CLASS C RF POWER AMPLIFIERS

A radio transmitter is a device for converting some form of intelligence into electrical impulses suitable for transmission through space. In its simplest form, a transmitter consists of a source of rf energy, called the master oscillator, and one or more stages of rf power amplification.

In practical transmitters, such as the one shown in block diagram form in Fig. 1, there are a number of stages between the master oscillator and the antenna. Since each stage is a form of rf power amplifier, let's briefly discuss the particular role each one plays in the overall operation of the transmitter.

Immediately following the master oscillator is a stage called the buffer amplifier. Its purpose is to present a light constant load to the oscillator, which helps maintain a stable oscillator frequency. The FCC requires that very close control of output frequency be maintained on all radio transmitters under its jurisdiction.

The next stage, called a frequency multiplier, produces an output whose frequency is some multiple of the input frequency. The presence of this stage permits the master oscillator to be operated at a frequency lower than the transmitted frequency. It is much easier to design highly stable oscillator circuits at the lower radio frequencies; therefore, one or more frequency multiplier stages are an essential part of most radio transmitters.

The driver and power output stages provide the remaining amplification necessary to supply power to the antenna. This output power may range from less than 100 watts to 1 million watts, depending on the transmitter type and the purpose for which it is to be used. In recent years low power circuits, which formerly used vacuum tubes, have been

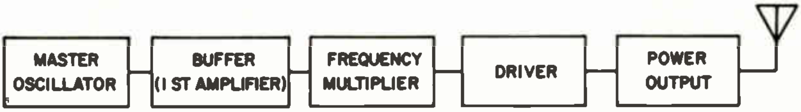

Fig. 1. Block diagram of a basic transmitter. All the stages are operated class C.

redesigned to use economical, efficient transistors. In many low to medium power mobile transmitters, transistors are used in all stages delivering as much as 75 watts of rf output power at 175 MHz. In other transmitters, all but the driver and final amplifier (power output) stages have been replaced by transistors. There is every reason to suppose that this trend will continue as the high-frequency power handling capability of transistors is improved.

The vacuum tube, however, is still used in high power stages of transmitters which are employed in the AM, TV and FM broadcast fields. It will no doubt remain so for quite some time to come. Very large vacuum tubes are required to handle the enormous power outputs of these transmitters. There are three characteristics of all rf power amplifiers, transistors or vacuum tubes which are of concern to us. They are linearity, power gain, and efficiency.

The linearity of an amplifier is a measure of how closely the amplified output follows the input; in other words, a measure of how much distortion is introduced into the output signal by the amplifier. Linear amplifiers, which introduce very little distortion into the signals they amplify, are a subject in themselves and will be considered in a later lesson.

The power gain of an amplifier, usually expressed in db, tells us how much the power level of the input signal is increased by the amplifier. Power gain depends on circuit design and the tube or transistor type used in the circuit. Beam power tetrodes have the highest power gain of any other conventional vacuum tube type. For this, as well as other reasons, the beam power tetrode is the most commonly used tube in modern transmitters. The power gain of transistors does not compare favorably with that of vacuum tubes at higher radio frequencies. This limitation may be partially overcome by adding more stages or using more than one transistor in each stage.

The efficiency of an amplifier, expressed as a percentage, is the amount of dc input power to the stage actually converted to rf energy at the output. In a vacuum tube stage, the power input is the product of the plate supply voltage times the average current. For example, suppose the plate supply voltage is 3000 volts, the plate current 450 milliamps, and the power output of the stage 1000 watts. The dc input power to the stage is:

$$P = E \times I$$

$$P = 3000 \times .45 = 1350 \text{ watts}$$

The efficiency of the stage can then be found by using the following formula:

$$\%\ \text{Efficiency} = \frac{\text{Power Out}}{\text{Power In}} \times 100$$

$$\%\ \text{Efficiency} = \frac{1000}{1350} \times 100 = 74\%$$

In a previous lesson, you learned that class C amplifiers give the highest practical efficiency, ranging up to 75%. This is compared to efficiencies of 35% to 50% for class B and as little as 30% to 35% for class A. However, the high efficiency of class C amplifiers is obtained at the expense of linearity. As you'll remember, output current flows for less than half the input cycle in a class C amplifier. This output current pulse bears little resemblance to the input signal which produced it and is therefore highly distorted.

If the output circuit of the class C amplifier is a resonant tank, this current pulse shock-excites the tank so that a complete sine wave is produced. Thus the nonlinearity of the class C amplifier is effectively eliminated when a single rf frequency (a sine wave) is to be amplified. This, along with the class C amplifier's high efficiency, makes it suitable to many rf power amplifier applications.

In the next section we'll discuss class C rf amplifier fundamentals. The information presented in this section applies to both vacuum tubes and transistors. Later, we'll discuss specific applications of vacuum tube and transistor amplifiers. In the final section, we'll talk about the various adjustments which may be made to both types of amplifier circuits.

RF Power Amplifier Fundamentals

In any amplifier, heat is generated by the current flow through the internal resistance of the stage. The power used to generate this heat represents wasted energy and subtracts from the power that could go to the output. The high efficiency of a class C amplifier is due largely to the fact that current flows for a relatively short portion of the input cycle. It is only during this short conducting period that power-wasting heat is generated within the amplifier. To begin our discussion of class C amplifiers, we'll consider the relationships between the current conducting time and the signal voltage waveforms in an operating class C amplifier.

CURRENT AND VOLTAGE RELATIONSHIPS

The graph in Fig. 2 shows the output current pulse produced by an input signal at various dc bias levels. Look first at the signal at bias level 1. This signal is below the cutoff value of the amplifier for all of the negative half-cycle and nearly all of the positive half-cycle. Output current flows only for the time the input voltage goes above cutoff. Now look at the signal at bias level 2. It has the same amplitude as the first signal but, because we've increased the bias, this signal exceeds the cutoff level for a shorter period. As a result, the output current pulse produced

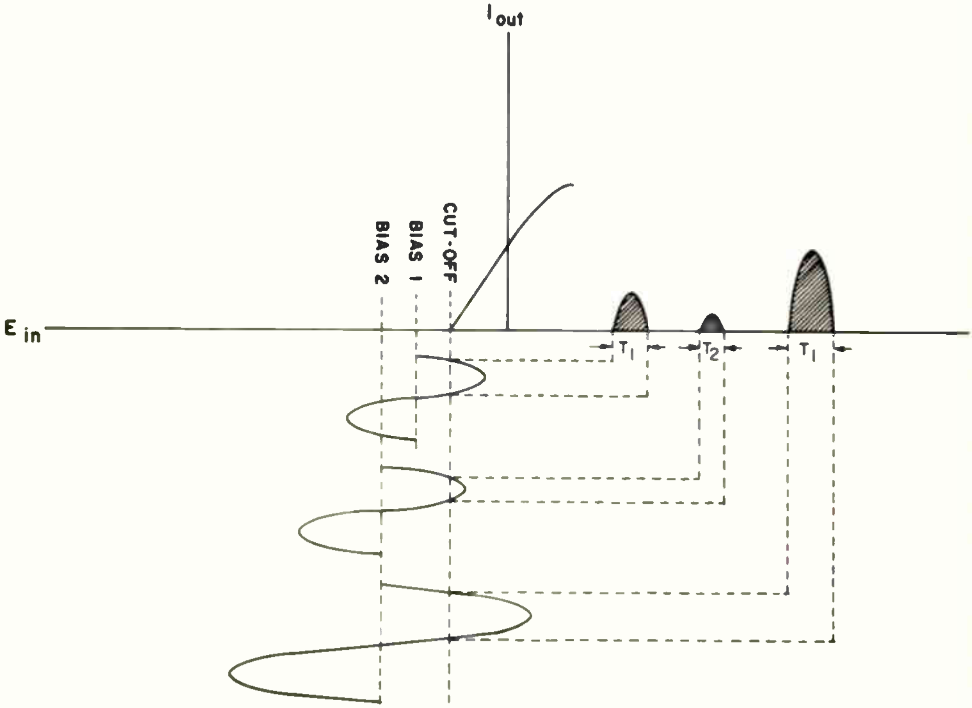

Fig. 2. Output current pulse produced by input signals at various amplitudes and bias levels.

also flows for a shorter period and is lower in amplitude. Increasing the amplitude of the input voltage has the same effect as decreasing the bias. That is, the output current flows for a longer time.

Another way of looking at these basic relationships is shown in Fig. 3. Fig. 3A shows two basic class C amplifiers; one uses a vacuum tube, the other a transistor. Fig. 3B shows the voltage and current waveforms appearing at the inputs and outputs of the amplifiers. Again notice that output current flows only during the period when the input signal exceeds the cutoff level of the amplifier. The output voltage waveform E_{out} is produced by the flywheel action of the resonant output circuit.

Conduction Angle. There are 360 electrical degrees in one complete cycle of a sine wave. The number of electrical degrees the output current flows in a class C amplifier is called the conduction angle or operating angle of the stage. As you've seen, the operating angle depends on both the dc bias and the amplitude of the driving signal. Although amplifier efficiency is higher at the smaller operating angles, the power output is less because the output current pulse is reduced in amplitude and flows for a shorter period. Therefore, the operating angle must be a compromise between maximum efficiency and the highest power output. In making this compromise, the driving signal is maintained at a level sufficient to drive the stage into saturation while the bias is adjusted for the correct operating angle.

Driving Power. To drive a vacuum tube amplifier into saturation requires that the grid be driven positive. The positive grid

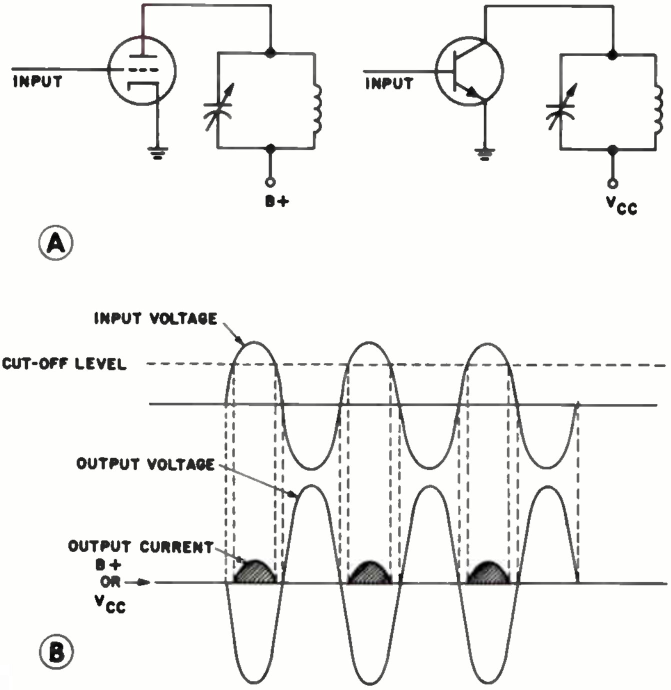

Fig. 3. Basic relationships between current and signal voltages in a class C amplifier.

draws current, causing power to be consumed in the grid circuit. Likewise, in a transistor amplifier, base current flows during the time the driving signal forward-biases the emitter-base junction. The result of this base current flow is that power is consumed in the base circuit.

The power consumed in the input circuit of a class C amplifier, called the driving power, must be supplied by the previous stage. Thus the input circuit of one class C amplifier represents the load on the stage which comes before it. Furthermore, this load presented by the input circuit varies over the period of an operating cycle, reaching a maximum when the input signal causes maximum current to be drawn. As we'll see later, we can use this current flow in the input circuit to develop bias for the stage.

TANK CIRCUITS

The resonant circuit in the output of a class C amplifier has several important jobs to do. We've already mentioned the most basic of these, that of changing the output current pulse into a complete sine wave. This resonant circuit is also required to present the proper load impedance to the stage, and to suppress the undesired harmonics generated within the stage. Let's discuss these last two in detail.

Load Impedance. In order to obtain the maximum power gain from a class C amplifier, or any other amplifier for that matter, the impedance of the load must match the internal impedance of the amplifier. However, do not confuse power gain with power output. It is quite possible that an amplifier operating with a matched load, for maximum power gain, is not delivering its maximum output power.

This is especially true for transistor rf power amplifiers. These amplifiers are very often designed to operate from automotive type battery supplies, thus limiting collector supply voltages to the 12 to 28 volt range. With the load matched to the internal impedance of the amplifier, there may be insufficient collector current flow to give the required power output. Using a value of load resistance lower than the input impedance of the stage results in a greater collector current flow and higher power output. Therefore, in some cases power gain must be sacrificed for power output.

Factors Affecting Impedance. Since the output tank circuit must offer the correct load impedance for the class C amplifier, let's look at some of the factors which affect this impedance. We know that to be resonant, the L and the C of the tank circuit must offer equal reactances at the operating frequency. If we increase the value of L, the value of X_L will increase. To maintain resonance, we must increase X_C by decreasing C. Having increased the value of X_L and X_C by equal amounts, we have increased the total impedance of the circuit without affecting the resonant frequency.

Any resistance present in the tank acts to decrease the total impedance of the circuit. The values of C, L, and R are related to total impedance by the following formula:

$$Z = \frac{L}{CR}$$

From the formula, you can see that increasing the ratio of L to C in the tank causes the impedance to increase. Increasing the resistance in the tank causes impedance to decrease. This leads us to a discussion of tank circuit Q.

Circuit Q. The Q of a coil, as you know, is the ratio of its reactance to its resistance or:

$$Q = \frac{X_L}{R}$$

A capacitor also has a Q, but its value is very large due to the capacitor's low internal resistance. The Q of a tank circuit, therefore, is equal to the Q of the coil.

Fig. 4 shows an amplifier with a parallel-tuned tank circuit in its output. At the operating frequency of this amplifier, let's assume the X_L of the coil is 6000 ohms and its resistance (R_S) is 20 ohms. The Q of this unloaded tank circuit then is:

$$Q = \frac{X_L}{R_S} = \frac{6000}{20} = 300$$

The Q of unloaded tank circuits in practical transmitters may range from 200 to 800. Fig. 5A shows the same amplifier of Fig. 4 inductively coupled to a load. This load might be a transmission line, an antenna, or another rf amplifier. The effect of this load is to reflect an additional resistance into the tank circuit. The equivalent circuit, shown in Fig. 5B, contains this reflected resistance ($R_L{}'$) in series with the resistance of the coil. The exact value of $R_L{}'$ depends on the value of the load resistance as well as the coupling to the load. We'll assume a value of 380 ohms for our discussion. The Q of the tank now becomes:

$$Q = \frac{X_L}{R_L{}' + R_S} = \frac{6000}{400} = 15$$

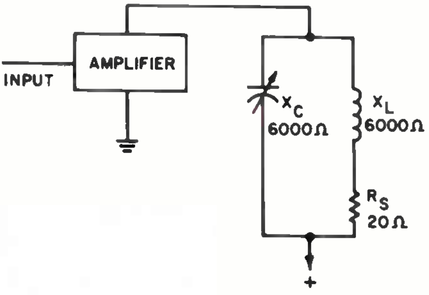

Fig. 4. Amplifier with a parallel tuned output tank showing impedances at resonance.

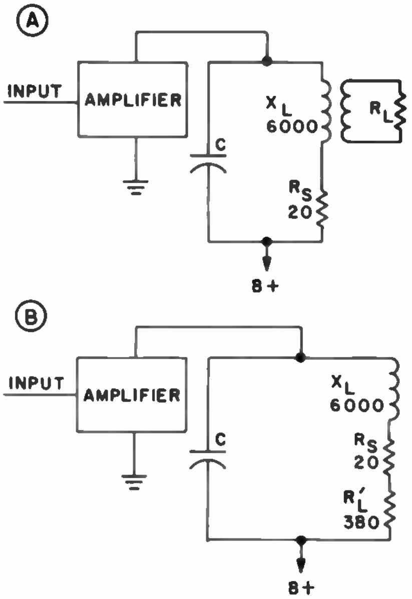

Fig. 5. Tank circuit coupled to a load and its equivalent circuit.

Thus, the Q of the tank circuit went from an unloaded value of 300 to the loaded value of 15 due to the resistance reflected into the tank circuit by the load. From the previous discussion of tank impedance, you know that this additional resistance in the tank also decreases the impedance of the tank. Tank Q and tank impedance are closely related quantities. Factors which change one will also change the other in the same direction.

Let's see now why this is important.

You know that only the resistance in a circuit consumes power. Inductive and capacitive reactances, under conditions of resonance, merely transfer energy back and forth between themselves. Therefore, when the tank is loaded, all of the power in the circuit is consumed by the resistances R_S and R_L'. The power consumed in R_L' represents power consumed by the load, while that consumed by R_S is dissipated as heat in the tank circuit. From Ohm's Law we derive that $P = I^2 R$, so the power consumed by the load far exceeds that lost as heat in the tank. This is because of a larger value of R_L'. We can actually calculate the efficiency of the tank circuit by the formula:

$$E_{ff} = \left(1 - \frac{Q_L}{Q_U}\right) \times 100$$

In our example, the unloaded Q (Q_U) was 300, and the loaded Q (Q_L) was 15. Therefore:

$$E_{ff} = \left(1 - \frac{15}{300}\right) \times 100$$

$$E_{ff} = (1 - .05) \times 100 = 95\%$$

Suppose we increased the coupling to the load and reflected a larger value of resistance into the tank. This would decrease Q_L without affecting Q_U, resulting in a higher tank circuit efficiency. But remember, tank impedance is dependent on the resistance in the tank, so changing the coupling to the load changes the tank impedance. Since the stage is designed for best operation at a particular tank impedance, there is only one correct value of loading on the tank.

Reducing Harmonics. The output pulse of a class C amplifier contains, in addition to the fundamental, numerous harmonic frequency components. As you'll learn later in this lesson, this fact enables us to operate a class C stage as a frequency multiplier. The output tank circuit offers maximum impedance at the frequency to which it is tuned. Harmonic frequencies, seeing a relatively lower impedance, are not developed across the tank circuit in any great magnitude. The circuit which couples the tank to its load is usually designed with harmonic suppression in mind. Sometimes, special traps must be used in output coupling networks which either shunt the harmonics to ground or block their passage to the antenna.

An additional precaution against harmonic radiation is to use an electrostatic shield between two inductively coupled circuits. A shield of this type, called a Faraday screen, is shown in Fig. 6.

The Faraday screen consists of a number of wires fastened together at one end and open at the other. The ends of the wires that are connected together are grounded. Capacitively coupled harmonic currents will flow to the screen wires rather than to the pickup coil. At the

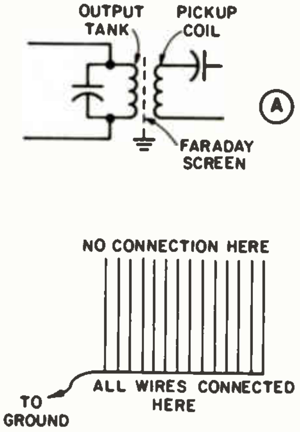

Fig. 6. An electrostatic shield or Faraday screen between the output tank and the antenna pick-up coil is used to prevent harmonic currents from flowing through the capacity between the coils.

same time, because the wires do not form closed circuits, there can be no voltage induced in them by the magnetic field. Therefore, they do not interfere with the inductive coupling between the output tank and the link coil. This method is very effective in reducing the transmission of harmonics from an output tank circuit to an antenna or transmission line.

COUPLING METHODS

The resonant tank in the output of a class C amplifier forms the basis of the coupling circuit to the amplifier's load. We know that the impedance presented to the stage by the output tank circuit depends, to a large measure, on the equivalent resistance in the tank. We also know that the value of this equivalent resistance is primarily that reflected into the tank by the load. To obtain the correct tank impedance for the amplifier, the coupling must reflect a certain value of resistance into the tank. In most cases, the actual value of the load resistance connected directly across the tank would not reflect the correct resistance into the tank. Therefore, the coupling method must give an impedance transformation. The simplest way to accomplish this impedance transformation is to use a transformer as a method of inductive coupling.

Inductive Coupling. Fig. 7 shows two amplifier stages inductively coupled together. In this circuit, the resistance reflected into the output tank for amplifier 1 is adjusted by varying the spacing between the coils. Varying this spacing also adjusts the drive to amplifier 2. The circuit is designed to reflect the correct resistance and provide the proper drive at the same setting.

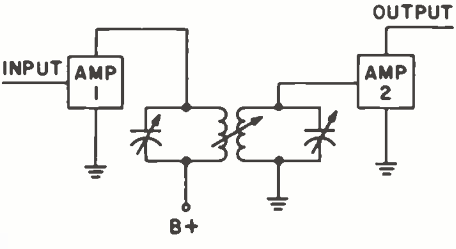

Fig. 7. Inductive coupled amplifiers.

A variation of inductive coupling is shown in Fig. 8. This method is called link coupling. It consists of a coil with only a few turns of wire inductively coupled to an output tank. A similar coil is inductively coupled to the load. The connection between the two coils is usually by means of shielded coaxial cable, so it may run some distance with very little loss. Link coupling may also be used between the final power amplifier in a transmitter and a low impedance transmission line. As in the conventional inductive coupling already discussed, the coupling is adjusted by varying the spacing between one of the link coils and the tank. Sometimes the link itself is tuned by a variable reactance. When this is done, the tuned link provides additional suppression of harmonics generated in the previous stages.

Notice that the method of applying B+ to the stage in Fig. 8 differs from that of Fig. 7. In Fig. 8, this voltage is applied through a radio frequency choke (rfc). The rfc offers a very high impedance at the operating frequency, so it keeps the signal voltage out of the power supply. When the power supply, the tank circuit, and the stage are connected in series, as in Fig. 7, the amplifier is said to be series-fed. When the power supply, tank circuit, and stage are in parallel (or shunt), as in Fig. 8, the amplifier is said to be shunt-fed.

Tapped Tank Circuits. Another

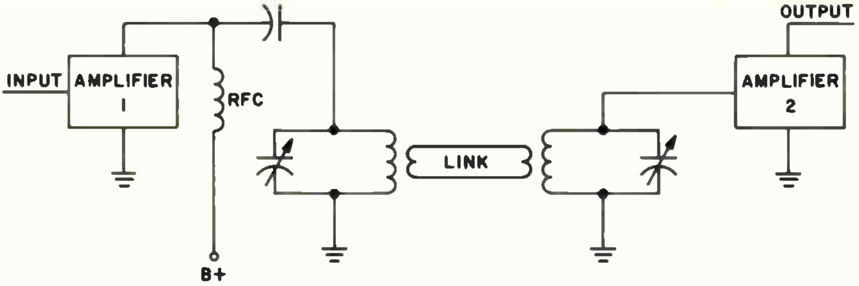

Fig. 8. Link coupled amplifiers.

method of obtaining an impedance transformation is to connect the load across only a portion of the tank coil. Such a method is shown in Fig. 9A. The value of resistance reflected into the tank is dependent on the position of the tap. In Fig. 9B, the tank capacitor is split to provide the impedance transformation. The values of C_1 and C_2 determine the value of load resistance seen by the tank (reflected resistance).

The methods shown in Figs. 9A and 9B may be combined as shown in Fig. 9C. With this circuit arrangement, the internal impedance of the stage, as seen by the tank, is transformed to a higher value by the tapped coil. Using this method the required value of loaded Q in the tank may be maintained in spite of low values of internal impedance (such as found in transistor stages). The values of C_1 and C_2, as before, determine the value of load resistance seen by the tank.

Network Coupling. Fig. 10 shows three types of networks frequently used to couple class C amplifiers to their loads. The various arms of each are shown as impedances in the figure. In practical networks of this type these impedances will be combinations of L and C components. Later on in your course you'll learn to calculate the reactance values for the arms of these networks to give a required impedance transformation. For now, it is enough for you to know

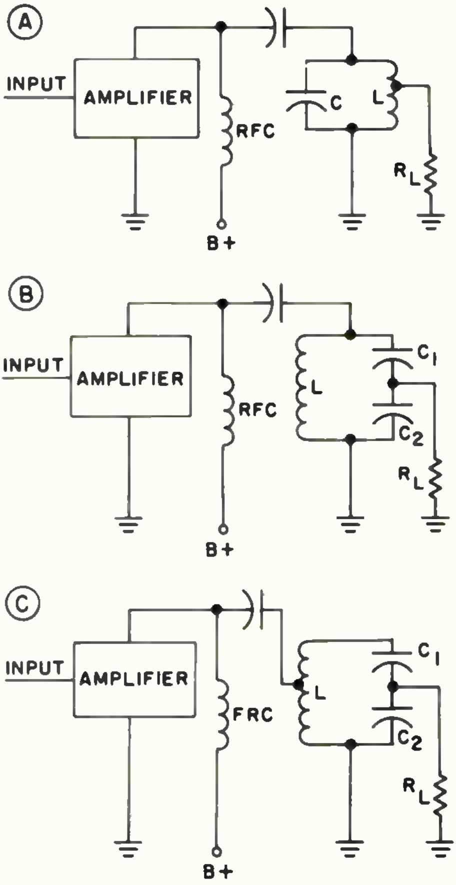

Fig. 9. Tapped tank circuits used for impedance transformation.

