are not new to you; you studied them in grade school. They are commonly used in newspapers to show economic trends. Although the same things could be shown with columns of figures, the line on a graph puts the idea over much better. It is hard to visualize trends or patterns from a column of figures, but a line on a graph lays the pattern out in front of you in a way that is easy to grasp.

USING GRAPHS

The most common type of graph is drawn on paper ruled with uniformly spaced horizontal and vertical lines. This type of paper is known as ***rectilinear*** or ***cross section*** or just plain graph paper. Cross-sectional paper is available with many different line spacings, but 4, 5, 10, and 20 lines per inch are the most common.

The data for plotting graphs may be obtained by measurements of both quantities. Or the data may be obtained by repeated solutions of a formula. A graph with two plots obtained in the latter manner is shown in Fig. 36. This graph shows the voltage across a 75-ohm resistor and the power dissipated in it for different values of current.

Fig. 36 was plotted by assuming different values for the current and calculating the corresponding voltage drops and power dissipations using the formulas shown. Since the calculated values of voltage and power depend on the assumed values of the current, voltage and power are called the ***dependent variables***. The current could be given any desired value and changed at will, so current is called the ***independent variable***. Following custom, the dependent variable is scaled along the vertical axis, and the independent variable is scaled along the horizontal axis.

Several important things about graphs are illustrated here. Both scales are labeled to show the quantity they represent, and the units in which that quantity is measured. The values assigned to each division of the scales are marked along them. Note that the two scales are not equally divided; one division of the horizontal scale is equal to .05 units and one division on the vertical scale equals 5 units. Each plot is labeled with the

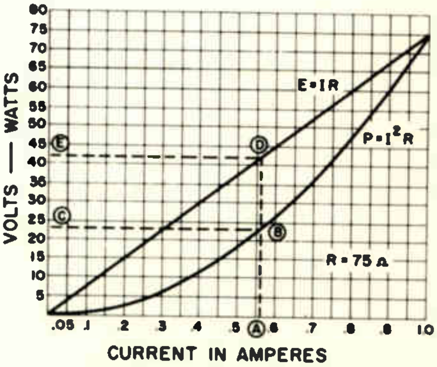

Fig. 36. Change in voltage across, and power in a 75-ohm resistor as current changes.

formula used to obtain the data. The formulas also serve as titles, telling what the graph shows. The value of the resistance used in the calculation completes the labeling. All the information needed to use or identify this graph appears upon it. Nothing is left to memory or imagination. Without this information no graph is complete.

Graphs like Fig. 36 are frequently made up to avoid repeated computations. For example, suppose you are checking the effect of changing tube voltages on the output of an amplifier. You are measuring the output with an ammeter in series with the 75-ohm load of the amplifier. In order to avoid making a very large number of calculations of voltage and power, you have constructed this graph. Now you can obtain the voltage and power for each value of current without having to work out each solution with pencil and paper.

The dashed lines on Fig. 36 show how the voltage and power for a current of .56 ampere would be read from the graph. Starting at .56 (point A) on the horizontal scale, trace upward to the intersection with the power curve (point B). Then trace over to the vertical scale and read 23 watts at point C. The .56 line intersects the voltage line at D. Tracing over to the vertical scale from D gives 42 volts at point E. The same graph could be used to determine the current for a specific power. You would simply reverse the procedure and start at the required power on the vertical scale. Then trace over to the power curve and down to the horizontal scale to read current.

It actually takes longer to tell how to read values from a graph than it takes to do it. The dashed lines which were drawn on Fig. 36 are not necessary in practice. They were used here only to demonstrate the procedure. With a little practice you will find that you can do the reading right at the curve without tracing to the scales. Try to determine the voltage drop and the power dissipation for the following currents: .72, .23, .07, and .48. What current is necessary for 60 watts, 36 watts, 7 watts, and 53 watts? Remember when reading the scale of a graph that, since an estimate is involved, all the rules for significant figures apply. You can check your readings by using the formulas to calculate the values.