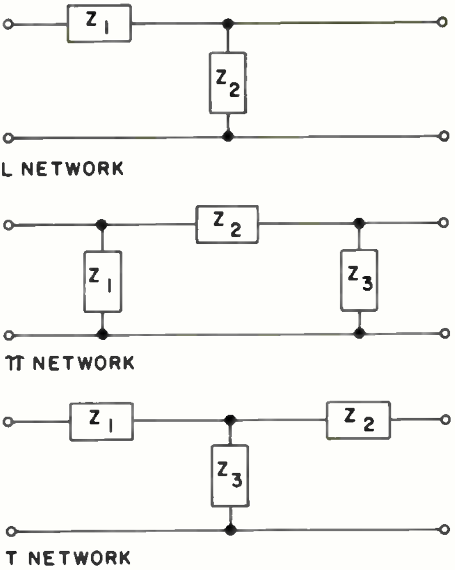

Fig. 10. Networks used to couple an amplifier to its load.

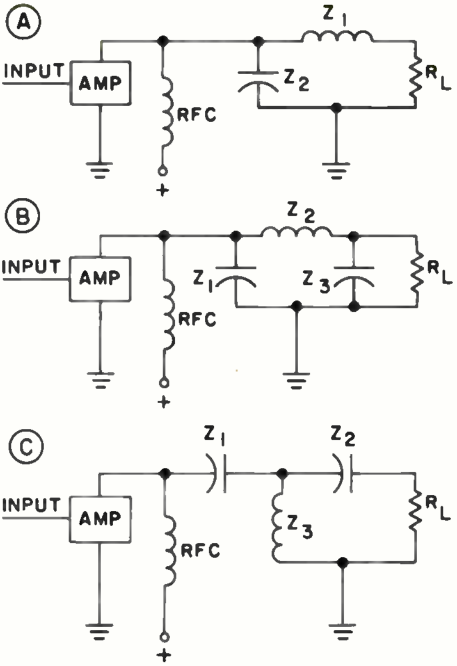

Fig. 11. Amplifiers using L, π, and T network coupling to load.

that they fulfill all the requirements of a tank circuit and can provide impedance transformations over a very wide range of values. In addition, these circuits can be easily designed to attenuate undesired harmonic frequencies.

Fig. 11 shows an example of how each of these networks (L, π, T) is used to couple an amplifier to its load. The network used in any particular application depends on the magnitude of the impedance levels to be transformed. The networks themselves may be coupled together in a variety of combinations to provide the proper load to the amplifier and greater harmonic attenuation. It is important to remember in the examples of this section that R_L may represent the input of another amplifier, a transmission line, or an antenna. The only difference between these three types of loads, as far as the amplifier is concerned, is the impedance level. An antenna or transmission line usually offers a lower impedance, and therefore a greater load, to an amplifier than the input circuit of another amplifier.

SELF-TEST QUESTIONS

(a) What is the primary reason class C amplifiers operate at higher efficiencies than class A or class B amplifiers?

(b) What two factors affect the operating angle of a class C amplifier?

(c) Is impedance matching between an amplifier and its load always desirable? Why?

(d) Suppose we wanted to increase the impedance of a parallel-tuned tank without changing the coupling or the resonant frequency. What components in the tank should be changed and in what direction?

(e) If the coupling to a tank is adjusted to increase the load on the tank, what would happen to the loaded Q? The unloaded Q? The efficiency of the tank?

(f) If the loaded Q of a tank decreases, what would happen to the tank impedance?

(g) How does the output tank circuit reduce the harmonics present in the output of a class C amplifier?

(h) How would you increase the coupling between two inductively coupled amplifiers?

(i) Is amplifier I (shown in Fig. 6) series-fed or shunt-fed?

(j) In a transistor rf power amplifier, the internal resistance of the stage is found to load the output tank so heavily that a high enough loaded Q cannot be obtained. If the amplifier is connected to the tank as shown in Fig. 6, what change could be made in the circuit to increase the loaded Q of the tank?

(k) Normally, which would more heavily load a class C amplifier: an antenna or another class C amplifier?

Vacuum Tube RF Power Amplifiers

Now that you have a basic understanding of rf power amplifiers, let's take a detailed look at some applications which use vacuum tubes. In the first section we'll discuss methods of obtaining the class C bias necessary to get the proper conduction angle from the amplifier. Then we'll look at some of the methods employed to insure stable amplifier operation. Finally, we'll take a look at some practical rf amplifier circuits, including frequency multipliers.

BIAS METHODS

Some typical class C bias methods are shown in Fig. 12. The three most common biasing methods are shown at A, B, and C.

External Bias. In Fig. 12A, the bias is obtained from an external bias supply and is coupled through an isolating rf choke to the grid of the stage. The rf choke acts as a high impedance and prevents the power supply circuit from acting as a shunt for the radio-frequency energy.

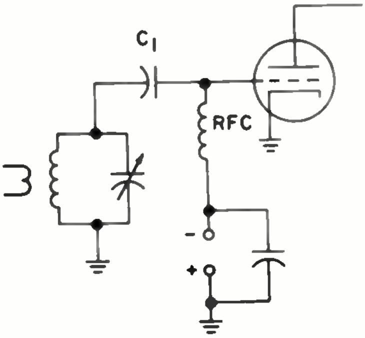

Fig. 12A. External bias.

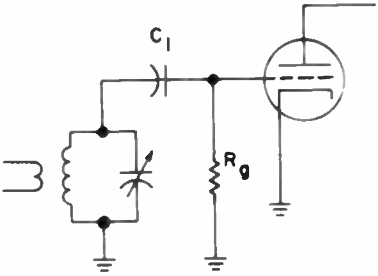

Fig. 12B. Grid-leak bias.

Grid-Leak Bias. In Fig. 12B, grid-leak bias is used. With this method of biasing, the grid current that flows during the crest of the positive half of the cycle of the incoming signal charges capacitor C_1 to a high negative value. During the interval between grid current pulses, the capacitor discharges through grid-leak resistor R_g. The discharge current develops a steady negative voltage across R_g. The value of this voltage depends upon the value of R_g and on the current through it. One advantage of this circuit is that the bias adjusts itself when the driving power is changed. Increasing the driving power increases the grid current and therefore increases the voltage drop across R_g. Thus, with grid-leak bias, changing the driving power does not appreciably change the operating angle.

A disadvantage of using grid-leak bias alone is that if there is a failure in the preceding stage, so that no excitation is supplied to the grid of the amplifier, there will be no bias developed. Excessive plate current will then flow, and if the circuit is not suitably protected, the tube and its associated components will be damaged.

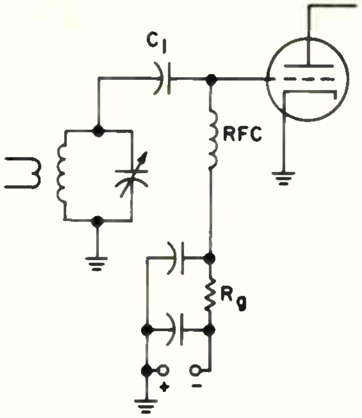

Fig. 12C. Combination external and grid-leak bias.

Combination External and Grid-Leak Bias. To protect the tube against loss of bias, a combination of external and grid-leak bias, shown in Fig. 12C, is often used. This circuit has the self-adjusting features of the circuit in Fig. 12B, and at the same time provides enough bias to protect the tube if there is a failure in the preceding stage.

Cathode Bias. The tube can also be protected against the loss of excitation by using the cathode bias combination, shown in Fig. 12D. The amount of protective bias, in either Fig. 12C or Fig. 12D, is chosen so that the plate current through the tube multiplied by the plate voltage is equal to or less than the maximum safe plate dissipation of the tube. The disadvantage of cathode bias is that part of the power supplied to the plate circuit of the tube is wasted in the cathode resistor. In large high-power stages this might be a substanial amount.

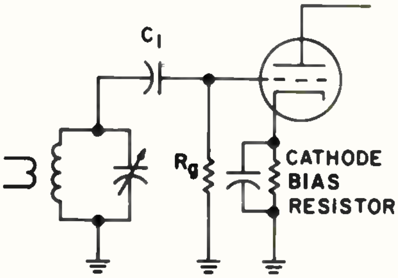

Fig. 12D. Cathode bias.

Variations. The circuits in Figs. 12A through 12D show the basic class C bias methods. There are also some minor variations of these circuits.

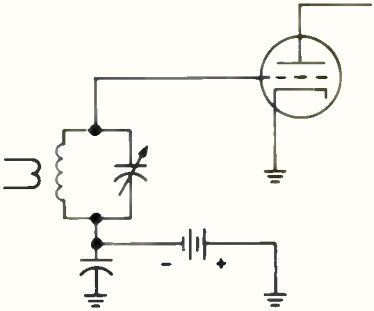

Fig. 12E. Variation of circuit shown in Fig. 12A.

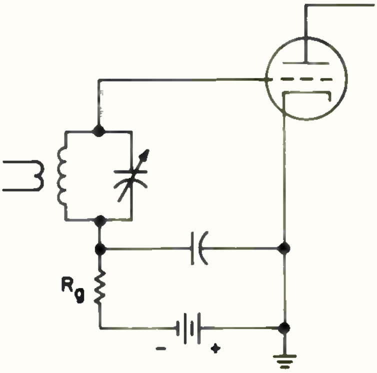

Fig. 12F. Variation of circuit shown in Fig. 12C.

For example, the circuit shown in Fig. 12A may be rearranged as in Fig. 12E, eliminating the rf choke and coupling capacitor. The circuit in Fig. 12C may be rearranged as in Fig. 12F. Perhaps we should remind you that you will find minor variations in many circuits.

Do not conclude that a circuit is necessarily different from the basic circuit you have studied just because it has been changed slightly. Study the circuit carefully and you will probably find that the method of operation is basically the same.

AMPLIFIER STABILITY

Class C amplifiers using triode tubes will go into self-oscillation easily because of feedback between the input and output circuits. As you will learn in a later lesson, a tuned-grid, tuned-plate oscillator is simply an unstable class C amplifier.

The feedback path in a triode is through the grid-to-plate capacity. Since this capacity is quite large in a triode tube, enough energy from the plate circuit can be fed back to the grid to overcome the grid-circuit losses and cause the stage to oscillate at a frequency near the resonant frequency of the tuned circuits.

Oscillation will not take place if the plate tank circuit is tuned precisely to resonance; the tank circuit must be slightly detuned to sustain oscillation. Precise adjustment, however, is very difficult. Even if you were able to make such an adjustment, the amplifier would be unstable. Slight changes in supply voltages and load would cause it to go into oscillation.

The feedback signal in a triode amplifier must be neutralized to prevent oscillation. The stage is neutralized by feeding a second signal back into the grid circuit. This second signal must be of opposite polarity and of the same amplitude as the signal fed into the grid circuit through the grid-plate capacity of the tube in order to cancel the feedback.

The most basic method of neutralization is shown in Fig. 13. In this circuit, a coil is inserted between the grid and the plate. In series with the coil is a blocking capacitor, which keeps the dc plate voltage off the grid of the tube. It has no other effect on the neutralizing circuit. The value of the coil is chosen to resonate with the grid-to-plate capacity at the frequency to which the amplifier is tuned.

The current through the coil lags the voltage 90°; the current through the capacity leads the voltage 90°. Therefore, the currents through the coil and the capacity are 180° out-of-phase and cancel each other. The disadvantage of this simple and basic method of neutralization is that it must be retuned when the operating frequency is changed. Let's look at other methods of neutralization.

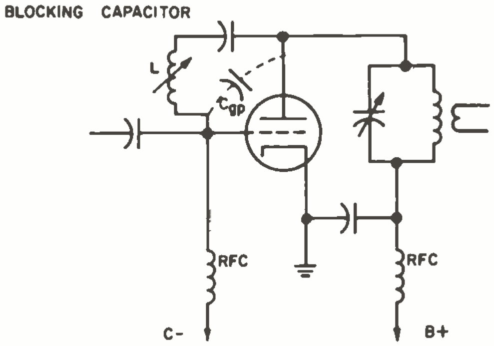

Fig. 13. Neutralization for a triode tube stage.

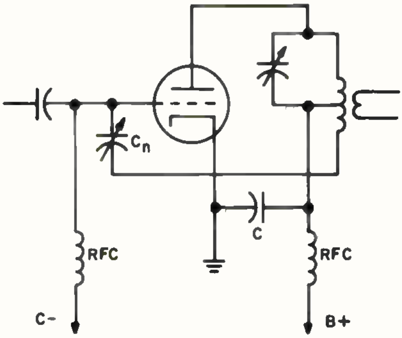

Fig. 14. Plate or "Hazeltine" neutralization.

Plate Neutralization. Fig. 14 shows a plate or "Hazeltine" neutralization. In this circuit arrangement, the coil used in the plate tank circuit is tapped, and the tap on the coil is operated at rf ground potential by grounding it through the capacitor C.

A signal voltage is developed between ground and the bottom end of the coil that is out-of-phase with the voltage at the plate end of the coil. By connecting the bottom of the tank circuit to the grid of the amplifier through the capacitor C_n, which is called the neutralizing capacitor, we can get a signal at the grid that will cancel the feedback from plate to grid through the tube capacity. Capacitor C_n is adjustable so that we can apply the exact amount of signal needed to cancel out the signal fed back through the tube.

The plate neutralization system can be considered as a balanced bridge circuit. A bridge circuit is shown in Fig. 15A. The input voltage is applied between terminals A and B and the output voltage is taken off between C and D. If the ratio of impedance Z_1 to impedance Z_2 is equal to the ratio of Z_3 to Z_4, the voltage between terminals C and D will be zero, and we say the bridge is balanced.

The plate neutralization system in Fig. 14 can be redrawn as a bridge circuit as shown in Fig. 15B. The voltage is applied to terminal A from the plate of the tube. The voltage applied to terminal B is the voltage induced in the lower half of the coil in the plate circuit of the tube. We have labeled this half of the coil L_2, and the upper half L_1. Terminal C of the bridge is connected to the grid of the tube and terminal D is grounded. L_1 is made equal to L_2 by center-tapping the coil. When C_n is adjusted to equal C_{gp}, the ratio of L_1 to L_2 will be equal to the ratio of C_{gp} to C_n. Then the bridge will be balanced, so there will be no voltage fed back to the grid circuit from the output circuit.

With this type of circuit, once the stage is neutralized it will remain neutralized over a reasonably wide frequency range, if the coil is exactly center-tapped, so that L_1 is exactly equal to L_2. If L_1 is not exactly equal to L_2, the stage can still be neutralized simply by making the ratio

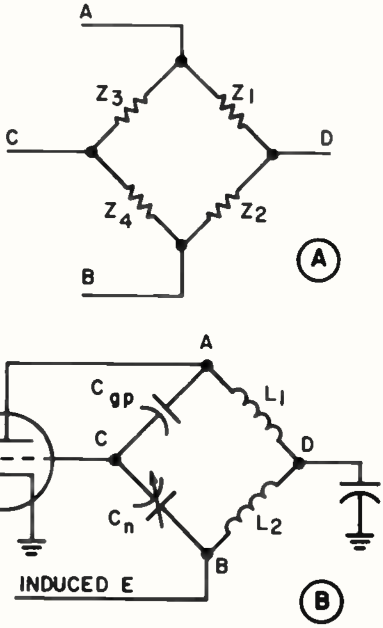

Fig. 15. Equivalent bridge arrangement of plate neutralization circuit.

of the impedance of C_{gp} to the impedance of C_n equal to the ratio of the impedance of L_1 to the impedance of L_2. If there is an appreciable difference between the values of L_1 and L_2, the frequency range over which the stage will remain neutralized becomes limited.

Another circuit for plate neutralization is shown in Fig. 16. In this circuit the center tap on the coil is not operated at rf ground potential; it is connected to B+ through an rf choke. The ground point is taken at the rotors of a split-stator tuning capacitor. A split-stator capacitor is a variable capacitor with one set of rotor plates and two sets of stator plates that are insulated from each other. The voltages at the two ends of the coil are equal and of opposite phase. The circuit in Fig. 16 can be shown as a balanced bridge by substituting the sections of the split-stator tuning capacitor for coils L_1 and L_2 in Fig. 15B. The rf ground in both circuits is made through a capacitor (marked C in Fig. 16).

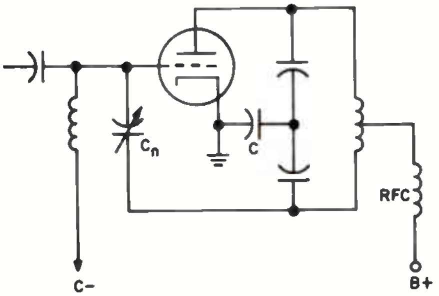

Fig. 16. Another plate neutralization circuit.

Grid Neutralization. The tapped-grid circuit arrangement shown in Fig. 17 can also be used for neutralization. This is referred to as grid neutralization or Rice neutralization. The neutralizing signal is taken from the plate and applied to one end of a tapped coil in the grid-tuned circuit. The rf ground connection is made to the center tap on the grid coil. The polarity of the feedback signal, introduced through the neutralizing capacitor C_n to one end of the grid coil, is in phase with the signal that is fed directly to the other end of the grid coil through the plate-grid capacity.

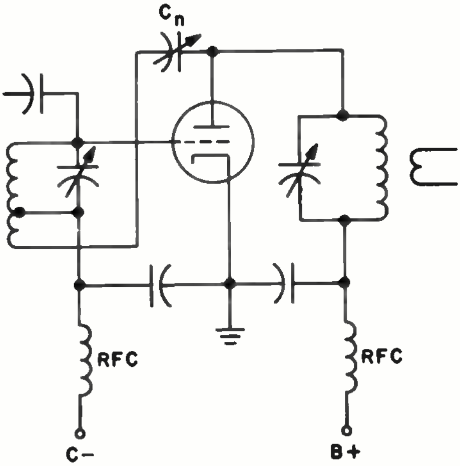

Fig. 17. Grid or "Rice" neutralization.

By properly adjusting the neutralizing capacitor C_n, voltage fed through it can be made equal to the voltage fed through the tube capacity. These two voltages will cause equal currents to flow through the

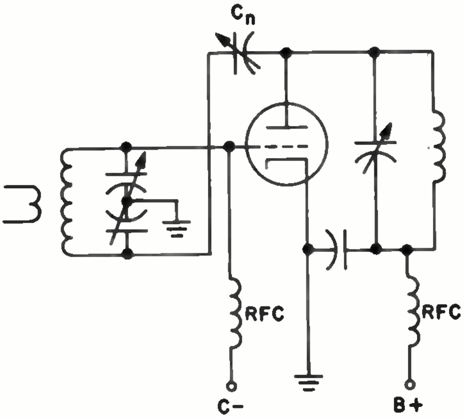

Fig. 18. Split-stator grid neutralization.

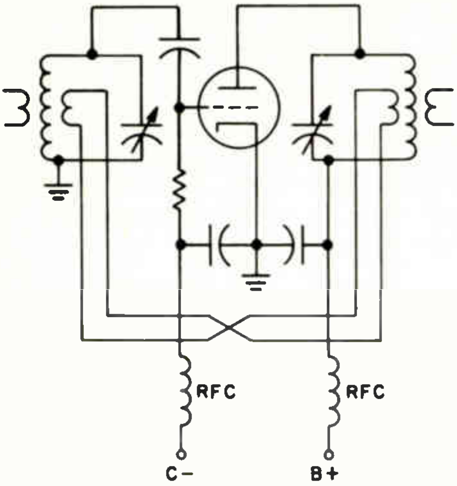

Fig. 19. Inductive neutralization.

grid coil in opposite directions. These currents will induce new voltages in the grid coil which will tend to cancel the voltage fed through C_n and C_{gp}. A split-stator version of grid neutralization is shown in Fig. 18. Its operation is essentially the same as that of Fig. 16.

Inductive Neutralization. Still another method of neutralization is shown in Fig. 19. This is referred to as inductive neutralization, because the neutralizing signal is obtained by inductive coupling between the plate and grid-tuned circuits. The signal induced in the grid circuit by the inductive link is opposite in polarity to the feedback signal, and gives feedback cancellation.

Parasitics. Neutralization of an amplifier is used to prevent oscillation at the frequency to which the grid and plate circuits are tuned, in other words, at the signal frequency. Some amplifiers go into oscillation at frequencies far removed from the desired signal frequency. Oscillations of this type are called "parasitic oscillations" or "parasitics."

The neutralization circuits we have just studied can do nothing to prevent this type of oscillation. Long leads, tube interelectrode capacities, rf chokes, and bypass capacitors are the major inductive and capacitive elements that cause parasitic oscillations.

Parasitics may exist at low or high frequencies, or at both low and high frequencies at once. They cause low operating efficiency and instability in the stage, erratic meter readings, radiation of improper carriers and sidebands, distortion, overheating of the amplifier tube, and premature breakdowns in the circuit parts. If grid-leak bias is used in the stage, parasitics will also cause changes in the grid bias.

Fig. 20A shows a typical class C amplifier stage. At the operating frequency, the grid and plate circuits are tuned by the coil and capacitor combinations L_1-C_1, and L_2-C_4. The stage is prevented from oscillating at the operating frequency by the signal fed back through neutralizing capacitor C_n.

Fig. 20B shows what the effective circuit would be if this stage were producing low-frequency parasitic oscillations. The grid circuit is now tuned by the parallel combination of the grid choke, RFC_1, and the grid bypass capacitor, C_2. Since these oscillations usually take place at frequencies below 200 kilohertz, coil L_1 has very little reactance and serves merely as a connecting lead from the grid to the junction of C_2 and RFC_1. This places the rf choke and grid bypass capacitor in parallel between grid and ground.

The tuned circuit in the plate at the low frequencies is the plate bypass C_3 and the plate rf choke. Here, too, the regular tank coil L_2 has practically no reactance at the oscillation frequency, and serves simply as a connecting lead. The neutralizing capacitor C_n is now

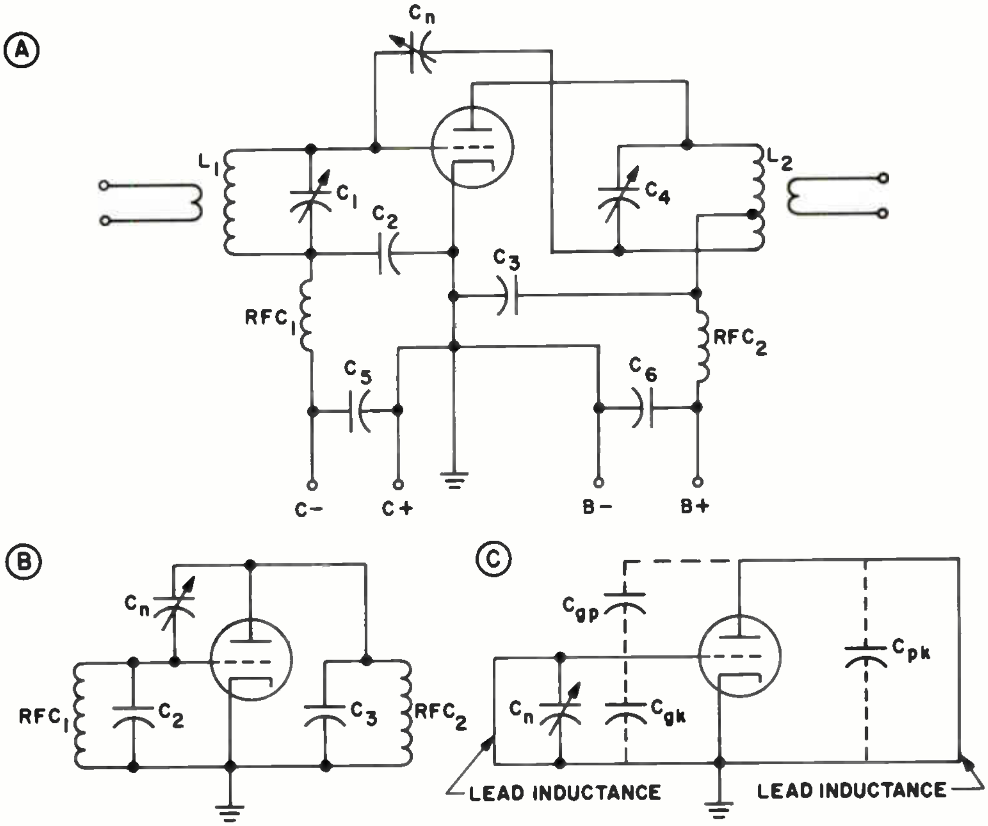

Fig. 20. A typical class C stage is shown at A; the effective circuit that produces low-frequency parasitics is shown at B; the effective circuit that produces high-frequency parasitics is shown at C.

effectively in parallel with the tube grid-plate capacity and increases rather than reduces feedback. Coils L_1 and L_2 do have a slight reactance at the parasitic frequency, so tuning capacitors C_1 and C_4 can make slight changes in the parasitic oscillation frequency.

The effective circuit for the stage, if it were producing high-frequency parasitic oscillations, is shown in Fig. 20C. In this case, the grid and plate circuits are tuned by the inductance of the leads between the tube elements and the tank circuits and the grid-to-cathode capacities. At the high frequencies, the capacities of C_1 and C_4 are so high that they act only as connecting leads in the inductive circuit. Capacitors C_2 and C_3, which are even larger in size, have practically no reactance at this frequency. The neutralizing capacitor C_n now appears between grid and ground and is effective in determining the frequency of the grid circuit. Feedback is through the capacity between grid and plate.

Preventing Parasitics. In the effective circuit of either Figs. 20B or 20C, parasitic oscillation can be prevented by making the resonant frequency of the grid circuit higher than that of the plate circuit. This may be done in Fig. 20B by making capacitor C_2 smaller than C_3 or by making R_FC_1 smaller than R_FC_2.

The most satisfactory method for suppressing very high-frequency parasitic oscillations in a class C amplifier stage is by using parasitic suppressors. The purpose of these parasitic suppressors is to increase the circuit losses at the parasitic frequency. Examples of these suppressors are shown in Fig. 21.

The suppressors are low resistances, usually around 100 ohms, in parallel with small rf chokes. At the normal operating frequency, these small coils, L_1 and L_2, have very low inductive reactances, and the signal frequency can pass through them with no loss. At the frequency of the parasitic oscillation, however, these coils have very high reactance and force the parasitic signal to flow through resistors R_1 and R_2. The loss of parasitic signal in the two resistors is great enough to prevent the tube from going into oscillation at these high frequencies.

Although a commercially manufactured transmitter should be free of parasitic oscillations, occasionally a new transmitter being tuned up for the first time will have them. Parasitics can also occur if parts are replaced by those of a different make. Whenever modifications are made in an amplifier stage, that stage should be checked for both high and low-frequency parasitics. Low-frequency parasitics will sometimes be evident as sidebands of the carrier frequency. The most common indication of high-frequency parasitics is an unusually high plate current and low output.

MULTIELEMENT TUBE STAGES

In a previous lesson you learned about the characteristics of screen grid, pentode, and beam-power tubes. Let us review briefly their characteristics with respect to their use as class C amplifiers.

If a tetrode or pentode tube is used in the stage, the screen grid of the tube acts as an electrostatic shield between the grid and plate, which reduces the grid-to-plate capacity. Therefore, tetrode and pentode tubes are less susceptible to feedback and self-oscillation, and usually do not require neutralizing.

Multielement tubes have a higher power gain than triodes. In other words, for the same amount of grid driving

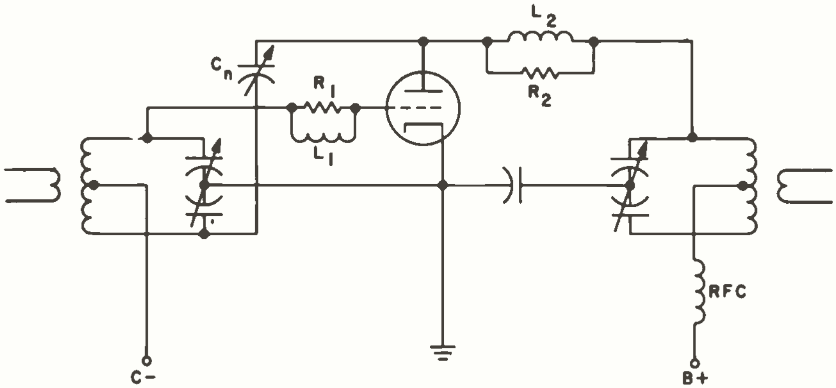

Fig. 21. Parasitic suppression methods.

power, you can get a higher power output from a stage using a multigrid tube than from one using a triode. This means that fewer stages are needed to get the desired power output. It also means that better shielding must be used between input and output circuits to prevent external feedback. Even a very small amount of feedback from the output of a stage back to the input can cause oscillation. Also because of the higher power gain, parasitic oscillations are more common in tetrode and pentode stages than in triode stages.

In screen-grid (tetrode) class C amplifiers, the minimum plate voltage must not be allowed to swing lower than the screen voltage because the screen then offers a greater attraction to the electrons than the plate. The secondary emission effect, due to electrons bouncing off the plate and being pulled to the screen instead of falling back onto the plate, determines the minimum the plate voltage can swing to. The grid excitation is adjusted so that the grid swings far enough positive so that the tube draws maximum permissible peak plate current without exceeding the dissipation rating of the plate and grid electrodes.

A pentode tube permits a greater plate voltage swing and, therefore, an even higher power gain. It does so by using a suppressor grid at cathode potential between the plate and screen grid to prevent secondary electrons from moving to the screen grid. Thus, the plate current remains independent of plate voltage to a much lower value of plate voltage. The suppressor grid forces the secondary electrons coming off the plate to return to the plate.

A beam-power tube has characteristics similar to those of a pentode. The tube elements are shaped in such a way that they control the electrons flowing between the cathode and the plate of the tube. Proper shaping of the electrodes sets up a potential barrier between screen and plate to suppress secondary emission.

You will find many multielement tubes used in transmitter equipment because of their higher power gain and simplicity of neutralization. Beam-power tetrodes are the most common.

In many circuits using multielement tubes, no neutralization is used. However, the power gain of these tubes is so great that only a small amount of feedback will set up instability and oscillations. Keeping feedback below the level that will cause instability or oscillation is a real problem. Even if a stage does not oscillate when it is first manufactured, there is no guarantee it will not be unstable when the tube in the stage is replaced. To overcome these problems, manufacturers often neutralize stages using multielement tubes.

In a class C stage using a multielement tube, the screen voltage has as much control, or more, on the plate current and power output as the actual value of the plate supply voltage. The plate supply voltage, however, must be high enough to obtain the necessary plate voltage swing across the plate-tuned circuit. Because the screen grid has so much control, the power output in some transmitters is controlled by varying the screen grid voltage.

The correct voltage must be applied to the plate of a multigrid tube at all times. If the plate voltage drops to zero or is lower than normal, the screen grid may be damaged. Under these conditions the screen current may be so high that it exceeds the safe dissipation factor.

Screen voltage and current also vary with the grid excitation, particularly if the screen voltage is obtained through a dropping resistor. An increase in grid excitation will cause the screen current to rise and the screen voltage to fall. A decrease in excitation will have the opposite effect.

When a tetrode or pentode stage is being tuned and loaded, the plate and screen voltages should be reduced. Most transmitters using tetrode or pentode power stages have provisions for reducing these voltages during tuning. A nonresonant or unloaded plate tank causes the minimum plate voltage to drop below the screen voltage. Under these conditions, the screen draws excessive current. This may destroy high-power tetrodes in a matter of a few seconds. After the tuning and loading are roughly adjusted, full voltage can be applied to the tube and the adjustments carefully peaked.

MULTITUBE STAGES

To get a higher output from a class C stage, two tubes can be connected in parallel, or in push-pull. For very high power, tubes are operated in push-pull-parallel; that is, two sets of parallel-connected tubes are operated in push-pull.

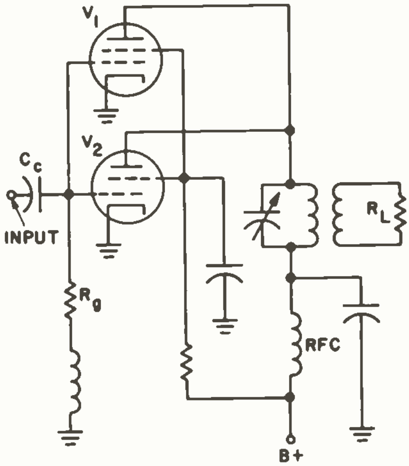

Fig. 22. Class C amplifier with two tetrodes connected in parallel.

Parallel Operation. Fig. 22 shows a stage with two tubes connected in parallel. In parallel operation, the output power is approximately twice that from a single tube, if the correct driving power is applied and the circuit components and electrode voltages have the correct values.

The grid current is doubled, because with two tubes the grid impedance is approximately halved. The driving power needed for the parallel amplifier is twice that needed for a single tube.

When grid-leak bias is used with the class C stage, the value of the grid resistor must be cut in half to get the same grid bias at twice the grid current.

The internal or plate resistance is also halved because of the parallel connection and doubling of the peak plate current. Thus, the same tuned circuit voltage is developed with twice the plate current. It is the higher amplitude plate current pulses exciting the tuned circuit that develop the added power delivered to the load in parallel operation.

Push-Pull Operation. A push-pull amplifier is shown in Fig. 23. The input excitation is applied with equal amplitude but opposite polarity to the grids of the push-pull stage. The ground point of the circuit is at the center of a split-stator variable capacitor.

As in the case of parallel tube operation, the grid and plate currents drawn are twice as great as those drawn by a single tube. To retain balanced operation of the push-pull stage where each tube performs an equal share of the work, the supply voltages are applied at the mid-

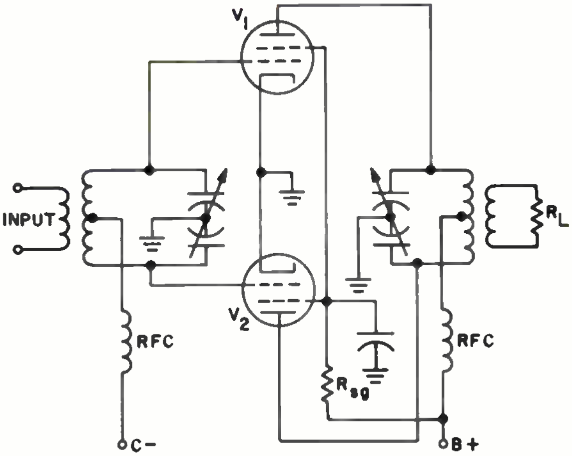

Fig. 23. Push-pull class C amplifier using tetrodes.

points of the coils so as not to imbalance the stages.

Balanced operation is necessary to prevent possible overloading of one of the tubes because of any uneven dissipation of power by the grid or plate. Imbalance can be caused by tubes that are not exactly matched or by a mismatch between the grid or plate circuit components. Thus, both the circuits and the tubes must be matched and balanced to get proper operation of the stage.

FREQUENCY MULTIPLIERS

A frequency multiplier stage is a class C amplifier that is used to generate an output signal whose frequency is some multiple of the applied signal frequency. For example, the frequency of the output of a doubler stage is twice the frequency of the input. The frequency of the output of a tripler is three times the frequency of the input. A doubler with an input frequency of 10 MHz would have an output signal of 20 MHz. A tripler with an input frequency of 10 MHz would have an output signal of 30 MHz. Multipliers can be used to generate signals of even higher multiples of their input signal frequency, but the higher the multiplication the lower the output. Thus, you can expect less output from a tripler than from a doubler using the same tube type. A multiplier generating a signal four times the frequency of the input signal would have an even lower output than a tripler using the same tube.

When a tank circuit is shock-excited into oscillation by a single current pulse, the circuit will continue to oscillate for a number of cycles. The number of cycles will depend on the losses in the circuit. Each cycle will be lower in amplitude than the preceding one because of these losses. With a high Q circuit, when the losses are low, there will be many cycles before the oscillation drops to zero.

In a frequency multiplier we take advantage of the fact that oscillation, once started, will continue for many cycles in a tank circuit. By using a tank circuit in the plate circuit of the tube that is resonant at some multiple of the input frequency, we can start the oscillation by feeding an rf signal to the grid. This will produce a plate current pulse that starts the tank circuit oscillating at its resonant frequency which may be two or three times the frequency of the input signal. This oscillation would soon die out, except on the second cycle, in the case of a doubler, or the third cycle in the case of a tripler, where the grid of the tube will be driven positive again by the rf signal. This produces another plate current pulse which adds to the energy in the tank circuit and supplies the power needed to make up the circuit losses, so the oscillation in the plate circuit continues. Now let's look at some typical frequency multiplier circuits.

Single-Tube Multipliers. The circuit of a frequency multiplier is very simple; one is shown in Fig. 24. It is even simpler than a regular class C amplifier. No neutralization is needed, even when the tube used is a triode, because self-oscillation occurs only if the input and output circuits are tuned close to the same frequency. In a doubler the output tank circuit is tuned to twice the frequency of the input circuit, in a tripler it is tuned to three times the frequency, etc.

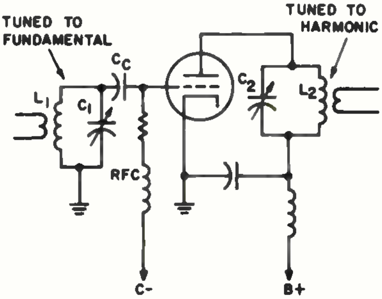

Fig. 24. Basic frequency-multiplier stage.

The current waveforms in the tank circuit of a class C amplifier are compared with those in a frequency multiplier in Fig. 25. Fig. 25A shows the waveforms for a fundamental class C amplifier. The plate current pulse flows during part of each cycle of the incoming signal. The flywheel action of the tank circuit develops the fundamental sine wave output, shown by the dashed curve.

Fig. 25B shows the waveforms for a single-tube doubler circuit. The tube is

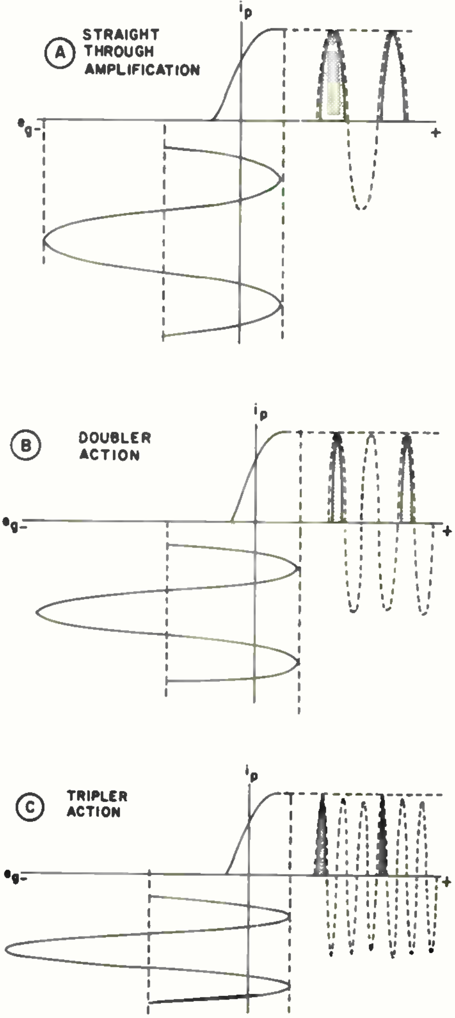

Fig. 25. Waveshapes of frequency multipliers compared to the "straight-through" amplifiers.

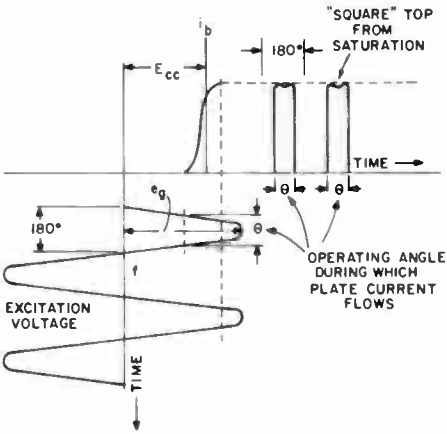
operated with a higher bias, so the plate current pulse flows during a smaller part of each cycle of the incoming signal, and the flywheel action of the resonant circuit carries through that cycle and another cycle before the next plate current pulse arrives. Since the plate current flows only on alternate cycles of the output, the power output and efficiency of the stage are lower than for fundamental operation. The efficiency is usually less than 50%.

The higher the harmonic signal to which the tank circuit is tuned, the lower the obtainable power output and efficiency of the class C stage. Fig. 25C shows the waveforms for a tripler. The tube is biased so that the plate-current flows a still smaller part of the cycle of the incoming signal, and the resonant circuit carries through three cycles before the next pulse arrives. Losses in the circuit cause the amplitude of each succeeding cycle to decrease. The efficiency of a tripler stage is even less than that of a doubler. The efficiency of a multiplier is kept as high as possible by using the proper values of L and C in the tank circuit and correctly shaping the plate current pulse.

The best pulse shape is a square top pulse like the ones shown in Fig. 26. This pulse shape can be obtained by operating the stage with a high bias and then driving the stage to plate-current saturation. For best doubler operation, the angle of current flow, indicated by the Greek letter θ (theta), should be somewhere between 90 and 120 degrees. With this angle of flow, the plate current pulse has a suitable and effective second harmonic content. For tripler operation, the angle of current flow is reduced to less than 90 degrees, and the third harmonic component is emphasized.



OUTPUT FREQ	OPTIMUM OPERATING ANGLE (θ)
2f	90°—120°
3f	80°—100°
4f	70°—90°
5f	60°—70°

Fig. 26. Multiplier operating characteristics.

The plate tank circuit of frequency multipliers can usually be tuned over a wide enough range to resonate at more than one harmonic of the signal at the grid. Therefore it is important that you check the output frequency to be sure you have the correct harmonic. You can do this with an absorption wavemeter. You'll learn more about this instrument later in the lesson.

Two-Tube Multipliers. A special higher powered and somewhat more efficient doubler can be obtained by using the push-push arrangement shown in Fig. 27A. In this circuit, the grids are supplied with signals in push-pull and the plates are connected in parallel.

The tubes are connected so that one will conduct on the positive alternation of the incoming signal, shown in dashed lines in Fig. 27B, and the other tube will conduct on the negative alternation.

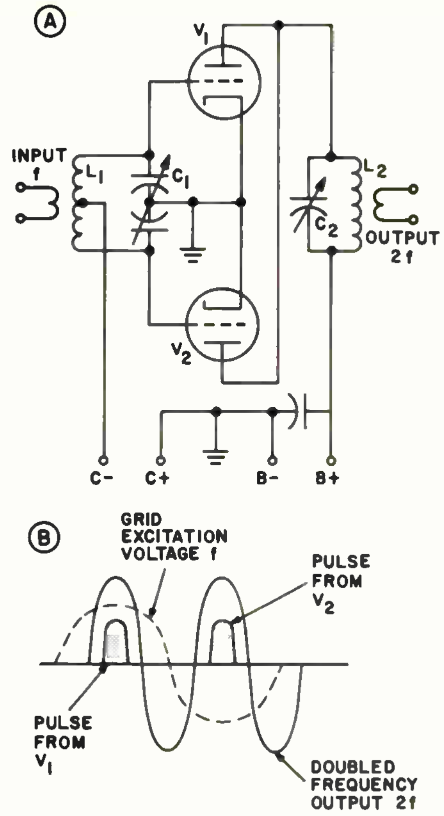


Fig. 27. Push-push doubler for even harmonics.

Thus, plate current pulses are fed to the output circuit once during each alternation of the doubled frequency. The efficiency and power output are higher than for a single-tube doubler.

The push-push frequency multiplier stage in Fig. 27A operates well on even harmonics, but not on the fundamental or odd harmonic frequencies. Frequency doublers are used more often in transmitters, especially low-frequency transmitters, than the higher harmonic generators because of the higher output and efficiency. The grids are connected in push-pull, so they must be fed with balanced signals to get the proper output signal.

Since the doubler is the most frequently used type of frequency multiplier stage, let us list some of its characteristics:

1. The plate tank circuit is tuned to twice the grid circuit frequency.
2. It does not have to be neutralized.
3. The operating angle of the plate current pulse is approximately 90°.
4. The dc bias is about 10 times the plate current cutoff value.
5. The plate current pulse has a greater harmonic content.
6. It requires a very large grid-driving signal.
7. It has a low plate efficiency compared to a fundamental class C amplifier.

As you can see, some of these characteristics vary widely from those of a class C amplifier operating as a fundamental frequency amplifier.

SELF-TEST QUESTIONS

(l) What is the disadvantage of using only grid-leak bias in a class C amplifier?

(m) What is the feedback path for oscillations near the operating frequency in a triode class C amplifier?

(n) What is the main advantage of plate neutralization over the method of connecting a coil and blocking capacitor from plate to grid?

(o) In Fig. 16, what is the phase relationship between the signal fed through C_N and the signal fed back through grid-plate capacitance?

(p) What inductive components in the grid circuit form part of the low-frequency parasitic resonant circuit?

(q) What might be the cause of unusually high plate current and low rf output from a transmitter?

(r) What two characteristics of tetrodes make them more useful as class C amplifiers than triodes?

(s) What characteristic of tetrodes make them more susceptible to parasitic oscillation than triodes?

(t) How would the values of L and C in a tank used in a parallel-connected stage compare with those used in a similar single tube circuit operating at the same frequency?

(u) How is balanced operation obtained in a push-pull stage?

(v) In general, which multiplier would have a higher output, a doubler or a tripler?

(w) Why are neutralization circuits unnecessary in a triode operated as a frequency multiplier?

Transistor Power Amplifiers

In their present state of development, transistors cannot amplify high-frequency signals to high power levels as well as vacuum tubes. However, power outputs greater than 100 watts or frequencies much above 400 MHz are seldom required in many communications applications. Chief among these is commercial mobile radio. In this application, the transistor's small size, low operating voltage, extreme ruggedness, and high overall efficiency make it ideally suited for use in mobile radio equipment.

The common emitter circuit is almost universally used for transistor rf power amplifiers because of its greater stability at radio frequencies. This circuit arrangement is often compared with the grounded cathode triode. As you might expect, it has much in common with the triode circuits you previously studied. With transistor amplifiers we are concerned with the biasing, efficiency, and stability, just as we were with the triode. In this section, we'll look at some typical circuits which illustrate the important features of transistor rf power amplifiers.

BIASING METHODS

You have learned that class C operation of a power amplifier results in the highest percentage of input power being converted to useful rf energy at the output. In the case of a transistor, where high-frequency power handling is a limitation, we are especially interested in getting the highest efficiency obtainable from the stage. It is not surprising, then, that most transistor rf amplifiers are operated class C.

Two practical methods of obtaining bias for class C operation are shown in Fig. 28. The circuits illustrated employ NPN transistors; PNP devices could just as well have been used (with all polarities reversed, of course).

In Fig. 28A, reverse bias across the emitter base junction is developed by the R_1-C_1 network in the emitter circuit. When the input signal to the stage goes sufficiently positive, base and collector currents flow over the paths indicated by the solid lines. Both these currents flow through the emitter resistor, dropping a voltage of the polarity indicated. Capacitor C_1 charges to the peak value of this voltage drop. During the time between positive-going portions of the input signal, C_1 slowly discharges through R_1

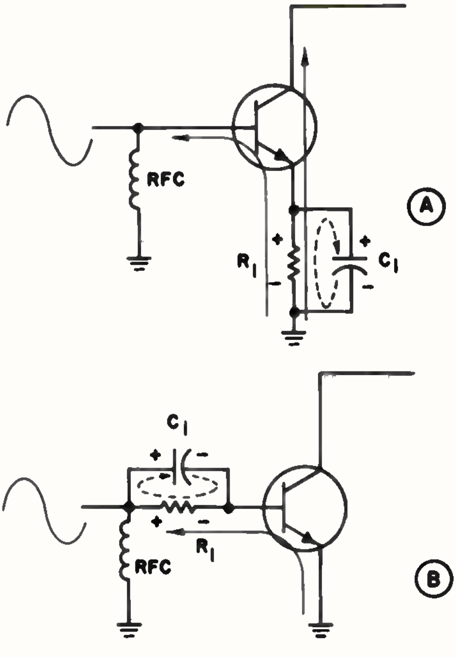

Fig. 28. Methods of obtaining emitter-base reverse bias.

as indicated by the dashed line. The values of R_1 and C_1 are such that C_1 does not discharge appreciably before the input signal again swings positive, thereby recharging C_1. The emitter is thus maintained slightly positive with respect to the base by the charge across C_1. Collector current does not flow until the input signal drives the base more positive than the emitter.

Reverse bias for the circuit of Fig. 28B is developed in the base circuit, again by a parallel combination of R_1 and C_1. The base current drawn during the positive-going portion of the input signal (indicated by the solid line) drops a voltage across R_1 as shown. C_1 charges to the peak value of this voltage drop and essentially maintains its full charge during the time between positive-going portions of the input signal. This is possible because the discharge path for C_1 (shown by the dashed line) is through R_1, the value of which is chosen to permit only a very small discharge current to flow. Notice that the polarity of the charge on C_1 is such that it subtracts from the positive-going portion of the input signal. This means that the input signal voltage must exceed the voltage across C_1 before the emitter base junction becomes forward-biased, allowing collector current to flow.

The two circuits shown in Fig. 28 depend on the presence of an input signal to develop bias. With no input signal present, zero bias is developed. Unlike vacuum tubes, however, transistors do not conduct under zero bias conditions and are therefore self-protecting.

Not only are transistors nonconducting under zero bias conditions, but also a small forward-biasing voltage must exist across the emitter base junction before collector current begins to flow. Fig. 29 shows collector current plotted against emitter-to-base voltage for a typical rf power transistor.

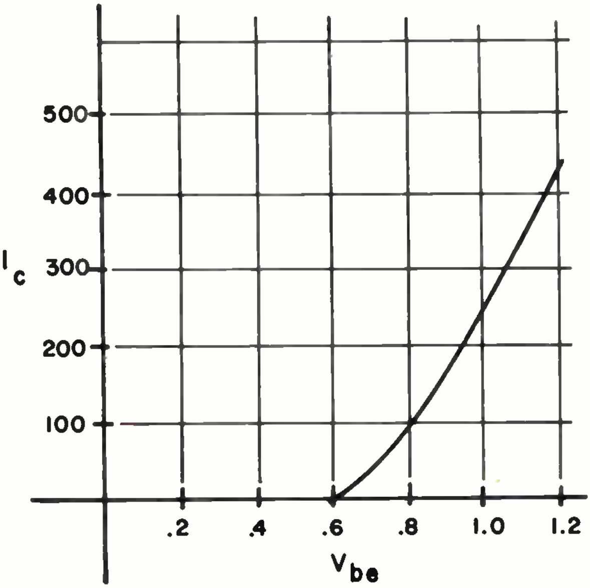

Fig. 29. Collector current plotted against emitter-to-base voltage of a typical RF power transistor.