Slope. One look at a graph can tell you a great deal about the way the dependent variable changes with changes in the independent variable. You have only to glance at Fig. 36 to know that voltage drop and power dissipation do not change in the same way with changes in current. The graph of voltage against current is a straight line. The increase in voltage for a given increase in current is the same at every point on the line. An increase of .1 ampere always produces an increase of 7.5 volts; an increase of .2 ampere always produces an increase of 15 volts. These relationships hold true no matter what value the current has at the start.

A special name is given to the rate at which the dependent variable changes with changes in the independent variable. This rate of change is called the slope. The slope is determined by dividing the span of the dependent variable over a section of the line by the span of the independent variable over the same section. Two examples of slope calculation are shown in Fig. 37. The two lines on this graph are plots of voltage against current for two different values of resistance. The slope of the line, R = 75 ohms, was calculated for the section between point A (.53, 40) and point B (.80, 60). The span of current is equal to the scale

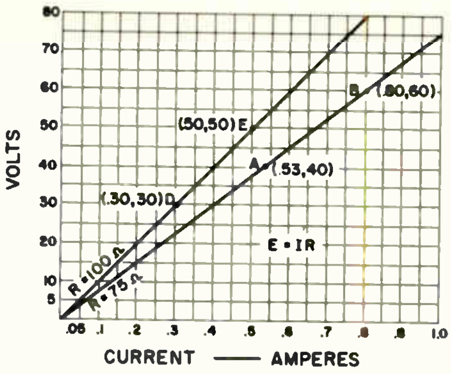

Fig. 37. Determining the slope of a line.

reading of B – A. The value of B (.80) minus the value of A (.53) is equal to .27 ampere. On the vertical scale, the reading of B is 60. We subtract the reading of A on the vertical scale (40) from B (60) to obtain the voltage span, which is 20. Dividing the voltage span by the current span gives 20 ÷ .27 = 75. The slope of the R = 75 ohms line is 75. The slope of the R = 100 ohms line is calculated between point D (.30, 30) and point E (.50, 50). The slope is (50 – 30) ÷ (.50 – .30) which works out to be 100.

You have undoubtedly already noticed that in both the examples of slope calculation the slope was numerically equal to the value of the resistance used in the formula which was plotted. Whenever the dependent variable is equal to the independent variable multiplied by a constant, the slope will always be equal to the constant. It is also true that the graph of the relationship will always be a straight line on rectilinear graph paper. Because the graph is a straight line, the relationship is said to be linear and the formula which expresses the relationship is called a linear equation.

The slope of a straight line is constant; that is, the slope is the same for all parts of the line. This is not true for all graphs. Unless the graph is a straight line on rectilinear paper, the slope will be different at different parts of the curve. In other words, the value of the slope depends on the value of the independent variable. Because the slope is continually changing, we must use a slightly different method to determine it. Fig. 38 shows how the slope of a curved line on a graph is obtained. First, it is necessary to draw a line tangent to the curve at the point at which the value of the slope is desired. (A tangent line is a line which touches the curve at only one point.) Three such tangent lines are shown on the curve. One is tangent at the point (.20, 3.0), another at (.40, 12), and the third at (.80, 48). The slope of the tangent line is determined by the same way as the slope of a straight line graph. The slope of the curve at the point where the tangent line touches it is the same as the slope of the line.

It is obvious that each of the three tangent lines has a different slope. It is also apparent that the slope is least when the current is least. As the current increases, the slope of the curve becomes greater. From a practical viewpoint this

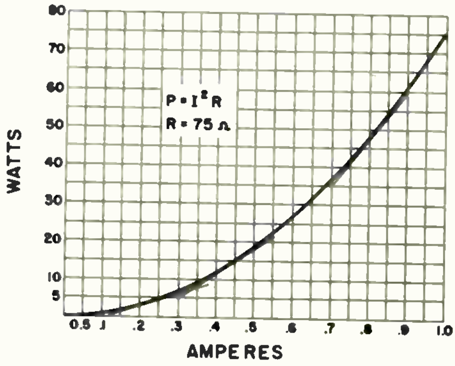

Fig. 38. Determining the slope of a nonlinear graph.

means that when the current is low, a small change in current results in only a small change in power, but when the current is large, a small change in current results in a large change in power. This type of curve will always result when the dependent variable is directly proportional to the square of the independent variable. Because the graph of the formula is not a straight line on rectilinear paper, the formula is said to be a nonlinear equation.