As you can see from the graph, collector current does not begin to flow until the emitter-base voltage reaches approximately .6 volts. When we operate a power transistor with zero bias, then, we are actually biased about .6 volts below collector current cutoff.

Fig. 30 shows the graph of Fig. 29 with an input signal of 1 volt peak amplitude applied. Collector current flows only during the time the input signal is above .6 volts. The conduction angle here would be about 120° of the input cycle, well within the class C operating range. Input signal levels of such low amplitude are not unusual in power transistors because of the transistor's low input impedance. Input impedances actually range from several ohms to less than 1 ohm. With such a low input impedance, a relatively large input current is permitted to flow when the base-emitter junction of the transistor is driven positive.

Recalling that P = EI, you can readily see that the driving power to the stage is accounted for primarily by the high current flow which develops only a small voltage across the low input impedance. It follows, then, that a reverse-biased emitter-base junction is not always necessary for class C operation.

MULTITRANSISTOR AMPLIFIERS

As mentioned earlier, the power obtainable from a transistor used as an rf amplifier is rather limited as compared to vacuum tubes used in similar circuits. When more power is required than can be obtained from a single transistor, several transistors can be arranged in push-pull or parallel. In a push-pull arrangement, an input transformer is required to feed the transistors out-of-phase signals. This transformer is also required to match the relatively high output impedance of the

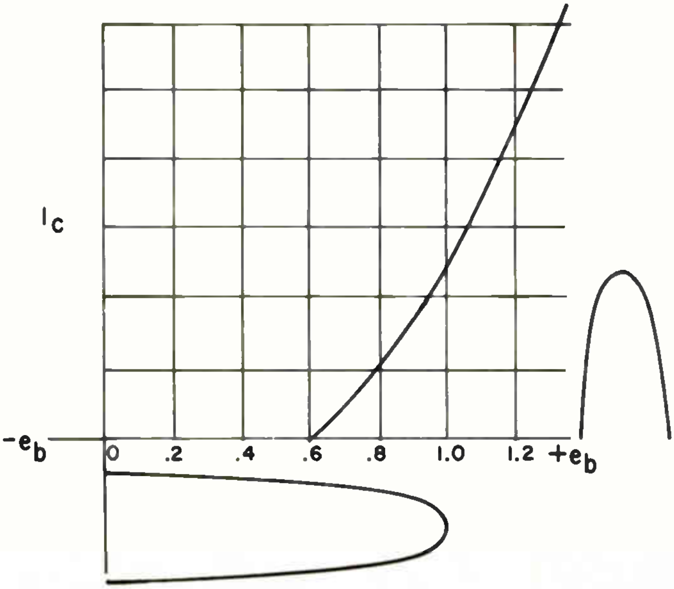

Fig. 30. Curve of Fig. B with signal applied showing collector current pulse.

driver to the very low input impedance of the push-pull stage. Such a transformer capable of operation at high frequencies is very expensive to build. For this reason, multiple transistor stages are nearly always parallel-connected.

Fig. 31 shows a two-transistor parallel-connected rf amplifier stage. C_1 and L_1 form an L network which provides the proper impedance match between the source and the input to the stage. The input signal is developed across RFC_1, amplified by the transistors, and applied to the load through the output coupling network. Notice that we can vary the operating bias of the two transistors by adjusting R_1 and R_2. These adjustments are necessary so that the two transistors will share the load equally. In practice we would insert a milliammeter in the collector or emitter circuit of each transistor and adjust R_1 and R_2 for equal currents. With the currents balanced, each transistor will be handling half of the power delivered to the output coupling network. C_4 is a coupling capacitor and may be considered a short circuit at the operating frequency. The output coupling circuit is a pi network consisting of C_5, L_2, and C_6. C_5 and C_6 are adjusted to provide the proper collector load and circuit Q for the transistors.

Another circuit employing transistors in parallel is shown in Fig. 32. Besides containing three transistors instead of two, this circuit differs from the one in Fig. 31 in two other important respects. First of all, load balancing is obtained by adjusting L_1, L_2, and L_3 in the base circuits. These adjustments vary the rf

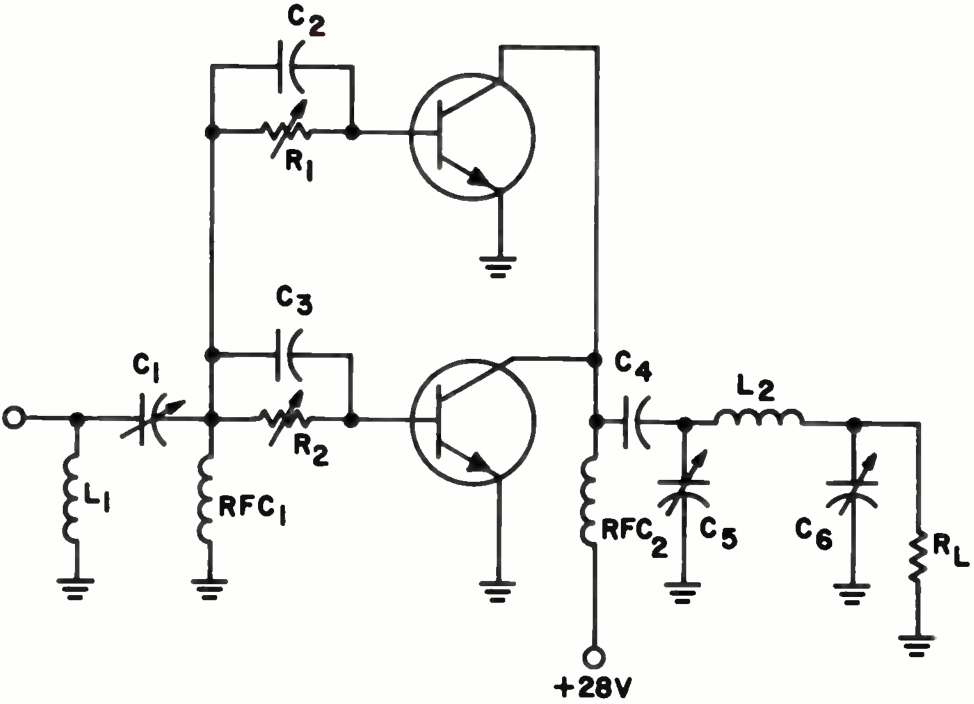

Fig. 31. Two-transistor parallel-connected RF amplifier.

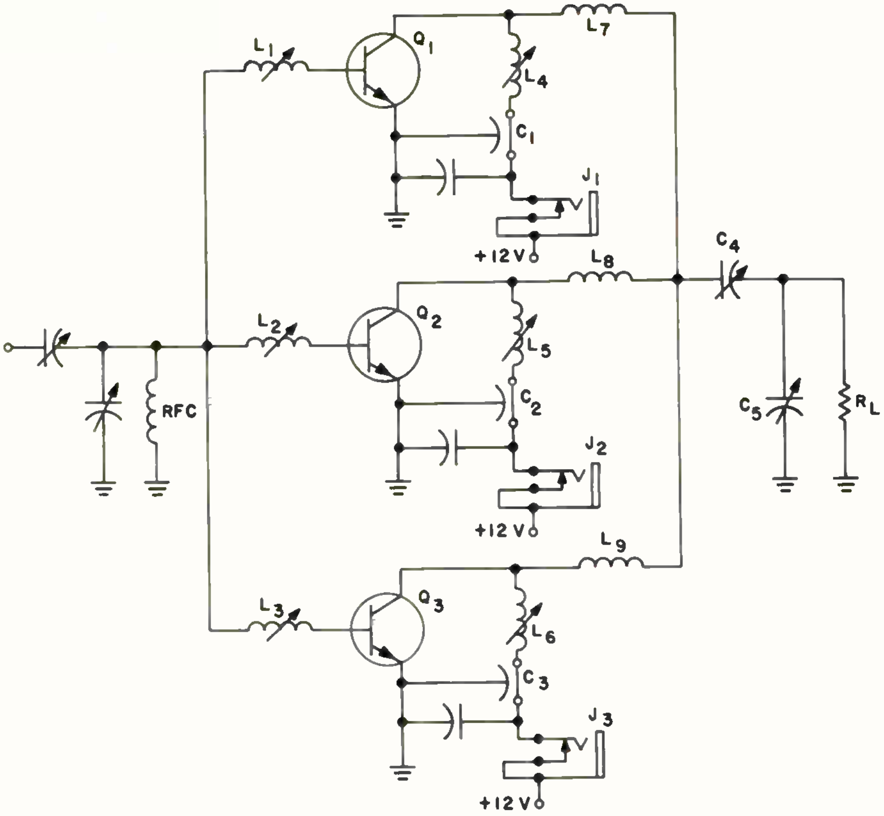

Fig. 32. Three-transistor parallel-connected RF amplifier.

drive to the transistors and equalize the load currents as previously discussed. Secondly, each of the three transistors in Fig. 32 has a separate output tank circuit connected to a common load as in Fig. 31.

The tank circuit for Q_1 is made up of L_4, L_7 and stray capacity. L_5 and L_8 are the tank inductances for Q_2; L_6 and L_9 are the tank inductances for Q_3. These tank circuits are also tuned by stray capacity. The right-hand ends of L_7, L_8 and L_9 connect to C_4 which, along with C_5, varies the coupling from the three tank circuits to the load R_L.

There are two reasons why separate tank circuits are used for the three transistors. First, each transistor is series-fed, thus eliminating the losses and other problems of an rf choke. Second, the dc collector currents are entirely separate so each transistor can operate essentially independent of the other transistors. Thus, if some trouble developed in Q_1, this stage could be disconnected and the amplifier could continue to operate at a lower power level. Directly paralleled stages would have to be completely retuned if one stage were to be removed.

Many rf power transistors have their emitters internally connected to the transistor case. This is done to eliminate the stray inductance of the emitter lead. When the case is connected to ground, as it would be in a circuit such as that shown in Fig. 32, current could not be conveniently measured in the emitter circuit. The use of separate collector loads, however, enables convenient monitoring of collector current. In Fig. 32, the jacks labeled J_1 through J_3 are provided for this purpose.

The symbol used to represent C_1 through C_3 may be unfamiliar to you. This is a special type of capacitor called a feed-thru and is often used for bypassing in high-frequency circuits. As the symbol suggests, one plate of the capacitor completes a dc path in the circuit; the other plate, usually connected to ground, surrounds the first much like the braided shield in a piece of coaxial cable.

FREQUENCY MULTIPLIERS

Fig. 33 shows two transistor frequency multiplier stages coupled together. The output of the tripler, Q_1, feeds a doubler, Q_2, to give a total frequency multiplication of six. The input signal, which we've designated as F_O, is applied to the base of Q_1. With the drive signal present, R_1 and C_1 develop a relatively high reverse bias across the emitter base junction. The high reverse bias results in a narrow conduction angle and collector current pulses with a high harmonic content. The collector tank is tuned to the third harmonic, $3F_O$, and offers a high impedance only at this frequency.

Signals at the fundamental, as well as those at other harmonics, are bypassed to ground by C_2 and C_3. The signal at the frequency $3F_O$ is inductively coupled into the base circuit of Q_2. Reverse bias for Q_2 is developed by the driving signal in a manner similar to that described for Q_1. The collector tank for Q_2 is tuned to $6F_O$ and inductively couples the signal at this frequency into the load. Undesired signals are again bypassed to ground, in this stage by C_5 and C_6.

While individual stages are seldom designed for frequency multiplications greater than three, any desired total multiplication may be obtained by connecting multipliers together. The usual arrangement in a transmitter is a straight-through class C amplifier following each one or two multiplier stages. In this

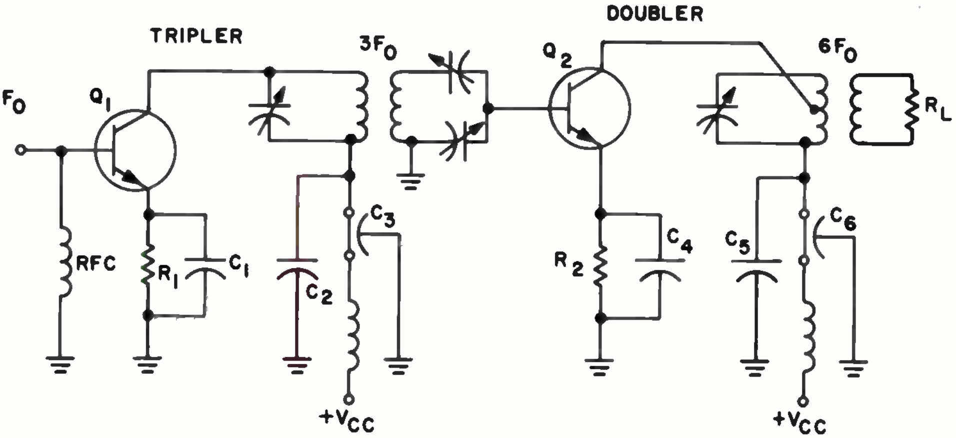

Fig. 33. Two frequency multiplier stages coupled together.

manner, the relatively low output from the multiplier is built up before being applied to the next multiplier. The straight-through amplifier also offers additional suppression to the undesired harmonics generated in the multiplier stage.

AMPLIFIER STABILITY

You learned that, in the triode power amplifier, in-phase feedback through plate-to-grid interelectrode capacitance could cause the amplifier to oscillate. To prevent these oscillations from occurring, components were added to feed back an out-of-phase voltage of equal amplitude and thus "neutralize" the interelectrode capacitance of the tube.

A similar capacitance exists between the collector and base of a transistor. However, the value of this collector-to-base capacitance in power transistors is voltage-dependent. That is, as the reverse bias across the collector base junction varies (which it normally does over the period of an operating cycle) the collector-to-base capacitance also varies. To be effective, a neutralizing circuit for a power transistor would have to continuously adjust itself to this variation. Because of this requirement, neutralization of a transistor rf amplifier is normally not practical. Instead, the need for neutralization is usually eliminated by careful circuit design using transistors with low values of interelement capacitance.

Parasitics. In the radio frequency range, the power gain of a transistor falls off rapidly as frequency increases. This characteristic of transistors works to advantage in preventing parasitic oscillations above the operating frequency. At these higher frequencies, the transistor has insufficient gain to overcome the circuit losses and sustain oscillations.

On the other hand, the power gain of a transistor is higher at the lower frequencies. To illustrate this, let's assume we have an rf power amplifier operating at 175 MHz. A typical transistor operating at this frequency might have a power gain of 5 db. This same transistor could have a gain as high as 30 db at 10 MHz. In other words, the power gain of the device is over 300 times greater at 10 MHz, the parasitic frequency, than at 175 MHz, the operating frequency. Consequently, the most common cause of instability in these power amplifiers is parasitic oscillation below the operating frequency.

The amplifier circuit shown in Fig. 34 illustrates a number of techniques used to prevent low frequency parasitics. These are discussed in the following paragraphs.

The rfc connected between base and ground (1) will at some frequency form a parallel-resonant circuit with the emitter base capacitance. To decrease the efficiency of this parasitic tank circuit, the rfc is designed to have a very low Q (high effective series resistance). Often this rfc is nothing more than a wire-wound resistor.

The emitter bypass capacitor (2) used is the smallest value which will provide effective bypassing at the operating frequency. At frequencies below the operating frequency, the reactance of this capacitor increases, resulting in degenerative feedback at these lower frequencies. This degeneration reduces the gain of the amplifier to low frequency parasitics.

The output coupling network is designed to include a portion of the network inductance in the collector dc supply line (3). With this arrangement, no

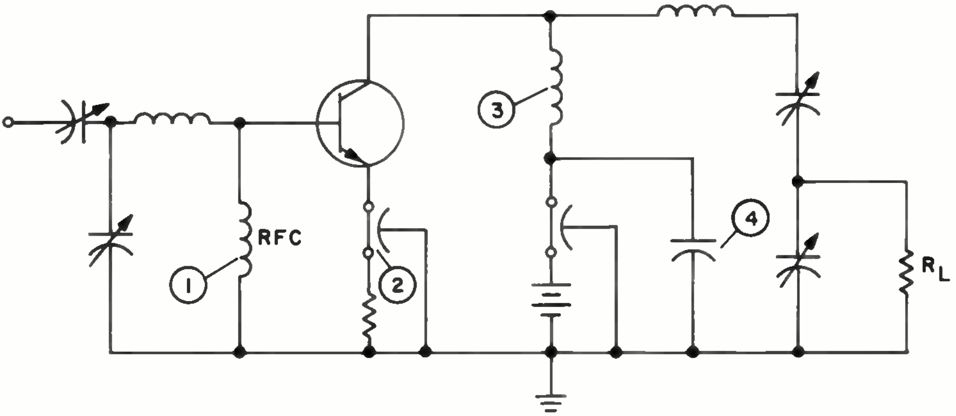

Fig. 34. Transistor power amplifier showing components used to prevent low frequency parasitics.

rfc is required in the collector circuit. Elimination of the collector rfc is desirable because this component can form a parallel-resonant circuit with the output capacitance at some relatively low frequency, thus becoming a possible source of low-frequency parasitics.

In addition to the feed-thru capacitor designed to bypass the power supply at the operating frequency, a second capacitor of larger value (4) provides a short circuit to ground at lower frequencies where parasitics usually occur. You might wonder why a larger capacitor, since it bypasses well at lower frequencies, wouldn't provide an even better bypass at the operating frequency where its X_c would be even less. The reason is that at higher radio frequencies the inductive reactance of the capacitor's leads becomes significantly large. The capacitor, instead of being a short circuit to ground, becomes an impedance to ground at these higher frequencies. The feed-thru capacitor, because of its physical construction, has very low lead inductance, and therefore provides an effective short circuit to ground at the high operating frequency. Feed-thru capacitors can only be manufactured with comparatively small values of capacitance, hence the need for the more conventional larger capacitor for the low-frequency bypass.

Fig. 35 summarizes what we have said about power supply bypassing. Shown in the figure are the equivalent bypass circuits for both the high operating frequency and the low parasitic frequency. At the operating frequency, the larger

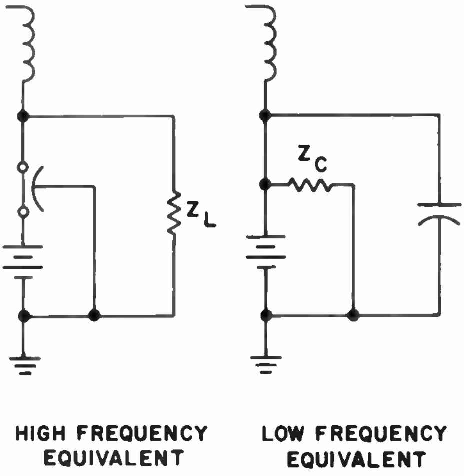

Fig. 35. Equivalent circuits for the power supply bypassing arrangement shown in Fig. 33.

capacitor appears as an inductive reactance, Z_L, and the feed-thru as an ac short circuit to ground. At a low parasitic frequency, the feed-thru appears as a high capacitive reactance, Z_C and the larger capacitor provides the ac short to ground.

SELF-TEST QUESTIONS

(x) Which transistor circuit configuration has the greatest stability at radio frequencies?

(y) What happens when loss of drive causes the bias on a transistor rf amplifier to drop to zero?

(z) Is reverse bias on the emitter base junction necessary for class C operation in a transistor rf amplifier?

(aa) What characteristic of transistor rf power amplifiers accounts for the low signal voltage developed in the input circuit?

(ab) Why is a parallel connection of transistors favored over a push-pull connection?

(ac) What are two advantages of having separate collector tank circuits for a parallel-connected transistor rf amplifier?

(ad) Why are feed-thru capacitors used for bypassing in high-frequency circuits?

(ae) What characteristic of power transistors makes neutralization impractical?

(af) What is the most common form of transistor rf amplifier instability?

(ag) Why is an additional capacitor placed in parallel with the feed-thru capacitor bypassing the power supply in Fig. 32?

Adjusting Class C Amplifiers

Adjustments to class C amplifiers in transmitter stages are performed following repairs, or routinely to compensate for normal circuit aging. The adjustment procedures for all class C stages, either frequency multipliers, intermediate amplifiers, or power output stages are basically the same. There are variations, of course; when you tune a frequency multiplier, for example, you must make certain that the plate circuit is tuned to the desired harmonic frequency.

In this section, we will go through the complete adjustment procedure for both a vacuum tube and a transistor class C amplifier stage. You should realize that adjustments such as those described in this section may be performed only by a person having the necessary authority. To obtain this authority, he must hold the proper class of FCC License or be under the direct supervision of another person who does.

THE VACUUM TUBE STAGE

Fig. 36 shows a typical class C amplifier circuit. Notice that there are current meters in the grid and plate circuits and that voltmeters are used to measure the bias, filament, and plate supply voltages. A power output stage using a screen-grid

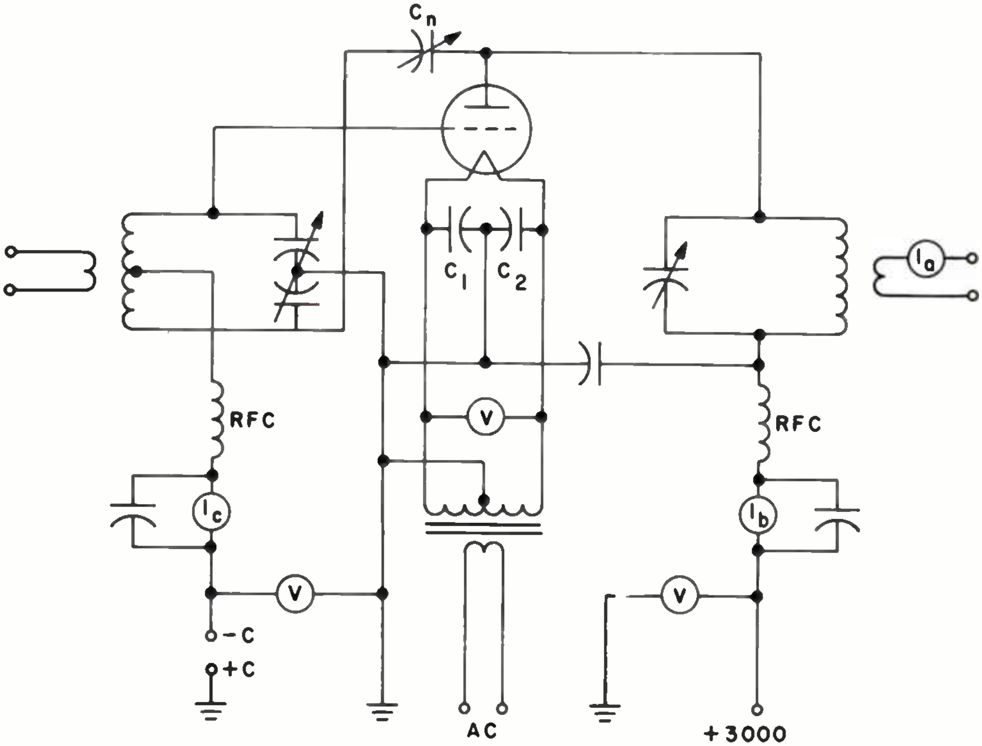

Fig. 36. Typical class C amplifier.

tube often has a current meter and voltmeter in the screen circuit. In some rf output stages, particularly in the low power exciter stages, only one voltmeter and one or perhaps two current meters are used. These meters are switched into the various stages to check the performance of the stage during operation or during the adjustment procedure.

Neutralization. The first step in the adjustment procedure is to insure that the amplifier is properly neutralized. Always check for neutralization with all interstage shields in place. If the amplifier is enclosed in a separate shield box within the transmitter cabinet, check it with the shield box closed. There will probably be stray magnetic or electrostatic coupling between output and input circuits unless all shields are in place and closed.

Neutralization can correct only for capacitive coupling directly from the grid to the plate of the tube. The simplest indication which can be used to determine correct neutralization is the grid current meter. With B+ removed from the stage, the need for neutralization will be indicated by a dip in the grid current when the plate tank is tuned through resonance. The grid current dips because the power loss in the resistance of the plate tank is greatest at resonance. Since this power is fed into the plate tank through the grid-plate capacitance, it subtracts from the grid current and causes a dip.

A second, more sensitive, method of checking for correct neutralization is by use of a wavemeter. As shown in Fig. 37, this simple device consists of a parallel L-C circuit connected to a diode and dc milliammeter. The variable capacitor, which is calibrated in units of frequency, may be adjusted to make the circuit resonant over a wide range of frequencies.