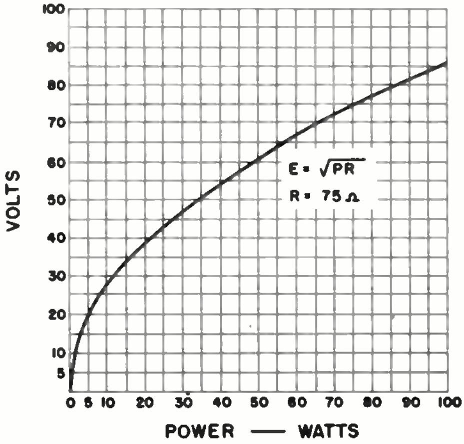

Fig. 39. Curve resulting when dependent variable is proportional to square root of independent variable.

Another common nonlinear curve results when the dependent variable is proportional to the square root of the independent variable. The curve of the formula $E = \sqrt{PR}$ for determining the voltage drop across a 75-ohm resistor for a given power dissipation is shown in Fig. 39. This curve has a high initial slope which decreases as the value of the independent variable becomes larger.

A third common nonlinear curve is shown in Fig. 40. This is the plot of current against resistance for a constant voltage drop.

The tangent to the curve at one point is also drawn in. Two points, A (2, 30) and B (8, 8) are marked on the tangent line and are used to determine the slope. In determining the span of the dependent variable, the value of the dependent variable at the point nearer the Y-Y′ axis is always subtracted from the value of the dependent variable at the farther point. Here we have

$$(8 - 30) \div (8 - 2) = \frac{-22}{6} = -3.66$$

This curve differs from the others you have studied in that it has a negative slope. The practical meaning of a negative slope is simply that the dependent variable becomes smaller as the independent variable becomes larger. The slope of this curve is greatest for small values of the independent variable, and least for high values. This curve shape and negative slope are characteristic of the graph of any equation in which the dependent variable is inversely proportional to the independent variable.

Each of the four types of formulas you are likely to use has its own characteristic graph curve. These curves show the way the dependent variable changes when the independent variable changes. The slope

of the curves gives a numerical value to the rate of change. Fig. 41 summarizes the four types of equations and their curves. In the equations, X stands for the independent variable, Y for the dependent variable, and M for the factor of proportionality. Remember the general characteristics of the curve of each equation; they are a big help in visualizing the relationship expressed in a formula.

TYPES OF GRAPH PAPER

Common rectilinear graph paper is best for showing the relationship between variables. However, it is not always the easiest type to use. An accurate graph of some formulas can be obtained only by plotting a large number of points. It is difficult to read values from a curve when the curve is nearly parallel to either the horizontal or vertical grid lines. The uncertainty of readings near the low end of either scale is much greater than the uncertainty near the high end.

The plotting and reading of graphs can be made much easier by using graph paper which has special scales. There are many special types of graph paper for use in science, engineering and business. Three of these types are common in electronics.

Logarithmic. Most of the disadvantages of rectilinear paper can be overcome by plotting the logarithms of the variables instead of the variables themselves. To avoid having to look up the logarithms of every number, a special type of graph paper is used. The scales on this paper are laid out so that the distance of each number from the lower left corner is proportional to the logarithm of the number. Fig. 42 shows rectilinear and logarithmic scales side by side for comparison. The numbers on the rectilinear scale are ten times the logarithm of the numbers opposite them on the logarithmic scale. Notice in particular that there is no "0" on the logarithmic scale. There is no logarithm for zero.

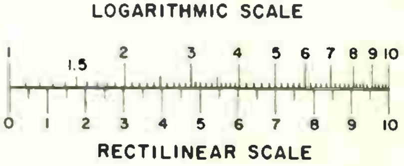

Fig. 42. Comparison of linear and logarithmic scales.