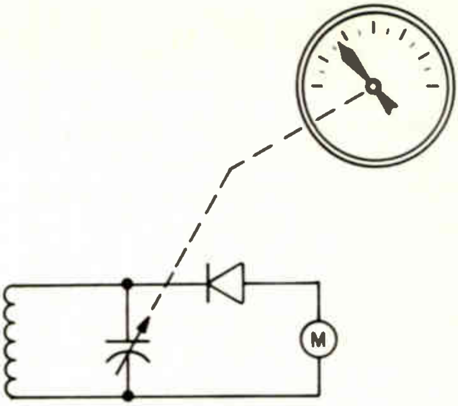

Fig. 37. Simplified schematic diagram of a wavemeter.

Any energy coupled into the tank circuit is rectified by the diode and causes the meter to deflect. In use, the wavemeter is inductively coupled to the plate tank circuit of the stage to be checked.

With plate voltage removed and grid drive applied to the stage, there should be no indication on the meter as the tuning knob is adjusted near the operating frequency. An indication on the meter indicates the presence of rf in the plate tank. This rf could only have come from the grid circuit -- coupled through interelement capacitance to the plate tank. Hence, the stage must be neutralized.

The procedure to be used in neutralizing an amplifier is as follows:

1. Remove the B+ from the stage. *Never attempt to neutralize an amplifier with the plate voltage connected.*
2. Set the neutralizing capacitor for minimum capacity.
3. Apply filament power and bias to the stage, and apply filament power, bias, and B+ to all stages ahead of the stage being neutralized.
4. Tune the grid circuit to resonance as indicated by maximum grid current.

5. Tune the plate tank circuit to resonance while watching the neutralization indicator. If it is a grid meter, it will dip; if you are using a wavemeter, it will peak.

6. Increase the capacity of the neutralizing capacitor slightly. Check grid and plate resonance; changing the neutralizing capacitor will sometimes detune both grid and plate circuits.

7. Continue to increase the neutralizing capacitance in small steps until there is no dip in the grid meter or no indication of power in the plate tank. The transmitter is then correctly neutralized.

As you come closer and closer to neutralization, make smaller and smaller changes in the neutralizing capacitor. There is only one correct setting; too much and too little capacitance are equally bad. Remember to retune both grid and plate each time you change the neutralizing capacitor. If the transmitter uses inductive link neutralization, start with maximum coupling to this link. Then reduce the coupling in small steps until you find the correct coupling.

Neutralization must be made as accurately as possible. Although steady oscillation will take place only when enough power is fed back from the output to overcome the input circuit losses, smaller amounts of feedback, which are not enough to cause steady oscillation, can still affect the operation of the stage. An amplifier operating like this is said to be "regenerative."

Several characteristics of an amplifier change when it is regenerative. One of the most pronounced is an increase in input impedance. This increase in impedance causes the Q of the grid and plate tuned circuits to increase also. The increase in Q makes the circuits selective and hard to tune. To make matters worse, changes in the plate tuning change the amount of feedback and, therefore, affect the grid tuning.

A regenerative amplifier is an unstable amplifier. A slight increase in filament current or plate voltage may cause it to go into steady oscillation. Reducing the load at the output will also cause oscillation.

In a keyed transmitter, a regenerative amplifier will cause damped oscillations every time the key is closed. As a result undesirable signals are generated. In a phone transmitter, an unstable amplifier causes still other effects.

Perfect neutralization of an amplifier is absolutely necessary. It takes time to do it right, but it does not have to be done often.

After you have completed the neutralizing procedure, apply a low plate voltage to the stage. Tune the plate tank capacitor to resonance as indicated by minimum plate current readings. You will notice that the plate current will dip sharply because the output tank circuit is not delivering power to the load. This is shown by the solid curve in Fig. 38.

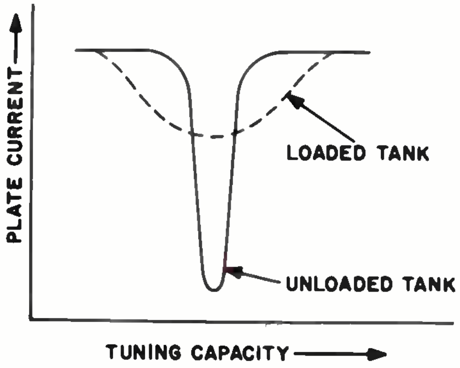

Fig. 38. How plate current dips as tank capacitor is tuned through resonance; the unbroken line shows the sharp dip that occurs if the tank is not loaded; the dashed line shows the broad dip that occurs if the tank is loaded.

The grid current meter will indicate maximum at resonance. Retune the grid tank capacitor, and increase the excitation until the grid draws the rated current.

Increase the loading in the plate tank circuit until any increase in loading causes the current through the antenna meter to drop. Increase the loading in steps. Check the plate circuit tuning for resonance each time you increase the load. Now apply the plate voltage and adjust it to the rated value.

Retune the plate tank to resonance, and then advance the loading until the tube draws the rated plate current. The minimum plate current point will not be as sharp because the tuned circuit is now loaded and more power is being fed into the load circuit. The loaded plate current tuning curve is shown by dotted lines in Fig. 38. Adjust the grid tank and excitation until the rated grid current is drawn.

Make final fine adjustments to the plate tuning and antenna loading. Be certain all meters show the recommended values for proper operation of the stage.

The output is indicated by the current readings on the rf antenna current meter. As the stage is resonated and the loading is increased, the antenna current increases, indicating power is being delivered to the antenna. The antenna meter is just as important as the plate ammeter when tuning. If the output current does not increase when the plate current increases, the plate circuit is not tuned to resonance or is overloaded. Reduce the coupling and retune the plate tank.

Parasitics. It is interesting to note that the wavemeter is also useful in detecting the presence of parasitics in the operating amplifier. As you know, these oscillations take place at a frequency far removed from the operating frequency. The most practical way to locate the oscillations is to reduce the bias of the stage so that the tube is no longer operated beyond plate-current cutoff. Then reduce the plate voltage so that the maximum plate dissipation of the tube is not exceeded. Disconnect the output and remove the drive from the stage. These changes make the circuit most favorable for the generation of parasitic oscillations.

With the wavemeter inductively coupled to the circuit suspected of oscillating, the wavemeter tuning knob is varied over its range. A meter deflection not only indicates parasitic oscillation, but the frequency may be approximately determined by the position of the tuning knob. Knowing the frequency at which parasitics are occurring often provides a clue to their origin.

THE TRANSISTOR STAGE

The transistor power amplifier, although used to some extent in low-level fixed station and broadcast transmitters, finds its widest application in low-powered mobile transmitting equipment. Since these units are operated largely by non-technical people working under less than ideal conditions, the emphasis in their design is on simplicity and reliability. Because of this emphasis, adjustment procedures for transistor class C amplifiers are usually simple and straightforward. The complete transmitter alignment of many of these units consists in its entirety of peaking the indication on a power output measuring device with as few as two transmitter adjustments.

Even in the more elaborate transmitters you'll seldom find more than one meter built into the equipment. This single meter is switched into the various points in the circuit where current or voltage is to be measured. Sometimes, all the monitoring points in the circuit are connected to a multipin jack on the transmitter chassis. When transmitter adjustments are to be made, an external meter equipped with a selector switch is plugged into this jack for monitoring.

Fig. 39 shows a parallel-connected output stage such as might be found in one of the higher powered transistor transmitters. We have shown separate meters at the various monitoring points for clarity. Before applying power to the amplifier, L_1 and L_3 should be adjusted for minimum drive to the transistors (adjusted for maximum inductance). With this accomplished, apply power and adjust the collector circuit of Q_1 to resonance. This is done by adjusting L_2 for a dip on M_1.

In like manner, adjust the collector circuit of Q_2 to resonance using L_4 and M_2. Next adjust the coupling to the load using C_1 to obtain the rated load current as measured on M_3. Finally, adjust the base drive to the transistors using L_1 and L_3 to obtain equal collector currents at the rated value. This completes the preliminary adjustment of the stage. Since there is some interaction between the various adjustments, recheck the setting of L_2, L_4, and C_1. At all times maintain the collector currents at or below the rated value by adjusting L_1 and L_3.

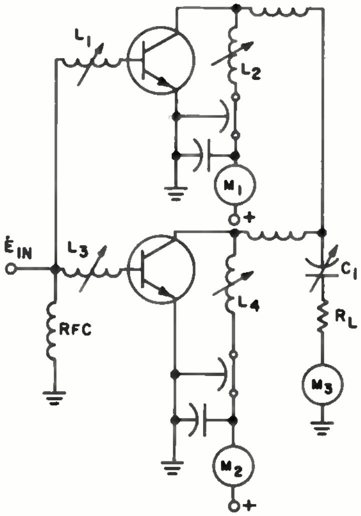

Fig. 39. Parallel-connected transistor stage.

In conclusion, the adjustments we've discussed in this section should not be considered as a procedure to be memorized and followed in any specific case. They are presented here to illustrate the basic approach to power amplifier adjustment. Before attempting any adjustment to a power amplifier, carefully consult and follow the manufacturer's literature. In making the adjustments, both the procedure and the sequence in which the steps are performed are of the greatest importance. An expensive tube or transistor may be destroyed as a result of any adjustments performed without complete knowledge of the correct procedure.

SELF-TEST QUESTIONS

(ah) How may a vacuum tube stage be checked for proper neutralization using the grid current meter as an indicator?

(ai) Why must B+ first be removed from a stage before checking the plate tank for the presence of rf?

(aj) What are some indications of a regenerative amplifier?

(ak) What tuning defect is indicated if the antenna current does not increase with an increase in plate current?

(al) Why is the drive to the transistor amplifier in Fig. 39 adjusted for minimum before collector power is applied.

Answers to Self-Test Questions

(a) Because output current flows in the amplifier only during the relatively brief conducting period.

(b) Both the bias level and the amplitude of the driving signal affect the operating angle.

(c) No. Sometimes, high power gain in an amplifier, obtained with a matched load, must be sacrificed for greater power output.

(d) The value of L and C would both have to be changed. L would be increased and C decreased.

(e) The loaded Q would decrease. The unloaded Q would be unaffected. The efficiency of the tank would increase.

(f) If the loaded Q decreases, the reflected resistance in the tank must have increased. The increased reistance in the tank causes tank impedance to decrease.

(g) By offering a high impedance only at the resonant frequency.

(h) By decreasing the spacing between the coils.

(i) Since the power supply, the tank, and the stage are in series, the amplifier is series-fed.

(j) The output connection to the tank could be tapped down on the tank coil, as is shown in Fig. 9C. This causes the internal resistance of the stage to appear to the tank as a higher value. This higher resistance seen by the tank reflects a higher resistance into the tank which increases the loaded Q.

(k) An antenna usually loads a power amplifier more heavily than the input circuit to another class C amplifier.

(l) If the drive to the stage is lost, no bias will be developed, allowing the tubes to conduct heavily. This heavy conduction could damage the tube.

(m) Through the plate-to-grid capacitance.

(n) Plate neutralization is effective over a range of frequencies, whereas the blocking capacitor and coil arrangement is effective only at one frequency.

(o) 180°. The signal fed back through a neutralizing circuit will always be 180° out-of-phase with the signal fed back through the grid to plate capacitance.

(p) The radio frequency choke.

(q) Parasitic oscillations in the amplifier.

(r) Their higher power gain and reduced grid-to-plate capacitance.

(s) Their higher power gain. Even a very small amount of feedback may cause the tetrode to oscillate.

(t) The value of L would be lower and the value of C higher. This would provide the lower value of tank impedance necessary for the parallel connected tubes.

(u) By connecting the supply voltages to the midpoints of the tank coils.

(v) The doubler. In general, the greater the frequency multiplication in a stage, the lower the power output.

(w) Since the output frequency is different from the input frequency, any signal fed back would not add to the input signal.

(x) The common emitter.

(y) The transistor stops conducting.

(z) Not always. A zero-biased transistor is already several tenths of a volt below collector current cutoff.

(aa) The low input impedance of the amplifier.

(ab) Because of the expense of the transformer required to drive a push-pull stage.

(ac) RF choke losses are eliminated and the transistors are electrically independent.

(ad) Because they have a very low lead inductance.

(ae) The collector base capacitance varies over the period of an operating cycle. Thus a varying amount of signal is fed back to the input.

(af) Low-frequency parasitics. The power gain of a transistor increases rapidly as frequency decreases. For this reason, a transistor amplifier is most susceptible to low-frequency parasitic oscillations.

(ag) Because of their physical construction, feed-thru capacitors cannot be manufactured with high values of capacitance. Proper bypass at low parasitic frequencies requires a large capacitance, so another type must be connected in parallel with the feed-thru.

(ah) With plate voltage removed, a dip in grid current when the plate tank is tuned through resonance indicates the need for neutralization.

(ai) With the B+ on the stage, rf in the tank circuit is a normal indication.

(aj) Changes in plate tuning affect grid tuning. Also, oscillations occur with reduced loading or slight changes in operating voltages.

(ak) The plate tank is not tuned to resonance or is too heavily loaded.

(al) To prevent possible excessive collector current flow due to the low impedance offered by the detuned output circuit.

NOTES

Lesson Questions

Be sure to number your Answer Sheet C205.

Place your Student Number on every Answer Sheet.

Most students want to know their grades as soon as possible, so they mail their set of answers immediately. Others, knowing they will finish the next lesson within a few days, send in two sets of answers at a time. Either practice is acceptable to us. However, don't hold your answers too long; you may lose them. Don't hold answers to send in more than two sets at a time, or you may run out of lessons before new ones can reach you.

1. What is the primary purpose of a buffer stage?

2. What is the efficiency of a transmitter output stage if the plate supply voltage is 2000 volts, the plate current is 330 ma, and the measured power output of the stage is 500 watts?

3. What is the probable cause of trouble if the plate current of a class C stage using grid-leak bias alone rises to a very high value and the grid and output currents decrease?

4. Why is neutralization necessary in a triode amplifier?

5. Why are transistor rf amplifiers more susceptible to low-frequency parasitics than to those at higher frequencies?

6. Why does a screen-grid tube usually not require neutralization?

7. (A) If the master oscillator in a transmitter using a single doubler stage operates at 7.6 MHz, what is the transmitter output frequency?
   (B) If a transmitter output frequency of 26.4 MHz is obtained by using a single tripler stage, what is the frequency of the master oscillator?

8. What is the purpose of a Faraday screen?

9. What precaution should be taken when tuning the output of a frequency multiplier stage?

10. In adjusting a class C transmitter stage, what direction (upscale or downscale) would you expect the pointers on the following dc current meters to deflect to indicate resonance: (A) the plate current meter; (B) the grid current meter?

THE VALUE OF KNOWLEDGE

Knowledge comes in mighty handy in the practical affairs of everyday life. For instance, it increases the value of your daily work and thereby increases your earning power. It brings you the respect of others. It enables you to understand the complex events of modern life, so you can get along better with other people. Thus by bringing skill and power and understanding, knowledge gives you one essential requirement for true happiness.

But what knowledge should you look for? The first choice naturally goes to knowledge in the field of your greatest interest–electronics. Become just a little better informed than those you will work with, and your success will be assured.

It pays to know–but it pays even more to know how to use what you know. You must be able to make your knowledge of value to others, to the rest of the world, in order to get cash for knowledge.

The NRI Course gives you knowledge, and in addition shows you how to use what you learn. Master thoroughly each part of your Course, and you'll soon be getting cash for your knowledge.

OSCILLATORS FOR COMMUNICATIONS EQUIPMENT

One of the most important circuits in electronics is the oscillator. If it were not for the oscillator, radio and television and many industrial electronics applications would not be possible. An oscillator is an amplifier which generates an ac signal. The frequency of the signal is determined by the value of the components in the oscillator circuit.

In this lesson you will begin with a study of the basic oscillator circuit. You will learn the characteristics of an oscillator and how the basic oscillator works. Then, you will study applications of the oscillator, learning the details of operation of various oscillator circuits. From there you will go into methods of controlling oscillator frequency. The lesson will conclude with a brief description of nonsinusoidal oscillators.

There are many different types of oscillator circuits. For convenience in studying them, we will divide them into two types: L-C oscillators and R-C oscillators. L-C oscillators are oscillators in which inductance and capacitance are used in the frequency-determining network. R-C oscillators are oscillators in which resistance and capacitance are used in the frequency-determining network. Both types of oscillators work on the same general principle, that of feeding some of the signal from the output circuit back into the input circuit. This feedback signal enables the oscillator to go on generating its own signal. The amount of signal that must be fed back into the input depends upon a number of things, but in general it must be enough to overcome the losses in the input circuit of the oscillator.

Perhaps one of the most important considerations in an oscillator circuit is how the energy is fed from the output circuit back into the input circuit. Although it is important to feed enough signal back into the input circuit, it is even more important for the signal fed from the output back into the input to be of the correct phase. If the phase of the feedback signal is not correct, instead of aiding the input signal, it will oppose it, and the oscillator will not oscillate.

Sometimes an oscillator is considered

as a converter circuit. In other words, it converts dc into ac. The dc is supplied by the power supply to the tube or transistor used in the oscillator circuit, which changes this dc energy to ac energy.

Oscillators are the only practical means of generating high-frequency radio waves. In the early days of radio, before practical oscillators were developed, rf signals were generated by means of high-frequency generators called alternators. However, there is a limit to how high a frequency a rotating machine such as an alternator can develop, and hence most radio transmission was carried out on very low frequencies.

The most important part of the oscillator is the resonant circuit, so before we begin let's review it. In a previous lesson, you learned that the resonant tank in a tuned amplifier biased class C could be made to store energy and to deliver that energy during periods when the tube or transistor was cut off. Oscillators function similarly to class C rf amplifiers in that the tank circuit must continue to supply an output once the input signal is removed.

One characteristic of a resonant circuit that we have not discussed is its ability to produce a damped wave when it is shock-excited. We will now see what we mean by a damped wave and see how it is produced by a resonant circuit.

DAMPED WAVES

Consider the circuit shown in Fig. 1. A coil and capacitor are connected in parallel and connected to a battery through a switch. For our discussion we must assume that the switch can be opened and closed instantaneously. Now let's see what happens when we close the switch for an instant.

At the instant the switch is closed, electrons flow from the negative terminal of the battery into side A of the capacitor. At the same instant, electrons will flow out of side B of the capacitor to the positive terminal of the battery. If the resistance in the circuit, which includes the battery resistance, is very low, the capacitor can charge up almost instantly to a voltage equal to the battery voltage. Thus, terminal A of the capacitor will be negative and terminal B will be positive.

At the same time, when the switch is closed, there will be some tendency for current to flow through the coil from terminal C to terminal D. However, you will remember that one of the characteristics of a coil or inductance is that it opposes any rapid change in the current flowing through it. The instant before the switch is closed, the current flowing through the coil is zero. The coil would like to keep it that way. When the switch is closed, the inductance of the coil tries to prevent a current from building up in the coil. Actually, there will be some small current flowing through the coil from terminal C to terminal D, but if the switch is closed only for an instant, the current will not be able to build up appreciably. Therefore, at the instant the switch is opened again we have the capacitor charged, as shown in Fig. 2A,

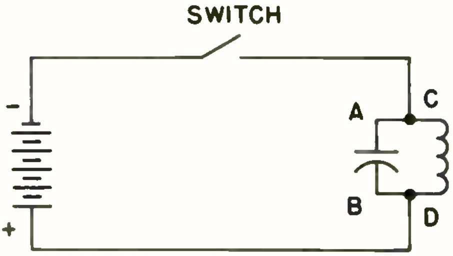

Fig. 1. A simple method of producing a damped wave.

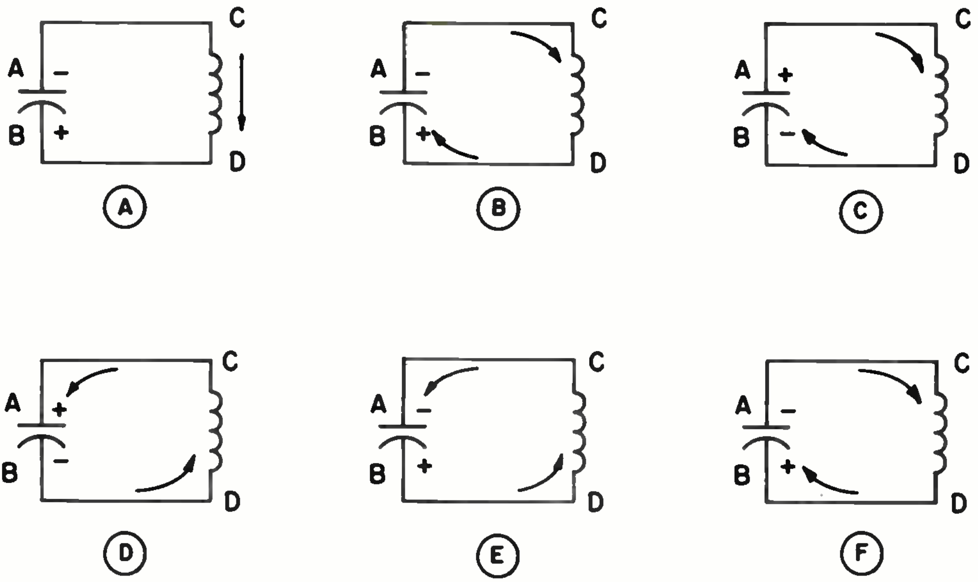

Fig. 2. How oscillation takes place in a resonant circuit.

and a small current flowing through the coil as indicated.

When the switch is opened and we have the situation shown in Fig. 2A, we have a capacitor that is charged, and immediately starts to discharge. As a result, a current flow will be set up in the circuit as shown in Fig. 2B. Now remember that a coil opposes a change in the current flowing through it. Therefore the capacitor cannot discharge instantly through the coil, but rather must build up a current in the coil which will build up a magnetic field about the coil. Eventually, the capacitor will build up a current flow in the coil and enough electrons will leave plate A to get to plate B to discharge the capacitor.

The discharge of the capacitor removes the voltage that caused current to flow through the coil. The magnetic field around the coil now collapses. The collapsing field generates an emf in the coil, which tends to keep the current flowing in the same direction as before. This continued current causes electrons to flow onto plate B of the capacitor, giving the capacitor a charge opposite to what it had at the start. This condition is shown in Fig. 2C.

After the field around the coil has collapsed, there is no emf to hold the charge on the capacitor. The capacitor now begins to discharge back through the coil as shown in Fig. 2D. The flow of current caused by the discharge of the capacitor builds up a magnetic field around the coil until the capacitor is fully discharged; the magnetic field collapses and keeps the current flowing. This current flow charges the capacitor with the same polarity it had at the instant the switch was opened. This is shown in Fig. 2E.

Again, the current will eventually drop to zero, and then the capacitor will once again begin to discharge through the coil in the opposite direction, this time with electrons flowing from plate A to plate B as shown in Fig. 2F.

Notice that in Fig. 2F we have the same situation as we had in Fig. 2B. In other words, we have gone through a complete cycle of events. The capacitor was charged with one polarity. This produced a current flow through the coil, which eventually charged the capacitor with the opposite polarity. The capacitor then began to discharge through the coil in the opposite direction, which built up a charge on it having the same polarity as the original charge placed on the capacitor. Once again this charge on the capacitor began the cycle of events all over again by attempting to discharge through the coil.

You might think that this oscillation, or backward and forward flow of current through the coil to charge and discharge the capacitor would continue indefinitely. Indeed, if we had a perfect coil and a perfect capacitor, once the oscillation was started, it would continue indefinitely. However, there is no such thing as a perfect coil or a perfect capacitor. There will be some losses in both parts, so instead of having an oscillation which continues indefinitely, we will have what is called a damped wave. The damped wave of voltage across the capacitor is shown in Fig. 3.

The important thing to notice in this damped wave is that the amplitude of each cycle is just a little bit less than the amplitude of the preceding cycle. In other words, the wave is slowly dying out because of losses in the resonant circuit. The lower the losses in the circuit, the greater the number of cycles that will occur before the wave disappears. On the other hand, the higher the losses in the circuit, the fewer the number of cycles.

If we could find some way of closing the switch in Fig. 1 for just an instant when plate A of the capacitor reaches its maximum negative charge, we could supply a small amount of energy to the resonant circuit to make up for losses in the circuit. If we continue to supply this small amount of energy once each cycle, then the resonant circuit will continue to oscillate indefinitely, and we could use it as a source of ac power. This is what an oscillator does, it supplies a pulse of energy at the correct time to make up for losses in the resonant circuit. We'll see how this is done later, but let's learn more about resonant circuits first.

FACTORS AFFECTING RESONANT CIRCUITS

There are several additional important things we should know about resonant circuits. For example, we should know the frequency at which oscillation takes place in a resonant circuit. We should also know what factors affect the loss of energy from cycle to cycle, in other words, how rapidly the wave train will die out.

Another term that we frequently encounter when dealing with resonant circuits is "period". We will now learn something about these factors.

Frequency. The frequency at which a resonant circuit oscillates will depend upon the inductance and capacitance in the circuit. We already know that resonance occurs when the inductive reactance of the coil is exactly equal to and

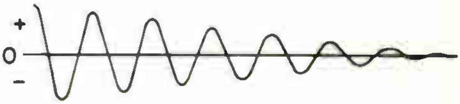

Fig. 3. Voltage across the capacitor.

canceled by the capacitive reactance of the capacitor. In other words, at resonance:

$$X_L = X_C$$

We know that the inductive reactance of a coil, X_L, is given by the formula:

$$X_L = 6.28 \times f \times L$$

and the capacitive reactance of a capacitor is given by the formula:

$$X_C = \frac{1}{6.28 \times f \times C}$$

Now, since resonance occurs when $X_L = X_C$, let's substitute the values for X_L and X_C and we will get:

$$X_L = X_C$$

$$6.28 \times f \times L = \frac{1}{6.28 \times f \times C}$$

and this can be manipulated to give us:

$$f^2 = \frac{1}{6.28^2 \times L \times C}$$

and now if we take the square root of both sides of the equation we get:

$$f = \frac{1}{6.28 \times \sqrt{L \times C}}$$

For convenience in expressing formulas of this type, the times sign is usually omitted, and in place of 6.28, the term 2π is often used, so you will usually see the formula for the frequency at which a resonant circuit will oscillate expressed as:

$$f = \frac{1}{2\pi \sqrt{LC}}$$

You should remember this formula because it is very important; but even more important, remember what the formula tells you. The formula says that the frequency of a resonant circuit varies inversely as the square root of the L-C product. Now remember as we mentioned before, when one factor varies directly with another, making one bigger makes the other bigger, and when two things vary inversely then we have the opposite situation; making one bigger makes the other smaller. Here we have a situation where the frequency varies inversely as the square root of the L-C product. This means that increasing the size of either L or C will reduce the frequency at which the resonant circuit oscillates, and reducing the size of either L or C will increase the frequency at which the resonant circuit oscillates. We can express this simply by saying: *Larger L or C, lower frequency; smaller L or C, higher frequency.*

In using this formula, the frequency of oscillation will be given in cycles per second and the value of L and C used must be in henrys and farads respectively.

Period. The period of a resonant circuit is the time it takes the resonant circuit to go through one complete oscillation. Thus, if we have a circuit that is resonant at a frequency of 1000 cycles per second, its period would be 1/1000 of a second, and if we have a resonant circuit that is resonant at a frequency of 1,000,000 cycles per second, the period would be 1/1,000,000 of a second.

The period of a resonant circuit is given by the formula:

$$P = \frac{1}{f}$$

where P represents the period of the resonant circuit in seconds and f the frequency in cycles per second.

Since in electronics we are usually dealing with comparatively high frequencies, it follows that the period of most resonant circuits will be only a very small fraction of a second. As a matter of fact, the period of many resonant circuits will be only a small fraction of a millionth of a second. Therefore, to simplify things, the microsecond is frequently used in electronics work as a unit of time. A microsecond is 1/1,000,000 (one millionth) of a second. Thus if a resonant circuit has a period of 5/1,000,000 (five millionths) of a second we can say that its period is 5 microseconds, or if another resonant circuit has a period of 1/10,000,000 (one ten millionth) of a second, we can say this period is one-tenth of a microsecond.

In order to show the cycle-time relationship, the frequency of a circuit is measured in units called HERTZ. One Hertz being equivalent to one complete cycle in one second, 1,000 cycles in one second would then be 1,000 Hertz (Hz) or one kilohertz (kHz). 1,000,000 cycles in one second would be one megahertz (MHz). These terms are replacing the older terms of kilocycles (kc) and megacycles (mc) still used in many publications.

The Q Factor. The number of cycles that will occur when a resonant circuit is shock-excited depends almost directly upon the Q of the coil. The higher the Q, the more cycles will occur.

The Q of a coil tells us essentially how good a coil we have. A coil that has a high Q has a high inductive reactance compared to the resistance of the coil. A coil with a low Q has high resistance compared with the inductive reactance.

The Q of a coil is expressed by the formula:

$$Q = \frac{X_L}{R}$$

and we can express X_L as equal to:

$$6.28 \times f \times L$$

and substituting this in the formula for the Q of a coil we get:

$$Q = \frac{6.28 \times f \times L}{R}$$

If we examine this formula, we see that the Q varies directly as the frequency and inductance and inversely as the resistance. Therefore, you might think that increasing the frequency of the resonant circuit by using a smaller capacitor in conjunction with the coil will result in a higher Q. This will often happen, but the increase in Q is not as great as might be expected, because the resistance of the coil is the ac resistance rather than the dc resistance. The ac resistance of a coil actually represents ac losses in the coil and this varies directly as frequency varies. Therefore, increasing the frequency of the resonant circuit increases the inductive reactance of the coil, but at the same time it increases the losses so that the Q normally does not increase as fast as we might expect.

In a resonant circuit with a high Q coil there will be a large number of cycles in a damped wave train set up by shock-exciting the resonant circuit. In other words, the amplitude of one cycle will be very little less than the amplitude of the preceding cycle. However, if the Q of the coil is low, then the losses in the coil will be quite high so that the amplitude of each cycle will be substantially less than the amplitude of the preceding cycle. This means that the oscillation will be damped out quite rapidly and the number of cycles that occur when the circuit is shock-excited will be somewhat limited.

In most oscillator circuits a comparatively high Q coil is used. The reason for this is that if the coil has a high Q, then only a small amount of energy must be supplied by the tube or transistor in the oscillator circuit in order to sustain oscillation. On the other hand, if the coil has a low Q, the losses in the resonant circuit will be quite high, with the result that the tube or transistor used in the oscillator circuit must supply a comparatively large amount of energy in order to keep the oscillation going.

SELF-TEST QUESTIONS

(a) What type of feedback is used in oscillator circuits?
(b) If the inductance of an L-C circuit is increased, what happens to the frequency?
(c) If the Q of the resonant circuit is increased, what happens to the damped wave train?
(d) If the resonant frequency of an L-C circuit is 2000 kHz, what is the period of one cycle?

The Basic Oscillator

The function of the switch in Fig. 1 is to supply energy of the proper phase and at the proper time to sustain oscillations in the resonant circuit. At radio frequencies it would be impossible for a mechanical switch to do this. Therefore, we must use an electronic switch such as a vacuum tube or transistor.

THE ELECTRONIC SWITCH

In order to see how the vacuum tube can be used as an electronic switch, let's go back to the basic circuit we had in Fig. 1. We have repeated this circuit as Fig. 4A. It is exactly the same as Fig. 1 except we have simply indicated where the battery voltage is to be connected instead of actually showing the battery in the circuit. In practice, we could use either a battery or the dc output of a suitable power supply. If we can momentarily close the switch, we will charge the capacitor C_1 and produce oscillation in the parallel resonant circuit consisting of C_1 and L_1. However, this oscillation will die out after a number of cycles because of the losses in a resonant circuit, unless we can find some way of supplying additional energy to the resonant circuit to make up these losses. If we could close the switch at the right instant each cycle, we could recharge capacitor C_1 once each cycle and keep the oscillation going. However, if the resonant frequency of the circuit is several hundred Hertz or higher, it would be impossible to close the switch manually at the correct instant to keep the oscillation going. As a matter of fact, it would be difficult to do this mechanically except at a very low frequency.

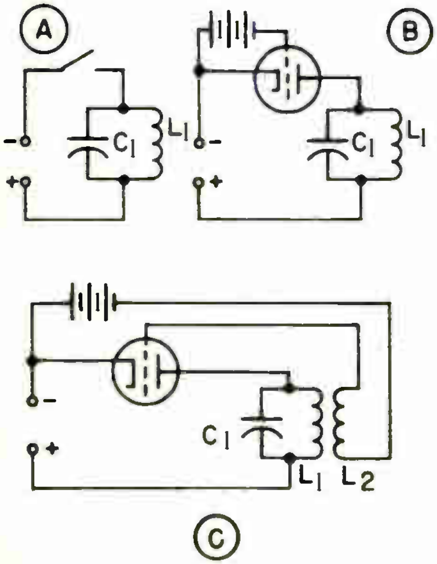

Fig. 4. Using a tube as an electronic switch to supply the losses in a resonant circuit.

In Fig. 4B, we have replaced the switch with a vacuum tube. The cathode of the vacuum tube is connected to the negative side of the power supply or battery, and the plate of the tube is connected to the resonant circuit. Between the cathode and the grid of the tube, we have connected a battery that will place a negative voltage on the grid of the tube. The battery voltage in the grid circuit is high enough to bias the tube beyond cutoff. Thus, with the circuit exactly as shown in Fig. 4B, the bias on the tube is so high that there will be no current flowing through the tube and hence no way to charge capacitor C_1 and start the resonant circuit oscillating. We have in effect the same situation as we have in Fig. 4A with the switch open.

Now let's look at the circuit shown in

Fig. 4C. Here we still have the tube connected in the circuit in exactly the same way except that we have added a coil, L_2, between the negative terminal of the grid battery and the grid of the tube. This coil is placed near L_1 so that it will be inductively coupled to L_1. Thus, .if there is any change in the magnetic field about L_1, the changing flux will induce a voltage in L_2.

Now let's consider what will happen if we momentarily short the plate and cathode of the tube together. If we do this, capacitor C_1 will be charged. As soon as we remove the short, C_1 will start to discharge through L_1 and in doing so will build up a magnetic field about L_1. The changing lines of flux will cut L_2 and induce a voltage in it. This voltage in L_2 will be in series with the battery voltage applied between the cathode and grid of the tube. If the end of L_2 that connects to the grid of the tube is negative, and the other end positive, then the voltage induced in L_2 will add to the grid bias, biasing the grid still further negative so that no current can flow from the cathode to the plate of the tube. However, if the voltage induced in L_2 has a polarity such that the end of L_2 that is connected to the grid is positive, and the other end is negative, then this voltage will oppose the battery bias voltage and reduce it so that the total grid bias will be reduced below the point where the plate current is cut off, and current can flow through the tube. Therefore, by connecting L_2 with the proper polarity, we can arrange the circuit so that when the plate side of capacitor C_1 reaches its negative peak, the tube will conduct, and a burst of electrons will flow through the tube, charging C_1 still further. Thus, any loss in the charge across C_1 due to losses in the resonant circuit will be made up for by the burst of electrons flowing through the tube.

In Fig. 5, we have shown a number of sine-wave cycles such as the oscillation that might occur in the L_1-C_1 resonant circuit. The shaded pulses represent the bursts of current flowing through the tube that will reinforce the oscillation and keep it going. Notice in Fig. 5 that the burst of current flowing through the tube occurs at the correct instant to aid the oscillation. Also, notice that the current burst occurs for only a small fraction of a cycle. The current does not flow through the tube during the entire cycle.

For several reasons the oscillator circuit shown in Fig. 4C is not a practical circuit. For one thing, the battery used to provide the negative bias on the grid is somewhat cumbersome. If we were using a power supply to furnish the voltage to operate this oscillator from a power line, we would not want to be bothered with a separate battery to supply the grid bias. Furthermore, with this type of arrangement, it would be possible to pick up such a high voltage pulse in L_2 that the tube would pass an extremely high current when it was driven in a positive direction. As the grid bias battery aged and the voltage from this battery dropped, an even higher current pulse would flow through the tube. As a matter of fact, the pulse might be so high that the tube could be damaged.

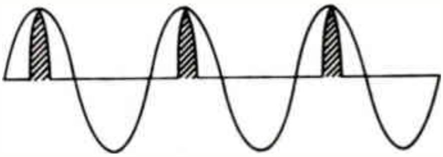

Fig. 5. The oscillator pulse is timed to occur at the peak of the oscillation in the tank circuit to reinforce the oscillation.

Both of these objections can be overcome by modifying the circuit as shown in Fig. 6. Let's look at Fig. 6A first. In Fig. 6A, you will see that we have replaced the battery in the grid circuit by a resistor, R_1, with capacitor C_2 connected across it. In other respects the circuit is identical to the circuit shown in Fig. 4C.

Let's see exactly how this circuit works. When voltage is first supplied to this circuit, there will be no grid bias on the tube. The tube starts to conduct and charges capacitor C_1. Electrons will flow into the side of this capacitor that connects to the plate of the tube and out of the other side. At the same instant, current will start to flow through L_1 and there will be a rapid change in the lines of flux about this coil. The changing magnetic lines will cut L_2, and induce a rather high voltage in it. Coil L_2 is connected so that the grid of the tube will be driven in a positive direction, which will result in a still further increase in current flowing from the cathode to the plate of the tube, which will charge C_1 still further.

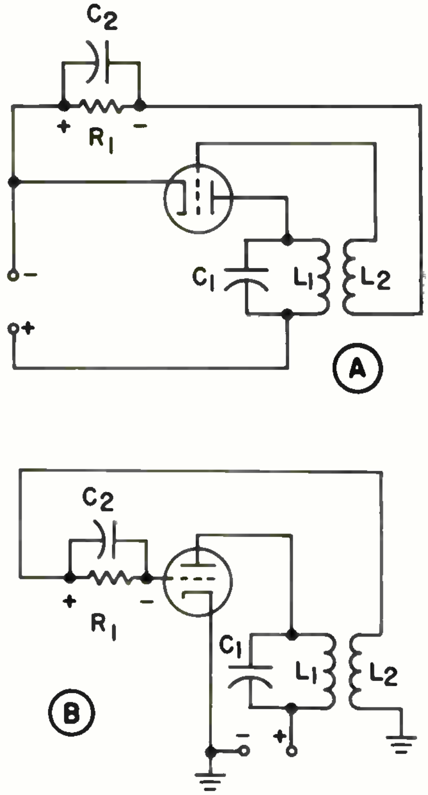

Fig. 6. A tuned-plate oscillator.

Since the grid of the tube will be driven in a positive direction, it too will attract electrons, and electrons will flow from the cathode of the tube to the grid, through L_2, and then through R_1 back to the cathode of the tube. In flowing through R_1, they will set up a voltage drop across it and charge capacitor C_2 with the polarity indicated on the diagram.

Eventually the rate at which the flux lines are cutting L_2 will decrease, so the voltage induced in coil L_2 will drop. The voltage across R_1 will cut off the flow of plate current in the tube. Capacitor C_2 starts to discharge through R_1 and keeps the grid of the tube at a high enough negative potential to keep it cut off. When this happens, we have opened the switch as in Fig. 1 and an oscillation starts in the tank circuit. The capacitor and coil begin exchanging energy back and forth. At the correct instant, once in each cycle, the grid of the tube will be driven positive by the voltage induced in L_2 by the changing flux from L_1 so that the tube will pass a burst of electrons to recharge C_1 and make up any energy lost in the tank circuit.

The oscillator we have been discussing is called a tuned-plate oscillator. In actual practice, the circuit is modified and you will usually see it like Fig. 6B. Notice that the position of the grid resistor and grid capacitor, R_1 and C_2, have been changed with reference to L_2. In other words, tracing from the grid of the tube, we come to the grid resistor and grid capacitor first and then through L_2 to ground. However, regardless of how the resistor and capacitor are connected in series with L_2, the action of the circuit is the same.

This type of oscillator has several disadvantages that can be eliminated by different circuitry. However, since it is a basic circuit and enables us to see exactly how the tube is acting as a switch, it is a good circuit to start our study of oscillators with.

SELF-REGULATION

The oscillator circuits shown in Fig. 6 are self-regulating. This means that they tend to control the flow of current through the tube themselves. For example, suppose the amplitude of the pulse picked up by L_2 should increase for any reason; if this happens, the pulse will drive the grid even more positive than normal. With a higher positive voltage on the grid, a greater number of electrons will be attracted to it. An increase in the number of electrons reaching the grid will mean that more electrons must flow through R_1. The voltage developed across R_1 depends upon two things: the size of the resistor and the number of electrons flowing through it. Therefore, if the number of electrons flowing through R_1 increases, the voltage developed across it will increase.

Notice the polarity of the voltage across R_1. The grid end of this resistor is negative, so this bias voltage tends to reduce the flow of current through the tube. Therefore, the increase in negative voltage across R_1 will subtract from the increase of positive voltage across L_2 so that the net drive voltage applied to the grid remains almost the same. Thus, even though something might cause the voltage developed in L_2 to increase, the tube will compensate for this change by developing an increased bias so that the burst of plate current flowing through the tube will remain essentially constant.

OSCILLATOR-AMPLIFIER

Up to this point, we have been considering the tube as a switch that closed at the proper instant to replenish the losses in the resonant circuit. We can also consider the tube as an amplifier that is amplifying part of its own output. For example, L_1 and L_2 in Fig. 6B are inductively coupled together. Part of the output produced across L_1 is coupled to L_2, where it is fed back into the input circuit. This signal fed into the input circuit is then amplified by the tube and fed to the resonant circuit L_1-C_1 in the output. The cycle then continues, with part of the output being coupled to L_2 and once again being fed back to the input. Thus, the oscillator can indeed be considered as an amplifier that feeds part of its own output signal back to the input, where it is amplified once again.

Of course, the signal fed back to the input must be of the proper phase to sustain oscillation. The signal must drive the grid in a positive direction when the plate current flowing through the tube should increase. Feedback of this type is called regenerative feedback. In some amplifiers a small amount of regenerative feedback is used to improve the gain of the amplifier. However, in an oscillator, enough regenerative feedback is used to start the stage oscillating, and to keep it oscillating.

OSCILLATOR FREQUENCY

You already know that the resonant frequency, f_0, of a circuit containing L and C is:

$$f_0 = \frac{1}{2\pi\sqrt{LC}}$$

The resonant frequency is also often expressed in terms of resonant angular frequency, ω_0:

$$\omega_0 = \frac{1}{\sqrt{LC}}$$

where $\omega_0 = 2\pi \times f_0$. This expression comes from the fact that there are 2π radians in 360°. A radian is an angular measurement equal to approximately 57°. Since there are 2π radians in 360°, a vector rotating at f_0 Hertz travels through $2\pi \times f_0$ radians per second.

You might at first expect an L-C oscillator to operate at exactly ω_0, the resonant frequency of the L-C circuit. However, there is always some resistance in the circuit that affects the oscillator frequency. Furthermore, the plate resistance of the tube affects the oscillator frequency so that the actual frequency of the oscillator, ω, is:

$$\omega = \omega_0\left(1 + \frac{R}{R_p}\right)$$

where ω_0 is the angular resonant frequency of the L-C circuit, R represents the resistance in the resonant circuit, and R_p is the plate resistance of the tube.

In most oscillator stages the value of R will be small, because the Q of the oscillator coil will be high. At the same time, the plate resistance of the tube will be reasonably high so the term R/R_p will be small and ω will be almost equal to ω_0. However, the fact that R and R_p do enter into the frequency means that if either of these values change, the oscillator frequency will change. Thus, oscillator stability depends not only on keeping the values of L and C in the resonant circuit constant, but also the value of R and R_p must be kept constant.

OSCILLATOR STABILITY

One of the most important considerations in oscillator circuits is the stability of the oscillator – in other words, how stable the oscillator frequency is. The output frequency of a radio transmitter is controlled by the oscillator, and if the oscillator frequency does not remain constant, the transmitter output frequency will not be constant.

We have already pointed out that the oscillator frequency depends not only upon the inductance and capacitance in the resonant circuit, but also on other factors such as the resistance of the oscillator coil and the plate resistance of the oscillator tube. Now, let us consider each of these factors to see exactly what effect each has on the oscillator frequency.

Tank Inductance and Capacitance. The inductance in the oscillator tank circuit is made up of the inductance of the oscillator coil, plus any stray inductance in the circuit. The capacitance in the oscillator tank circuit is made up of the capacity connected across the oscillator coil plus any tube capacity that may be in parallel with the coil and capacitor, and the distributed wiring capacity in the circuit. The inductance in the circuit consists of the oscillator coil, the inductance of the leads connecting the coil to the tube and other parts in the circuit, and any inductance that other parts in the circuit may have. The capacity in the circuit consists of the capacity of the variable capacitor across the oscillator coil, the input capacitance of the tube, the stray wiring capacity in the circuit, plus any stray capacity the coil may have. This total inductance plus this total capacity are the major factors that determine the oscillator frequency.

When an oscillator is first turned on, the values of the inductance and capacitance in the tank circuit will usually change as the tube and other parts in the circuit heat. Therefore, the oscillator stability is usually measured in terms of the oscillator's ability to maintain a constant frequency after enough time has been allowed for the tube and parts to reach normal operating temperature. It is common practice in some transmitters to leave the oscillator on at all times to avoid any frequency drift during the warmup period. In some transmitters, the oscillator coil and capacitor are placed in an oven that is kept at a constant temperature by a thermostatically controlled heater to minimize changes in inductance and capacity due to temperature changes. In some oscillators, special temperature compensating capacitors are connected across the oscillator tank circuit to minimize frequency drift due to temperature changes. These capacitors usually have a negative temperature coefficient. This means that their capacity decreases as the temperature increases. By using a capacitor of this type with the correct temperature coefficient, it is possible to compensate for any increase in inductance or capacitance in other parts in the circuit as the temperature increases.

Changing a tube in the oscillator circuit can result in a change in oscillator frequency. The input capacity of the tube used in the oscillator circuit makes up part of the oscillator tank circuit. The input capacity of different tubes of the same type may vary appreciably, so putting a new tube in this or any other oscillator circuit may change the tank circuit capacitance, and hence the frequency. Therefore, if you replace the oscillator tube in a transmitter you should check the output frequency.

Tank Losses. Earlier we pointed out that the angular resonant frequency, ω_o, of the oscillator tank circuit is given by:

$$\omega_o = \frac{1}{\sqrt{LC}}$$

and at the same time, the actual frequency at which the oscillator oscillates is given by:

$$\omega = \omega_o\left(1 + \frac{R}{R_p}\right)$$

where R is the resistance in the tank circuit and R_p the plate resistance of the tube.

The term R represents the ac resistance of the tank circuit, and as such represents all the losses in the tank circuit. Thus, this term includes such factors as coil resistance and losses from the oscillator circuit due to loading of the circuit. Therefore, any change in the oscillator coil resistance will result in a change in oscillator frequency. Similarly, a change in the loading on the oscillator will result in a change in oscillator frequency. Thus, for maximum stability, the oscillator should be lightly loaded and the load on the oscillator must remain constant.

The Plate Resistance. Since the plate resistance of the tube enters into the frequency of the oscillator, any change in plate resistance will produce a change in the oscillator frequency. The plate resistance of the tube will change if either the plate or grid voltage is changed in the case of a triode, and if the grid or screen voltage (and to some extent the plate voltage) is changed in the case of a pentode. Thus, it is important that the voltages supplying the oscillator be kept constant. These voltages must also be free of hum, which actually is a changing voltage superimposed on the dc supply voltage, because the hum voltage could produce a constantly changing plate resistance which will result in a frequency-modulated signal being generated by the oscillator.

Changes in loading on the oscillator may affect the bias developed on the grid of the tube. When this happens, the grid voltage will change, causing the plate resistance and hence the frequency to shift.

Looking at the expression for the oscillator angular frequency, we see that the frequency is equal to the angular frequency of the tank circuit times one plus a fraction. Thus, the oscillator frequency will be higher than the resonant frequency of the tank circuit. Also, if the term R/R_p is small, which it usually is, the oscillator frequency will differ from the tank frequency by only a small percentage. However, at high frequencies, this small percentage or fraction can represent a great enough frequency change to cause concern. For example, if the resonant frequency of a tank circuit is 10 MHz and the value of R/R_p is only .01, .01 X 10,000 kHz represents 100 kHz so the oscillator frequency would be 10,101 kHz, or 10.1 MHz. If the value of R_p changed because of changing voltages on the tube, the oscillator might drift 50 kHz or more above or below this frequency.

TRANSISTOR OSCILLATORS

Of the three basic transistor configurations, the common emitter is the most frequently used in rf oscillator circuits. There are several reasons for this. The power, current and voltage gains of the common-emitter configuration are all greater than one, and the highest possible power gain can be had. Also in the common-emitter circuit, moderate input and output impedances make less power necessary for feedback. In the common-base configuration, low input and high output impedances inherent in the circuit cause a mismatch in the feedback circuit, producing greater losses and requiring more feedback. The current gain in the common-base circuit is less than one, even though voltage and power gains are greater than unity. A somewhat similar condition exists in a common collector circuit where high input and moderate output impedances exist. Voltage gain is less than unity, but current and power gains are greater than one.

Transistor oscillators may be designed to operate class A, B or C depending on the desired efficiency. Since rf oscillators are also amplifiers, bias supply and temperature stabilization are similar to rf amplifiers discussed in a previous lesson.

A combined voltage divider and feedback type biasing arrangement is often used because it helps produce oscillation and at the same time establishes a stable dc bias point. Emitter biasing with a bypass capacitor is also used, the operation being similar to grid leak biasing. Usually the amplitude is regulated by driving the transistor into saturation or by using special diode limiting circuits. Either shunt or series type collector feed may be used, the shunt type being preferred for greater output efficiency.

Frequency stability of the transistor oscillator is equivalent to, and sometimes greater than the electron tube oscillator. The use of lower voltages, currents and power, permits construction of better tank circuits. In particular, the low power used with transistors aids in stability due to the decrease in heat. One major disadvantage of transistors is their critical operating point. A slight bias change can cause a large shift in frequency.

The collector-to-emitter capacitance of the transistor also affects frequency stability. This internal capacitance will vary with changes in collector or emitter voltages and with temperature. In high frequency oscillators it is sometimes necessary to place a swamping capacitor across the collector to emitter leads. The total capacitance of the two in parallel results in a circuit which is less sensitive to voltage changes. The added capacitor may be a part of the tuned circuit.