In order to extend the scale from 10 to 100, it is necessary only to repeat the 1 to 10 scale to the right of the 10. For numbers less than 1, it would be necessary to add additional 1 to 10 scales to the left of 1. Each complete 1 to 10 scale along an axis is called a cycle. Logarithmic graph paper is described by the

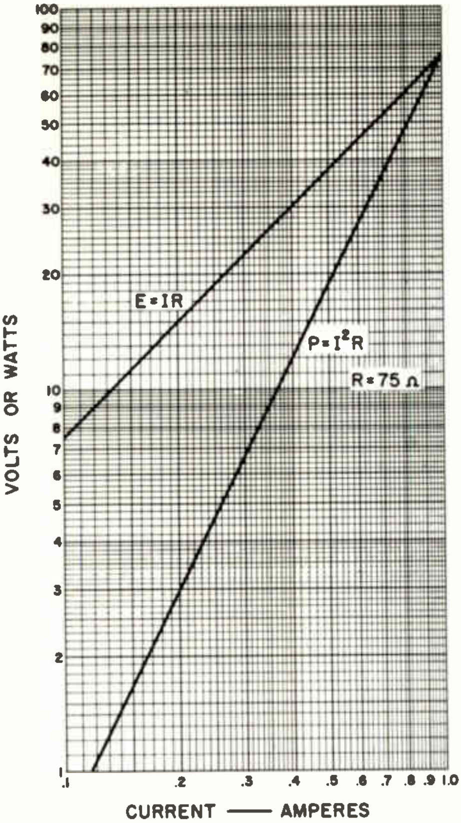

Fig. 43. Power against current and voltage against current plotted on logarithmic paper.

number of cycles along the horizontal and vertical scales. The chart on which Fig. 43 is drawn is called a "1 X 2 cycle."

One big advantage of logarithmic graph paper is that the uncertainty in reading numbers from the scale is the same at both ends of a cycle. The low end of the cycle can be read to three significant figures; the upper end of the cycle can be read to two significant figures. In both cases the uncertainty is about 1 part in 100. This is very important when a graph is used as an aid to computation.

Another advantage of logarithmic scales is shown in Fig. 43. The two lines on this graph are plots of the same relationships that gave one straight line and one curved line in Fig. 36. Both the voltage and the power plots are straight lines on this type of paper. In fact, all four of the typical equations in Fig. 41 are straight lines when plotted on logarithmic paper. This greatly simplifies the work of plotting. No more than three points need be calculated. (Actually two points are enough; the third is just a check.)

Although it is much easier to plot and read values from graphs on logarithmic paper, these plots have two big disadvantages. They do not show the exact manner in which changes in one variable affect the value of the other variable. Furthermore, you cannot determine the slope except in the case of the linear equation ($y = mx$).

A second disadvantage is the fact that there is no zero on the scales. On the 1 X 2 cycle paper used here, currents below .1 ampere, voltage drops below 7.5 volts, and powers below 1 watt do not show. If these lines had been plotted on 2 X 3 cycle paper, the lowest values would have been .01 ampere, .75 volt, and .1 watt. However, no matter how many cycles were used, zero would not appear.

Semilogarithmic Paper. Another type of special graph paper has a logarithmic scale on one axis and a linear scale on the other. The logarithmic scale may have from 1 to 5 cycles; the linear scale may have any convenient number of lines. The most common are 10 or 20 lines to the inch. One use for this type of paper is to obtain a straight line plot of an equation in which one variable is proportional to the logarithm of the other. Another use is where a large range of numbers must be covered on one scale. A linear scale would not show details on the low end, whereas a logarithmic scale would open up the