Partial compensation of voltage changes may be obtained by use of a common supply. Since an increase in collector voltage tends to increase oscillator frequency and an increase in emitter voltage decreases oscillator frequency, the use of a common bias source for both the collector and emitter helps stabilize the frequency. By using a common bias source, a change in one is somewhat counteracted by the change in the other.

The three basic transistor configurations used for oscillators are shown in Fig. 7. Bias and feed arrangements are omitted for simplification. Although any of the three basic transistor configurations can be used, generally only two, the common-emitter and common-base, are used in actual practice. The common-emitter configuration offers the advantages of easily matched input and output impedances and its close parallel to the electron tube.

The major advantage of the common-base circuit is that at high frequencies collector-emitter capacitance helps feedback an in-phase voltage independently of tickler coil L_1, and oscillation is more easily obtained. In the common-emitter circuit, this capacitance feeds back an out-of-phase voltage which requires additional feedback from the tickler coil to

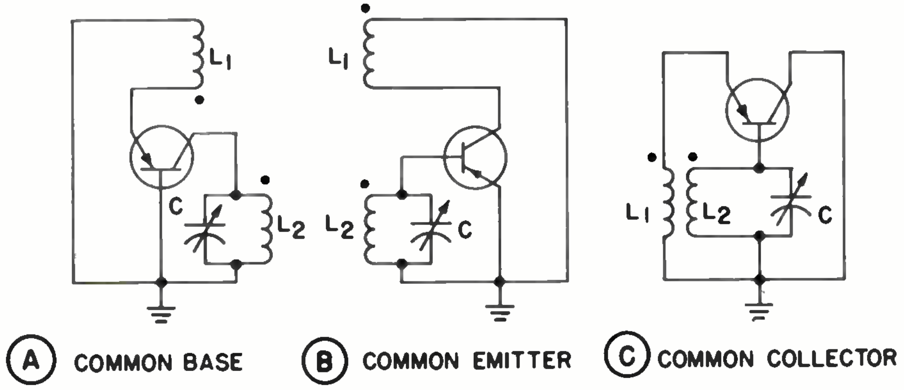

Fig. 7. Tickler coil oscillators.

overcome it. In both the common-base and common-emitter circuits, oscillation is easily sustained. This is the result of feedback provided by voltage induced through the mutual inductance of L_1 and L_2. In the common-collector circuit, the voltage gain is always less than unity, therefore feedback tends to be insufficient for stable oscillations at the lower frequencies. At the higher frequencies it is assisted by the collector-emitter capacitance. Sometimes, an external capacitor is added between the collector and emitter to give additional feedback.

Operation of the L-C circuit is similar to that of the electron tube circuit. As the oscillator is switched on, current flows through the transistor as determined by the biasing circuit. Initial current produces a feedback voltage between the collector and the emitter which is in-phase with the input circuit. As emitter current increases, collector current increases and additional feedback between L_1 and L_2 causes the emitter current to increase until saturation is reached. When saturation is reached, emitter current is no longer changing (increasing), and the induced feedback voltage is therefore reduced. At this time the collapsing field around the tank and tickler coils induce a reverse voltage into the emitter circuit which causes a decrease in the emitter current, thus causing a decreasing collector current. The decreasing current then induces a greater reverse voltage in the feedback loop driving the emitter current toward cutoff.

Although the emitter is cut off, a small reverse (leakage) current flows. This current has no effect on the operation of the circuit but it does represent a loss which lowers the efficiency. In this respect the transistor differs from the electron tube, which has zero current at cutoff.

The discharge of the tank capacitor through L_2 will cause the voltage applied to the emitter to rise from a reverse-bias to forward bias condition. Emitter and collector current start to increase and the cycle repeats itself.

The transistor oscillator circuit that most closely resembles the tuned-plate vacuum tube oscillator is the tuned-collector oscillator. This circuit is shown in Fig. 8.

Notice that in this circuit the resonant circuit consisting of C_1-L_1 is in the collector circuit of the transistor. L_2 is inductively coupled to L_1 so energy is fed from L_1 to L_2. The signal developed in L_2 is fed back to the base of the transistor.

In the operation of this oscillator, resistor R_1 and capacitor C_2 develop a bias voltage sufficient to cut off the transistor. The signal needed to overcome this cutoff bias is induced in L_2 and applied between the base and the emitter. Since this is a PNP transistor, the signal in L_2 must make the base negative and the emitter positive at the instant that a pulse of current is needed from the collector in order to sustain oscillation in the resonant circuit consisting of L_1 and C_1.

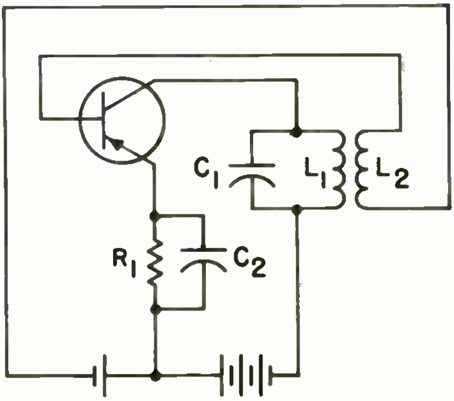

Fig. 8. A tuned-collector oscillator.

SELF-TEST QUESTIONS

(e) Describe the phase relationship between the plate current wave shape and the voltage wave shape developed across L_2 in Fig. 4C.

(f) What makes the oscillator in Fig. 6B self-regulating in regard to the amplitude of the grid signal?

(g) List three methods of reducing frequency drift due to changes in temperature in a resonant circuit.

(h) In high frequency transistor oscillators what is sometimes used to compensate for collector-to-emitter capacitance?

(i) In the oscillator circuit in Fig. 8, where is the bias developed and what component develops the signal that overcomes this bias?

Practical Oscillator Circuits

The oscillator circuits we have discussed up to this point weren't very practical. They were used to illustrate some of the basic characteristics of oscillators. Let us now look at some practical circuits actually found in communication equipment. These oscillators are grouped according to the type of resonant circuit used, inductance-capacitance (L-C) or resistance-capacitance (R-C).

L-C OSCILLATORS

The L-C oscillators can be placed into one of two classifications: those using inductive feedback and those using capacitive feedback. The inductive feedback oscillator uses inductive coupling to return a portion of the output back to the input. The capacitive feedback circuit uses capacitive coupling to accomplish this. Although there is some difference in the circuitry involved, both types are L-C oscillators, and the net result is essentially the same.

OSCILLATORS USING INDUCTIVE FEEDBACK

One of the most important and most widely used oscillators in electronics work is the Hartley oscillator. This oscillator uses inductive feedback. The resonant circuit is placed in the grid circuit of the tube or the base circuit of the transistor instead of in the output circuit as in the case of the tuned-plate and tuned-collector oscillators. However, before we look at the Hartley oscillator let's look at another oscillator which will help you understand how the Hartley oscillator works. Let's first look at the tuned-grid oscillator.

Tuned-Grid Oscillator. Two versions of the tuned-grid oscillator are shown in Fig. 9. The circuits are basically the same; the only electrical difference is in the connection of the grid resistor R_1. In the circuit shown in Fig. 9A, R_1 is connected directly across the grid capacitor C_2, whereas in the circuit shown in Fig. 9B, R_1 is connected between the grid and the cathode of the tube. The action of R_1 is the same in both cases; it provides a path for the electrons striking the grid of the tube to get back to ground or the cathode

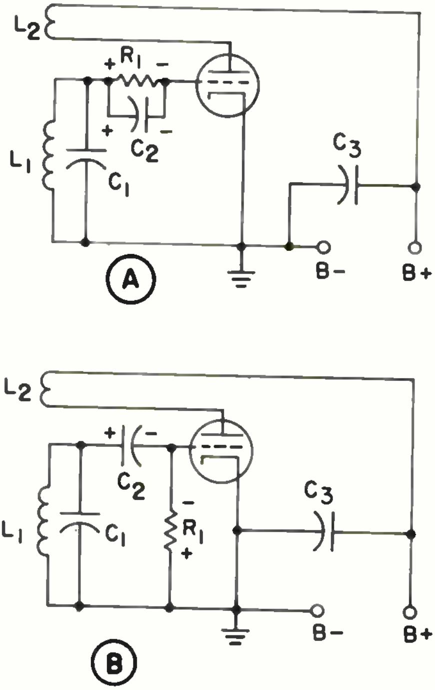

Fig. 9. Two versions of the tuned-grid oscillator.

of the tube. In the circuit of Fig. 9A, when C_2 discharges through R_1 to develop negative bias for the tube, there is no discharge through the tank circuit. In Fig. 9B, when C_2 discharges through R_1, the discharge current also flows through the tank circuit.

Actually, the biggest difference between this oscillator and the tuned-plate oscillator that you already studied is that the resonant circuit is in the grid circuit instead of the plate circuit. With this circuit, when the power is turned on, changes in plate current will set up a changing magnetic field about L_2. L_2 is inductively coupled to L_1 so the changing magnetic field about L_2 will induce a voltage in L_1. The induced voltage charges capacitor C_1, starting the oscillatory discharge in the tank circuit consisting of L_1-C_1. The voltage across C_1 becomes the grid voltage because the value of C_2 is large enough so that its reactance is so small at the frequency of oscillation, that the grid is, in effect, connected directly to C_1.

Now since the increasing plate current causes the end of C_1 that is connected to the grid through C_2 to swing in a positive direction, the grid of the tube is driven in a positive direction. Driving the grid positive produces two effects; it increases the plate current, causing C_1, and hence the grid, to be driven still further in a positive direction, and it causes grid current to flow, which charges C_2 with the polarity shown on the diagram.

Now if the plate current of the tube could keep on increasing indefinitely, the grid end of C_1 would be driven more and more positive. However, there is a limit to how high the plate current can become, because a balance will be reached between the positive voltage across C_1 and the negative voltage across C_2. When this happens, the plate current flowing through L_2 will no longer change. We will no longer have voltage induced in L_1, and C_1 will begin to discharge through L_1, setting up an oscillation in the L-C circuit. As soon as this happens, the positive voltage on the grid end of C_1 begins to disappear, and the plate current will be cut off by the negative voltage across C_2. The L-C circuit is now free to oscillate as though the tube were removed from the circuit. C_2 meanwhile starts to discharge through R_1, setting up the voltage drop across it as shown on the diagram. During the next half cycle when the voltage on the grid end of C_1 again becomes positive, it will drive the grid in a positive direction enough to let some plate current flow through the tube; this will result in a change in the field about L_2 which will induce a voltage in L_1 which drives the capacitor and the grid voltage still further in a positive direction.

The important point to remember about this oscillator is that the energy needed to sustain the oscillation in the tank circuit, consisting of L_1 and C_1, is inductively coupled to L_1 from L_2. This energy comes from the plate of the tube in the form of bursts of plate current which produce a changing magnetic field about L_2. These bursts of current are the result of the grid of the tube being driven positive by the voltage across C_1 swinging positive once each cycle.

The Hartley Oscillator. Two Hartley oscillators are shown in Fig. 10. The circuit shown in Fig. 10A uses a vacuum tube, whereas the one shown in Fig. 10B uses a transistor. Although the operation of the two circuits is so similar that if you understand one, you will understand the other, we will go through both circuits in considerable detail.

Notice the difference between the

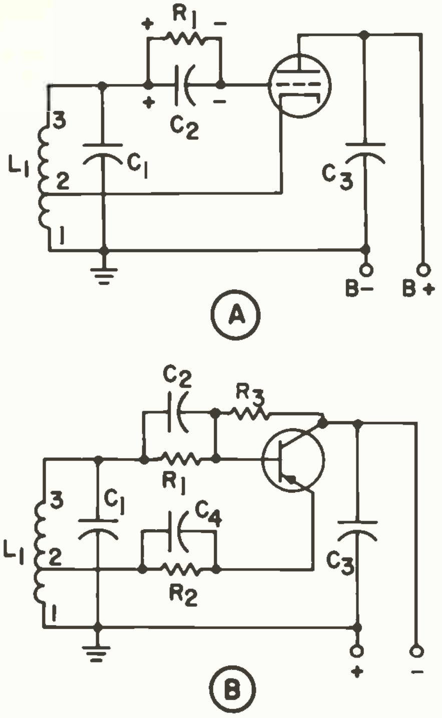

Fig. 10. Typical Hartley oscillators; a vacuum tube Hartley oscillator is shown at A, and a transistorized one at B.

Hartley oscillators and the tuned-grid oscillators. The tuned-grid oscillator has two coils, whereas the Hartley oscillator uses only a single tapped coil. In the circuit shown in Fig. 10A, the cathode of the tube is connected to the tap, and in the circuit shown in Fig. 10B, the emitter of the transistor is connected to the tap.

In the circuit shown in Fig. 10A, when the plate current starts to flow through the tube, current must flow through the lower half of the coil between terminals 1 and 2. Since the entire coil is wound on a single form, all the various turns of the coil are inductively coupled together. Therefore the increasing plate current flowing between terminals 1 and 2 will produce a changing magnetic field which will induce a voltage in the portion of the coil between terminals 2 and 3. This voltage will charge capacitor C_1 with the polarity such that the end of the capacitor that connects to the junction of C_2 and R_1 is positive. Again since the value of C_2 is chosen so that its reactance is practically zero at the oscillation frequency, the grid of the tube is in effect connected directly to C_1. This means that the increase in plate current will drive the grid of the tube in a positive direction, causing a still stronger burst of current through the coil. This in turn causes still higher induced voltage between terminals 2 and 3 which again charges capacitor C_1 still further. At the same time when the grid is driven positive, it will attract electrons, and C_2 will be charged with the polarity shown.

As in the tuned-grid oscillator, the point is eventually reached where there is a balance between the positive voltage applied to the grid by C_1 and the negative voltage applied to the grid across C_2 and R_1 so that there is no further increase in plate current. This means that the magnetic field produced by the current flowing between terminals 1 and 2 becomes constant and no further voltage will be induced in the coil. C_1 starts to discharge through the coil, and the oscillating cycle is started. Furthermore, the positive voltage on the end of C_1 that connects to the grid of the tube through C_2 disappears, and the tube stops conducting.

Again, the tube will be biased beyond cutoff by the discharge of C_2 through R_1. These electrons charge C_2 during the portion of the cycle when the grid is conducting. When grid current stops flowing, C_2 will discharge through R_1, setting up a voltage drop across it such that the grid end is negative. This voltage across R_1 maintains the bias on the grid of the oscillator tube.

In some cases you will see slight variations of the Hartley oscillator circuit. In some instances, R_1 may be connected between the grid and cathode or from the grid of the tube directly to ground. In another variation the cathode connects directly to ground, R_1 connects between the grid of the tube and ground, and then the plate of the tube connects directly back to terminal 1 of the oscillator coil. The B+ voltage is then applied to terminal 2 of the coil. This is simply a modification of the Hartley oscillator circuit; it works in exactly the same way as the Hartley oscillator shown in Fig. 10A.

In the circuit shown in Fig. 10B we have a PNP transistor. When holes begin to travel from the emitter to the collector, electrons will flow from the emitter through R_2 to terminal 2 on the coil. From terminal 2 they will flow through the coil to terminal 1 and back to the positive terminal of the battery. The electrons, in flowing through the coil from terminal 2 to terminal 1, will build up a field about this part of the coil. This field will be a changing field as the current builds up, and this will induce a voltage in the portion of the coil between terminals 2 and 3. This induced voltage will charge C_1 with the polarity such that the end connecting to terminal 3 of the coil is negative and the other end is positive. This negative voltage on one end of C_1 will be applied to the base of the transistor through capacitor C_2 because C_2 has a low reactance at the frequency of oscillation. The negative voltage on the base of the transistor will increase the forward bias across the emitter-base junction, causing an increase in the number of holes flowing from the emitter to the collector. This causes a still further increase in the electron movement from terminal 2 to terminal 1 of the coil, causing the base of the transistor to be driven still further in a negative direction.

In this circuit when the number ot holes flowing from the emitter to the collector increases, terminal 3 of the coil will be driven in a negative direction, and when the holes flowing from the emitter to the collector decrease, terminal 3 will be driven in a positive direction. Remember that in a PNP transistor, driving the base in a negative direction causes the holes moving through the transistor to increase, whereas driving it in a positive direction causes the number of holes flowing from the emitter to the collector to decrease. The burst of hole movement through the transistor causes the electron movement from terminal 2 to terminal 1 of coil L_1 to flow through the coil in burst, and this burst of energy makes up for any losses in the resonant circuit consisting of L_1 and C_1.

It is interesting to note the similarity between the circuits shown in Fig. 10A and Fig. 10B. Although we have a vacuum tube used in one circuit and a transistor in the other, there is a great deal of similarity between the two circuits and the way they work. In each case we have energy lost in the resonant circuit being replaced by bursts of energy; from the tube in one case and from the transistor in the other case. Also notice that the energy is fed across only part of the coil in each case, but the voltage induced in the entire coil is enough to set up a current flow that will replace the capacitor charge that is lost because of resistance or other losses in the resonant circuit.

OSCILLATORS USING CAPACITIVE FEEDBACK

There are a number of different oscillator circuits in which capacitive feedback rather than inductive feedback (as in the preceding examples) is used to sustain oscillation. Let's look at some of them now.

Colpitts Oscillator. Perhaps the most important of the oscillators using capacitive feedback is the Colpitts oscillator shown in Fig. 11. The one in Fig. 11A uses a vacuum tube while the one in Fig. 11B uses a transistor.

The operation of the two oscillators is quite similar. When the equipment is first turned on, current flows through L_2, which is the small rf choke used to complete the cathode circuit in Fig. 11A and the emitter circuit in Fig. 11B. Current flowing through the coil produces a voltage drop across the coil, and this charges capacitor C_2. The charge on capacitor C_2 will start an oscillation in the tank circuit, which consists of coil L_1 and two capacitors, C_1 and C_2. Remember that when we have two capacitors connected in series they will act like one capacitor insofar as the coil is concerned, and the circuit will start to oscillate. The voltage developed across C_1 is the feedback voltage. It is applied between the grid and the cathode in the circuit shown in A and between the emitter and the base of the circuit shown in B. When this voltage swings in a direction that makes the end of C_1 connected to C_3 positive and the other end negative, it will increase the current flowing through the tube or transistor, causing an increase in current flow through L_2, which charges C_2 still further. When the polarity of the voltage across C_1 reverses, the voltage will oppose the current flow and in Fig. 11A simply add to the bias between the grid and the cathode, reducing the plate current to zero; or in Fig. 11B, put a reverse bias across the emitter-base junction, reducing the current flowing through the transistor to practically zero.

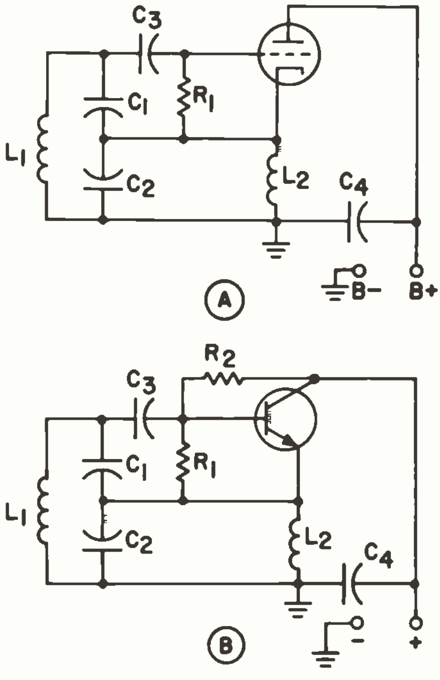

Fig. 11. Two Colpitts oscillators.

The amount of feedback voltage applied to the input of the circuit depends upon the ratio of C_1 to C_2. If C_1 is large compared to C_2, the reactance of C_1 will be low and the reactance of C_2 will be high. Most of the voltage developed across the capacitors will be developed across the higher reactance, in this case C_2. This means that the feedback voltage applied to the input will be low. However, if C_1 is small compared to C_2, the reactance of C_1 will be high compared to the reactance of C_2 and the feedback voltage supplied to the input of the circuit will be high.

The ratio of C_1 and C_2 can be altered to provide the required feedback to the input circuit to sustain oscillation. If the value of C_1 is increased and the value of C_2 decreased by the correct amount, the total capacity in the circuit formed as the result of two capacitors in series remains the same, and hence the resonant circuit of the oscillator does not change.

In some Colpitts oscillators an additional capacitor is connected directly across L_1. This is done to provide some means of changing the resonant frequency so we can vary the frequency at which the oscillator oscillates. It is impractical to try to vary both C_1 and C_2 at the same time, but an additional capacitor placed directly across the coil can be varied, and this will change the resonant frequency of the oscillator. At the same time, since C_1 and C_2 will still form a voltage divider, part of the total voltage developed across the two capacitors in series is fed back to the input circuit; this part can still be controlled by the proper selection of C_1 and C_2.

There are a number of variations of the Colpitts oscillator circuit. It is sometimes found in radio transmitting equipment that must be designed so that its frequency can be varied. The Colpitts oscillator can be designed with excellent frequency stability. By this we mean that once the oscillator is adjusted to operate at a certain frequency it will not drift from that frequency very much. Some oscillators, on the other hand, do not have good frequency stability and will drift appreciably.

Another variation of the Colpitts oscillator circuit is shown in Fig. 12. Here we have the capacitor C_1 connected across L_1 in addition to the voltage divider capacitors C_2 and C_3.

Notice that in this circuit the plate of the tube is fed back directly to L_1, C_1, and C_3 and that the choke coil L_2 has been moved from the cathode circuit to the plate circuit of the tube. The cathode in this oscillator circuit is connected directly to ground.

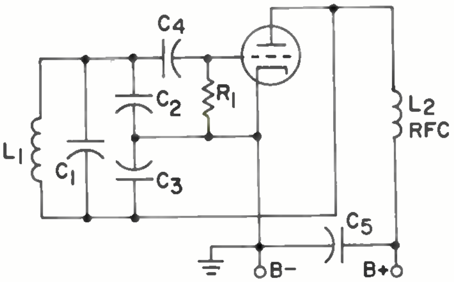

Fig. 12. A variation of the Colpitts oscillator.

In this oscillator when the plate current increases there will be a voltage developed across the rf choke, L_2, in the plate circuit of the tube, and this voltage will charge C_3. Once this capacitor is charged, oscillation starts in the circuit just as in the Colpitts oscillators shown in Fig.11.

The Ultra-Audion Oscillator. Another oscillator that uses capacitive feedback is the ultra-audion oscillator shown in Fig. 13A. When this type of oscillator was first developed, it was considered as a new type of oscillator. However, with careful analysis, we can see that it is actually a Colpitts oscillator, practically identical to the oscillator shown in Fig. 12. We have used the same designations to identify the parts in the circuits shown in Figs. 12 and 13. As you can see, the parts are all the same except for C_2 and C_3, which Fig. 13A does not seem to have. However, in Fig. 13B we have shown these two capacitors. C_2 is the grid-to-cathode capacity of the tube, and C_3 is the plate-to-cathode capacity of the tube. When we consider these two capacities, we have a capacitive voltage-divider network just like the one in Fig. 11. C_2 in Fig. 13B is between the grid and the cathode of the tube. Notice that C_2 in Fig. 12 also is in effect connected between the grid and the cathode of the

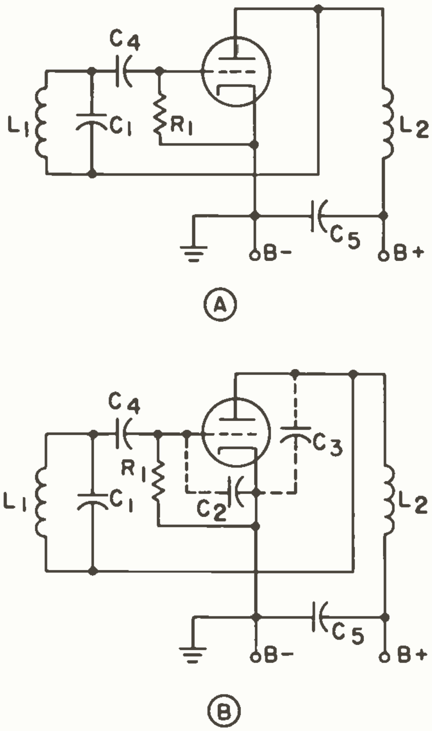

Fig. 13. The ultra-audion oscillator.

tube. C_2 and C_3 are in series in both circuits and they are connected across the tank circuit. C_3 connects directly to the lead going from the plate of the tube to one side of the resonant circuit, and C_2 connects through capacitor C_4 to the resonant circuit. Therefore, this oscillator is simply another form of Colpitts oscillator.

This type of circuit is frequently used in the vhf oscillators in the tuners of television receivers. Of course, it is usually shown in the schematic in the form shown in Fig. 13A. Manufacturers seldom draw in the distributed capacities; they expect the technician to know enough about oscillator circuits to recognize this as the ultra-audion oscillator and to know that this is simply a modified form of Colpitts oscillator.

The Electron-Coupled Oscillator. So far all of the vacuum tube oscillators we have discussed have been triode oscillators. These oscillators are widely used in receiving equipment and are sometimes found in transmitters and other rf power-generating equipment. However, they have some disadvantages, one of which is the direct coupling between the output and input circuits through the grid-to-plate capacity of the tube. Loading the output circuit of the oscillator has an effect on the input circuit and hence often results in an appreciable shift in the frequency at which the oscillator is oscillating. The net result is that triode oscillators are not stable enough for some purposes.