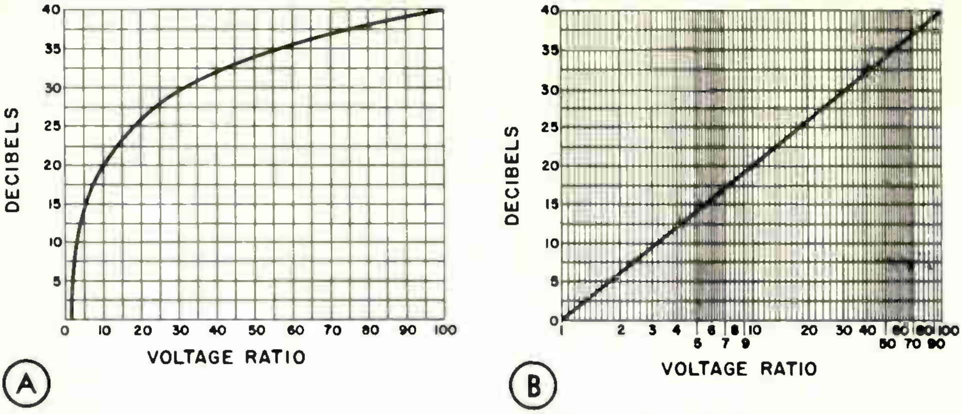

Fig. 44. Plots of voltage against decibels: (A) rectilinear; (B) semilogarithmic.

low end and make all parts equally readable.

Two plots of a logarithmic relationship between variables are shown in Fig. 44. Fig. 44A shows the plot of voltage ratio against decibels on rectilinear paper. At least 20 points must be calculated and marked to get a smooth plot. Even then the graph is very difficult to read below 15 on the voltage ratio scale. Fig. 44B shows the same relationship plotted on semilogarithmic paper. It can be drawn with only three calculations, and can be read with equal ease on all parts of the line.

Polar Graphs. A third type of special graph paper is laid out in polar coordinates. Points are located by means of radial lines marked in degrees and a series of circles with common centers which show the distance along the radials. This paper is used when you want to show the radiation patterns of antennas, loudspeakers, light sources, and other forms of energy transmitters. A polar plot is used for this type of graph since it gives a pattern of direction in space that is immediately apparent. Fig. 45 is an example of a graph plotted on polar coordinate paper. The graph shows the radiation pattern of an ideal quarter-wavelength antenna in free space. The distance of the points along the radials is proportional to the field strength in percent of the field strength in the direction of maximum radiation.

38. $R = 55$ ohms; $X_L = 437$ ohms. First find the dc resistance of the coil:

$$R = \frac{E}{I} = \frac{110 \text{ volts}}{2 \text{ amps}} = 55 \text{ ohms}$$

This means that a 55-ohm resistor is in series with a perfect coil. We can find the impedance of the coil when connected to ac by:

$$Z = \frac{E}{I} = \frac{110 \text{ volts}}{.25 \text{ amps}} = 440 \text{ ohms}$$

Now we know the impedance and the resistance in the circuit. This is equivalent to a right triangle in which the hypotenuse and the side adjacent to the angle θ are known. Now find angle θ:

$$\cos\theta = \frac{\text{adj}}{\text{hyp}} = \frac{R}{Z} = \frac{55}{440} = .1250$$

And, since a leading power factor is required, the angle must be −45°. Therefore, at 60 Hertz the X_C of the capacitor must be large enough to cancel the 20-ohm X_L and still have enough reactance left over to shift the current 45° ahead of the voltage. We have seen that a 45° shift occurs when $R = X$. Therefore, the X_C of the capacitor must be $R + X_L$ or 40 ohms. Thus,

$$C = \frac{.159}{fX_c} = \frac{.159}{60(40)} = \frac{.159}{2400} = .0000663$$

$$C = 66.3 \text{ mfd}$$

41. 553 watts. First find the current through Z_b.

$$I_b = \frac{E}{Z_b} = \frac{220}{71\,\underline{/-36^\circ}} = 3.1\,\underline{/36^\circ} \text{ amps}$$

Now find the apparent power of Z_b:

$$P_a = E_T I_b = 682 \text{ watts}$$

Since $P = P_a(\text{PF})$ and $\text{PF} = \cos\theta$, then:

$$P = P_a(\cos \theta)$$
$$P = 682(\cos 36^\circ)$$
$$P = 682(.809)$$
$$P = 553 \text{ watts}$$

42. $891\,\underline{/77.2^\circ}$ ohms. First find X_L and X_C.

$$X_L = 904 \text{ ohms}$$
$$X_C = 883 \text{ ohms}$$

Now find the overall impedance of the two parallel branches. To do this you must first find the impedance (Z_{RC}) of R_2 and C in series.

$$\tan \theta = \frac{\text{opp}}{\text{adj}} = \frac{XC}{R_2} = \frac{883}{250} = 3.5320$$

$$\theta = -74.2^\circ$$

$$\sin \theta = \frac{\text{opp}}{\text{hyp}}$$

$$\text{hyp} = \frac{\text{opp}}{\sin \theta}$$

$$Z_{RC} = \frac{X_C}{\sin 74.2^\circ} = \frac{883}{.9618} = 920$$

$$= 920\,\underline{/-74.2^\circ}$$

Next, assume a voltage across the two parallel branches to establish a current.

$$I_{RC} = \frac{100\,\underline{/0^\circ} \text{ volts (assumed)}}{920\,\underline{/-74.2^\circ} \text{ ohms}}$$

$$= .11\,\underline{/74.2^\circ} \text{ amps}$$

$$I_{R3} = \frac{100 \text{ volts}}{200 \text{ ohms}} = .5 \text{ amp}$$

Then convert the two currents to j-operator form so that they can be added.

$$I_{RC} = I_{RC}(\cos \theta + j \sin \theta)$$
$$I_{RC} = .11\,(.2720 + j.9618)$$
$$I_{RC} = .03 + j.106$$

And since the other branch contains only R_3:

$$I_{R3} = .50 + j0$$

Now add the two currents to find the total current:

$$I_T = I_{RC} + I_{R3}$$
$$= (.03 + j.106) + (.50 + j0)$$
$$I_T = .53 + j.106$$

Next convert I_T to polar form:

$$\tan \theta = \frac{\text{opp}}{\text{adj}} = \frac{.106}{.53} = .2000$$

$$\theta = 11.3^\circ$$

$$\sin \theta = \frac{\text{opp}}{\text{hyp}}$$

$$\text{hyp} = \frac{\text{opp}}{\sin \theta} = \frac{.106}{.1929} = .55$$

$$I_T = .55\,\underline{/11.3^\circ}$$

Thus the overall impedances of the parallel branches can now be found:

$$Z_p = \frac{E \text{ (assumed)}}{I_T} = \frac{100\,\underline{/0^\circ}}{.55\,\underline{/11.3^\circ}}$$

$$Z_p = 182\,\underline{/-11.3^\circ} \text{ ohms}$$

Then convert Z_p to j-operator form so that it can be added to the series impedance:

$Z_p = Z_p\ (\cos\theta - j\sin\theta)$
$Z_p = 182\ (.9805 - j.1929)$
$Z_p = 178 - j35$

Now add Z_p to the series impedance of R_1 and L_1.

$Z_T = 20 + j904 + 178 - j35$
$Z_T = 198 + j869$

Finally, convert to polar form:

$$\tan\theta = \frac{\text{opp}}{\text{adj}} = \frac{X}{R} = \frac{869}{198} = 4.3889$$

$$\theta = 77.2^\circ$$

$$\sin\theta = \frac{\text{opp}}{\text{hyp}}$$

$$\text{hyp} = \frac{\text{opp}}{\sin\theta}$$

$$Z = \frac{X}{\sin 77.2^\circ}$$

$$= \frac{869}{.9751}$$

$$= 891\underline{/77.2^\circ}$$

43. $75\underline{/-48^\circ}$ ohms. First find the reactances of the capacitors and coils.

$X_{C_1} = 67.7$ ohms

$X_{C_2} = 145$ ohms

$X_{L_1} = 62.8$ ohms

$X_{L_2} = 94.2$ ohms

$Z = 50 - j67.7 - j145$
$\quad + j62.8 + j94.2$

$Z = 50 - j55.7$ ohms

$$\tan = \frac{-55.7}{50} = -1.11$$

$$\theta = -48.0^\circ$$

$$\sin\theta = \frac{X}{Z}$$

$$Z = \frac{X}{\sin\theta}$$

$$Z = \frac{-55.7}{\sin -48^\circ}$$

$$Z = \frac{-55.7}{-.7431} = 75 \text{ ohms}$$

44. $1.33\underline{/48^\circ}$ amps

$$I = \frac{E}{Z}$$

$$I = \frac{100/0^\circ}{75\underline{/-48^\circ}}$$

$$I = 1.33\underline{/48^\circ} \text{ amps}$$

45. 89 watts.

$P = P_a\ (PF)$
$P_a = E_T I = 100 \times 1.33 = 133$ watts
$PF = \cos\theta = \cos 48^\circ = .6691$
$P = 133\ (.6691)$
$P = 89$ watts

46. 89 watts. R_1 is the only component which can dissipate power. Therefore, it dissipates the entire 89 watts.

You can arrive at this conclusion by:

$P = I^2 R = (1.33)^2 \ (50) = 89$ watts

47. The slope of a line is the rate at which the dependent variable changes with changes in the independent variable.
48. The slope of a curved line can be determined by drawing a line tangent to the curve at the point of interest and calculating the slope of the tangent line.
49. Both the horizontal and vertical scales are logarithmic on logarithmic graph paper. On the other hand, semilogarithmic paper has a logarithmic scale on one axis and a linear scale on the other.
50. Polar graph paper is useful for plotting the radiation patterns of antennas, loudspeakers, and light sources.

Lesson Questions

Be sure to number your Answer Sheet X206.

Place your Student Number on every Answer Sheet.

Most students want to know their grades as soon as possible, so they mail their set of answers immediately. Others, knowing they will finish the next lesson within a few days, send in two sets of answers at a time. Either practice is acceptable to us. However, don't hold your answers too long; you may lose them. Don't hold answers to send in more than two sets at a time or you may run out of lessons before new ones can reach you.

1. Give the sines of the following angles: 23°, -47.5°, 290°, 163°, 215°.

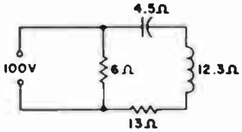
2. Convert $12 + j10.8$ to polar coordinates.

3. Convert $30\underline{/-50.5^\circ}$ to rectangular coordinates.

4. What are the power factors of circuits having the following impedances: $67.1\underline{/68^\circ}$; $123\underline{/-84^\circ}$; $.015\underline{/72^\circ}$; $1.49\underline{/60^\circ}$; $15.1 - j7.7$?

5. What is the impedance in polar coordinates at 60 Hertz of the circuit at the right?

6. What is the current through the circuit at the right? Give your answer in polar form.



7. What is the power dissipated in the circuit at the right?

8. Express as exponential numbers: 57 pf, 10 megohms, .16 microsecond, 26.7K ohms, 4503 kHz.

9. Solve the following problem and express your answer as an exponential number with the correct number of significant figures:

$$\frac{.0073(14.689 - 3.2)}{569} \times \frac{117 \times 9.64}{.00857}$$

10. Sketch graphs, as in Fig. 44, for capacitive reactance with capacity as the independent variable, and inductive reactance with inductance as the independent variable. Label the axes.

CONFIDENCE

Whatever project you undertake, *confidence* in yourself, and in your ability, will make the job easier.

By *confidence*, I do not mean "cockiness," and I most certainly do not refer to *fake confidence* which is simply "bluffing."

I'm speaking of the *confidence* which comes only from a thorough understanding of your work – and a genuine desire to do a good job.

This kind of *confidence* is felt by the people with whom you associate. It *causes them to have confidence in you* – to rely upon your judgment – and to entrust important work to your care.

Successful businesses – important jobs – are managed by men with *confidence* in their ability and desire to do a good job.