An oscillator that overcomes this difficulty is the electron-coupled oscillator. In this circuit a tetrode or a pentode tube is used so that the only coupling between the input and output circuits is in the electron stream flowing from the cathode to the plate of the tube. Schematic diagrams of two electron-coupled oscillators are shown in Fig. 14. The circuit shown in Fig. 14A is for an electron-coupled Hartley oscillator and the one shown in Fig. 14B is for an electron-coupled Colpitts oscillator.

The operation of these oscillators is similar to the operation of the triode oscillators, except that in the electron-coupled oscillator the screen grid of the tube acts like the plate of a triode tube. In other words, insofar as the oscillator action is concerned, we have three elements in the tube to be concerned about, the cathode, the grid and the screen grid. The screen grid acts like the plate of the oscillator tube. The oscillation is set up in this circuit by these three tube elements. However, the electron stream flows from the cathode of the tube to the plate of

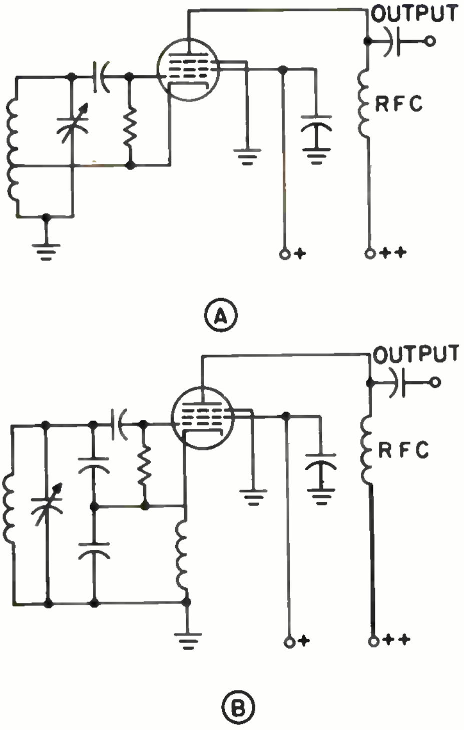

Fig. 14. Electron-coupled oscillators; the circuit at A is a Hartley oscillator.

the tube, and it is controlled by the grid. Since the grid is biased beyond cutoff during most of the rf cycle, but receives a strong positive pulse during a portion of the cycle, the plate current flowing through the tube flows in the form of pulses, which flow only when the grid of the tube is driven in a positive direction.

In the plate circuit of both oscillators we have shown an rf choke and a capacitor through which the oscillator can be coupled to the following stage. In some electron-coupled oscillators you will find a resonant circuit in the plate circuit of the tube instead of the rf chokes shown in Fig. 14. In some oscillators, this resonant circuit will be tuned to the same frequency as the resonant circuit in the grid circuit of the oscillator, but in other oscillators you'll find that it is tuned to a frequency equal to twice or three times the frequency to which the resonant circuit in the grid circuit of the tube is tuned. If we tune the resonant circuit in the plate circuit of the tube to twice the frequency of the resonant circuit in the grid circuit of the tube, we will have a frequency doubler. The resonant circuit in the plate circuit of the tube is set into oscillation by the burst of plate current flowing through the tube. However, since the resonant frequency of this circuit is twice the resonant frequency of the input circuit, the circuit in the plate circuit begins to oscillate at a frequency equal to twice the frequency being generated in the grid circuit. The oscillation in the plate circuit therefore goes through two complete cycles before a second pulse is received from the plate of the tube. This is called a frequency-doubler circuit. If the resonant circuit in the plate circuit is tuned to three times the frequency of the input circuit, the oscillation set up in the plate circuit will go through three complete cycles before it receives an additional pulse from the plate of the tube. This is called a frequency tripler. Now, you might expect this to result in a damped wave, with the amplitude of the cycles which do not receive a reinforcing pulse from the plate of the tube being considerably less than the amplitude of the particular cycles during which the pulse is received. Of course, there will be some loss in the resonant circuit and there will be some change in amplitude. However, by the use of a high Q resonant circuit in the plate circuit, the change in amplitude that occurs each cycle is very small and for all practical purposes all the cycles of the sine wave produced in the resonant circuit will have essentially the same amplitude.

R-C OSCILLATORS

Resistance-capacitance (R-C) oscillators use the charging and discharging action of a capacitor and a resistor in the feedback path to cause oscillation. The R-C oscillator is used in audio and low rf ranges. They offer an inexpensive method of obtaining a fairly stable sine wave within the range of their operation. Although many variations of the R-C oscillators exist, there are only two basic types, the phase shift and the bridge.

The phase shift uses a series of R-C phase shifting circuits between the output and the input to produce a feedback in-phase with the input. The bridge circuit usually uses an additional tube or transistor to obtain the phase shift and a bridge type circuit to control the feedback at the proper frequency.

Phase Shift. The phase shift oscillators in Fig. 15 consist of a conventional amplifier and a phase shift feedback circuit. As in L-C oscillators, the feedback must be positive. In the circuits in Fig. 15A and B, the output signal will be 180° out-of-phase with the input signal. Therefore the phase shift network must shift the phase of the feedback signal 180 degrees. This phase shift is provided by C_1, C_2, C_3 and R_1, R_2, R_3. One section, C_1-R_1, of the feedback loop is shown separately in Fig. 15C. The impedance of the circuits is capacitive and the feedback voltage, e_f, produces a current, i, through C_1-R_1 which leads e_f. The angle of the current lead is determined by the ratio of the reactance of C_1 to the resistance R_1. As the value of R_1 is reduced, the circuit will become more capacitive and more current will lead the voltage up to a maximum of 90°. If resistance is increased the current lead will decrease.

By increasing the number of R-C networks, the losses of the total feedback circuit will decrease and a less amount of phase shift will occur in each section of the feedback loop. For this reason some oscillators use five or six R-C sections. In Fig. 15 each section produces a 60 degree phase shift. The reactance of the capacitors is inversely proportional to the frequency; therefore, only one frequency

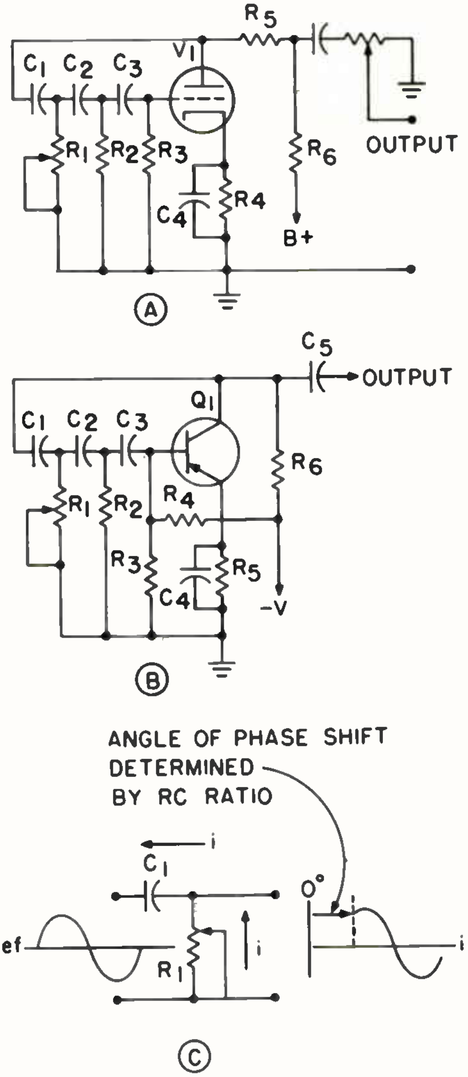

Fig. 15. Phase shift oscillators.

will pass through the feedback loop. Normally the output is fixed in frequency due to the constant value of the capacitors. A variable output may be obtained by using ganged variable capacitors or resistors since an increase in the value of either R or C will decrease the frequency.

Let us examine the operation of the circuit in Fig. 15B. R_3 and R_4 establish the base bias while R_5 and C_4 furnish thermal stabilization and furnish an rf ground to the emitter. R_6 is the load across which the output is taken and C_5 is the coupling capacitor.

Once power is supplied, operation is started by any random noise in the power source or the transistor. This noise causes a change in base current which causes a large change in collector current. This change in collector current develops an output voltage across R_6 which is 180° out-of-phase with the original change in base voltage. Part of the signal developed across R_6 is returned to the base shifted 180 degrees by the R-C network. The shift in phase through the R-C network causes the feedback to aid the output, resulting in positive feedback.

With fixed values of R and C, the 180 degree phase shift occurs at only one frequency, therefore, the output is a sine wave of fixed frequency. At all other frequencies, the reactance either increases or decreases, causing a variation in the phase relationship resulting in degenerative feedback.

The Bridge Oscillator. The Wien-bridge oscillators shown in Fig. 16 consist of low

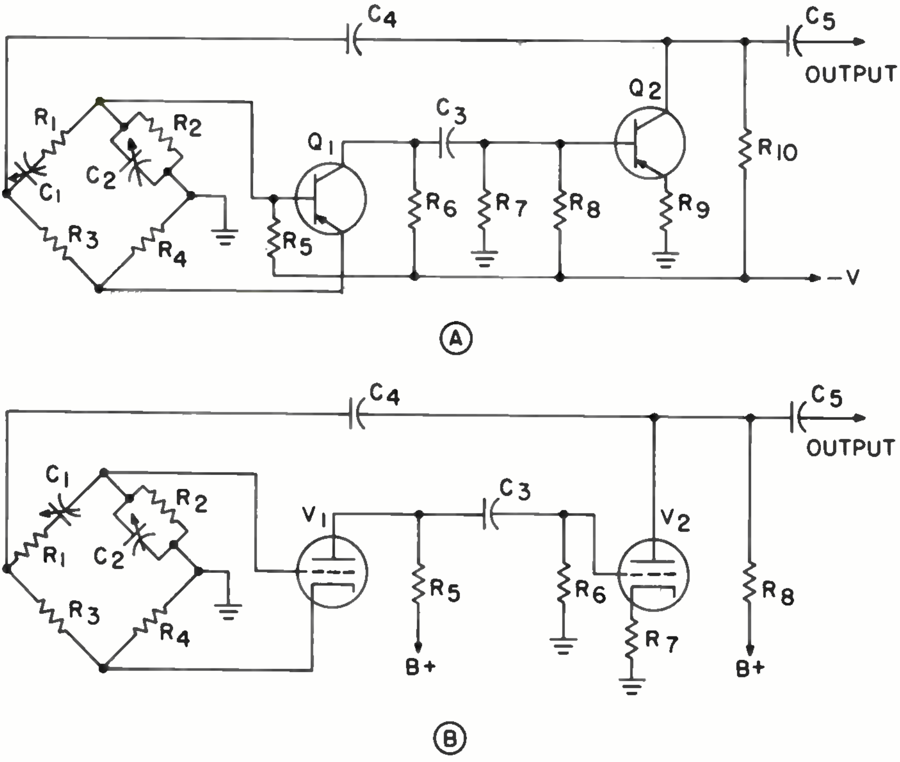

Fig. 16. Wien-bridge oscillators.

gain amplifier stages and a resistive-capacitive bridge circuit. The feedback is taken from the second amplifier and returned to the bridge circuit. Since there are two 180 degree phase shifts between the input of the first amplifier and the output of the second amplifier, the feedback will be positive. The resistive-reactive bridge circuit is designed to be balanced at the operating frequency; therefore, only feedback of the desired frequency reaches the input of the first stage. Let's examine Fig. 16A and see how this works.

The voltage divider, R_2 and R_5 supply base bias for Q_1 and R_7, and R_8 furnishes bias for Q_2. Thermal stabilization is provided by R_4 and R_9. R_3 and R_4 form a resistive leg of the bridge which is in shunt with the output of Q_2. A portion of this output coupled by C_4 and R_3 appears across R_4 as negative feedback. Since R_4 is not frequency sensitive, the negative feedback is constant regardless of the frequency of the output. At frequencies other than the operating frequency, the negative feedback furnished by R_4 will prevent oscillation. At the frequency of operation, which is controlled by the bridge reactive leg of R_1-C_1 and R_2-C_2, the positive feedback to the base of Q_1 is maximum. This in-phase feedback signal is applied to the base of Q_1 and is of sufficient amplitude to overcome the negative feedback across R_4. The total feedback is therefore positive at the operating frequency.

The amplified output of Q_1 is coupled to the base of Q_2 by C_3 and R_7. Q_2 further amplifies the signal and the voltage developed across R_{10} is coupled to the output by C_5, and a feedback signal is coupled through C_4 to Q_1.

We have not covered all of the various L-C and R-C oscillator circuits you are likely to encounter. There are many different variations of the circuits we have discussed, and some entirely different circuits. However, most of the circuits you are likely to encounter will be one of the circuits we have discussed in this section of the lesson or a variation of one of these circuits. If you come across a circuit you do not recognize immediately, first determine whether it is R-C or L-C and, in the latter case, whether capacitive or inductive feedback is used. Once you have decided on the type of feedback that is used, you should be able to figure out how the oscillator circuit works if you keep in mind that its operation is similar to one oscillator we have described in this lesson.

SELF-TEST QUESTIONS

(j) When plate current increases in the tuned grid oscillator (Fig. 9B), what happens to the voltage at the junction of R_1 and C_2?

(k) Where is the feedback voltage developed in the Colpitts oscillator (Fig. 11B)?

(l) The ultra-audion oscillator is a modification of what type oscillator?

(m) How is the 180° phase shift in feedback voltage accomplished in the phase shift oscillator?

(n) What component(s) develops the feedback voltage in the Wien-Bridge oscillator (Fig. 16)?

Crystal Oscillators

Although L-C oscillator circuits have been developed that have very good frequency stability characteristics, the master oscillators in most transmitters still use crystals. Better frequency stability is the main reason for using crystals instead of L-C resonant circuits in master oscillators. The frequency tolerance allowed by the FCC for most transmitting services is very small. The tolerance of a transmitter operating in the broadcast band, for example, is a frequency deviation of only 20 Hertz from the assigned frequency. Some services are permitted slightly more frequency tolerance, but in all cases, the tolerance is rather strict. This restriction is necessary to keep the large number of stations operating in the frequency spectrum from interfering with each other.

Several types of materials can be used for crystals. These include quartz, Rochelle salts, and tourmaline. The most often used crystal material for generating radio frequency signals is quartz. Rochelle salts work better in low-frequency applications, such as in loudspeakers and microphones. Tourmaline will work as well as quartz, but because it is a semiprecious stone, it is more expensive.

The assembly usually referred to as a crystal is composed of a small piece of crystal material mounted in a holder. The crystal material is in the form of a small slab or wafer cut from a larger crystal. The way in which the wafer is cut from the natural crystal determines many of its electrical characteristics. In this section, we will find out how the crystal works, how the crystal is used in oscillator circuits, and finally we will discuss some of the most-used crystal oscillator circuits.

THE PIEZOELECTRIC EFFECT

A quartz crystal exhibits a property called the piezoelectric (pronounced pi-ee-zo) effect when it is compressed mechanically or when a current is applied to it. To illustrate this effect, suppose we have a small crystal wafer with leads attached to its two surfaces. If we squeeze the wafer or bend it in some way, a voltage will appear between the leads. If, on the other hand, we apply a small voltage across the leads, the crystal slab will bend, expand, or contract, depending on the polarity of the applied voltage and the crystal type. These two effects are used in many types of electronic equipment.

A crystal wafer has a definite mechanical resonant frequency at which it will vibrate most readily. This resonant frequency is determined by the physical dimensions of the wafer, particularly the thickness. The thinner the wafer, the higher the resonant frequency. Thus, when an ac voltage, whose frequency is near the crystal resonant frequency, is applied, the crystal will vibrate the greatest amount and produce the greatest output. Because of the large amount of vibration at the resonant frequency, there is a limit to how thin the wafer can be before it becomes too fragile for practical use.

CRYSTAL CUTS

The natural quartz crystal, as shown in Fig. 17, is said to have 3 major axes at right angles to each other. These axes, called the X, Y, and Z axes, are shown in the illustration. The X axis is called the electrical axis; the Y axis is called the mechanical axis; and the Z axis is called the optical axis. The way that the crystal wafers are cut with respect to these axes determines many electrical characteristics, including the frequency range in which the crystal will oscillate and the amount that the resonant frequency will change with changes in the temperature (the temperature coefficient).

If the crystal wafer shown by the shaded section in Fig. 17 is cut so that its face is perpendicular to the Y axis, it is called a Y-cut crystal. Similarly, if its face is perpendicular to the X axis it is called an X-cut crystal. Crystal wafers cut perpendicular to the Z axis have no piezoelectric properties.

Crystal cuts can be made at different angles to the major axes to produce crystals having slightly different electrical characteristics. The type of cut depends on the purpose for which it is to be used.

One of the most important characteristics of a quartz crystal used in oscillator circuits is the amount the crystal frequency varies with variations in temperature. We call this the temperature coefficient of the crystal. Y-cut crystals have a range of about –25 to +100 Hertz/°C/MHz (Hertz per degree centigrade per MHz). In other words, a one-degree centigrade increase in temperature may cause the frequency to decrease as much as 25 Hertz, or increase by as much as 100 Hertz for each MHz of the frequency for which the crystal is ground. To take an extreme case, the frequency of a 4-MHz crystal might increase by 400 Hertz for each degree of temperature change. Because of this rather high temperature coefficient and also because Y-cut crystals have a tendency to oscillate at a second frequency near the design frequency, they are seldom used.

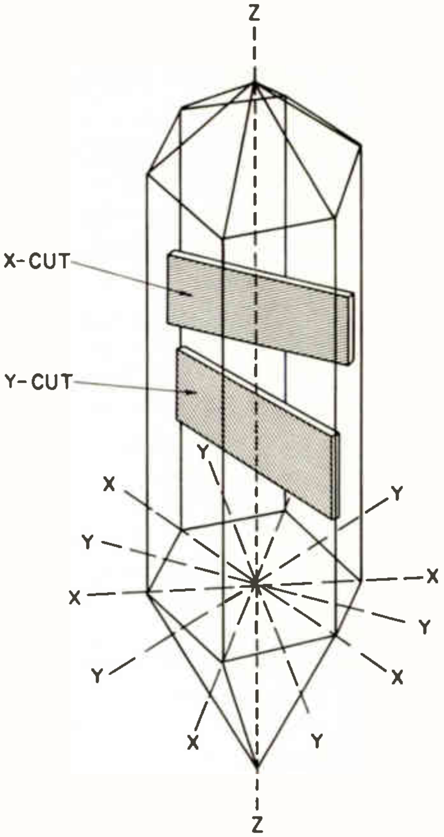

Fig. 17. Major axes quartz crystal.

X-cut crystals have a range of about –10 to –25 Hertz/°C/MHz. The minus sign means that the crystal frequency decreases with an increase in temperature. We call this a negative temperature coefficient. Even though the frequency variation is less, close temperature control is still required to keep the crystal oscillating at the correct frequency.

As an example of how temperature affects the crystal frequency, consider an X-cut crystal that has an operating frequency of 4650 kHz at 50° C. If it has a temperature coefficient of −20 Hertz per degree centigrade per MHz, let's determine what its operating frequency would be if the temperature changes ten degrees.

4650 kHz = 4.65 MHz

therefore the change in frequency per degree centigrade is:

4.65 X 20 = 93.00 Hertz

The change in frequency with a temperature change of ten degrees will be:

93 X 10 = 930 Hertz
and 930 Hertz = .930 kHz

Thus we see that with a temperature change of only 10 degrees, the frequency will change almost 1 kHz. With a 20-degree change, the frequency change would be almost 2 kHz. If the temperature increases 10°, the frequency will decrease to about 4649 kHz (4649.07 kHz), and if the temperature drops 10°, the frequency will increase to almost 4651 kHz (4650.93 kHz). Where there are many stations operating on frequencies close together, this shift in frequency could be enough to cause interference.

We can reduce the temperature effect on the resonant frequency of the crystal by cutting the crystals at angles to the major axes. Examples of such crystal cuts, called the AT-cut and the BT-cut, are shown in Fig. 18. These crystals are really Y-cut crystals with the face of the wafer at an angle of about 39° to the Z axis instead of parallel to it in the case of the AT-cut crystal, and about 45° to the Z axis in the case of the BT-cut crystal. Notice that the angle of the AT-cut crystal is opposite to that of the BT-cut crystal with respect to the Z axis. The temperature coefficient of these cuts is about ±2 parts per million at a temperature of 40°C to 50°C. Thus, the angle cut practically cancels the effects of temperature variation on the frequency of oscillation if it is operated within the temperature range.

Other angular cuts can be made to get other electrical characteristics and effects. Some examples are the CT and DT cuts used for lower frequency operation below 500 kHz. A CT-cut crystal is cut perpendicular to the BT-cut crystal, and the DT cut crystal is cut perpendicular to the AT-cut crystal. Another cut is the GT cut.

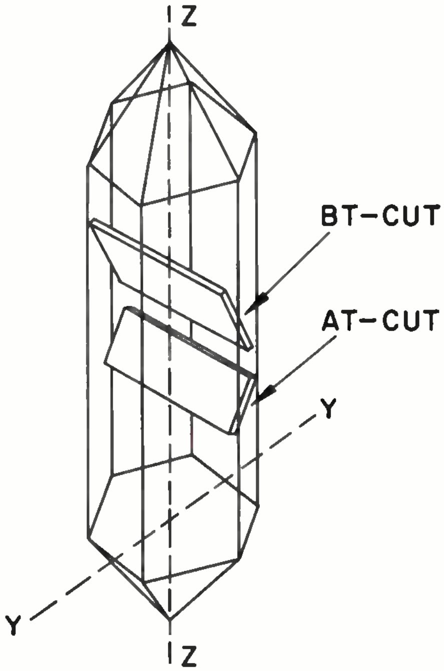

Fig. 18. AT-cut and BT-cut crystals are cut on an angle to the Z axis as shown.

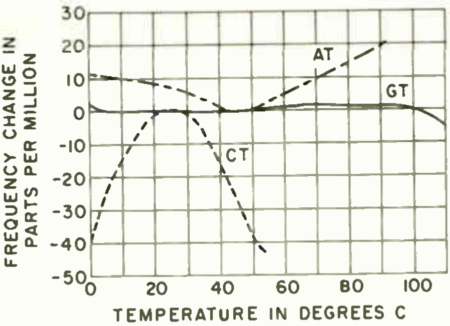

Fig. 19. Frequency changes of different crystal cuts with changes in temperature.

This crystal is cut on an angle of about 45° to either the CT- or DT-cut crystals.

Fig. 19 illustrates the variation of the resonant frequency with temperature for various crystal cuts. Notice that the frequency of the GT-cut crystal is practically constant from 0° to about 100° This cut, therefore, is the best to use in equipment that will be subjected to wide temperature variations. The other cuts have zero temperature coefficients at or near specific temperatures.

CRYSTAL HOLDERS

After the crystal has been ground, or etched by means of chemicals, until it is of the proper thickness, it is placed in a holder. The holder is then sealed so that no air, dirt, or oil can reach the crystal wafer. These can cause erratic operation of the crystal. A crystal in its hermetically sealed holder is shown in Fig. 20.

There are two ways of mounting the crystal in the holder. In one way, a very thin film of metal is formed directly on the surface of the crystal by spraying or firing. The metal can be either silver, gold, or aluminum. The crystal is supported by flexible wires fastened to this metallic film with solder having a low melting point. The leads are attached to a node or non-oscillating portion of the crystal. The node can be either in the center of the crystal face or at an edge where inhibiting the vibrations will do no harm.

Another method of mounting the crystal in a holder is to arrange it so that it is pressed between two metal plates. The metal plates make electrical contact with the crystal surfaces. Another type uses an air gap .001 to .005 inch thick between the crystal and the upper plate. This air gap produces a damping effect on the amount of crystal vibration. Often, however, the crystal holder is evacuated so that the damping will be reduced.

Regardless of the type of mounting used, the holder itself is designed to keep the crystal free of grit, dirt, and oil film. Even a speck of dirt or a greasy film can change the characteristics of the crystal. Therefore, the crystal holder should never be opened, nor should the crystal be handled. If it is ever necessary to take one apart, the crystal may be cleaned with a

Fig. 20. A quartz crystal in its holder.

good nonflammable commercial cleaner. The crystals should be handled with clean, lint-free cloths, not with bare fingers (bare fingers leave traces of perspiration on any object they touch).

Equivalent Circuit. The symbol in Fig. 21A is used in schematic diagrams to represent the crystal in its holder. The equivalent electrical circuit of the crystal and holder assembly is shown in Fig. 21B. As you can see, we have here a series-parallel circuit composed of the series components L, R, and C_1 shunted by capacity C_2. The crystal, therefore, acts electrically as an L-C circuit; as an inductance at frequencies above the resonant frequency and as a capacitance at frequencies below resonance. The apparent inductance L is due to the mass of the crystal, resistance R is the result of internal mechanical losses, and capacity C_1 is the stiffness (piezoelectric properties) of the crystal. Capacity C_2 is the capacity between the electrode plates, with the quartz crystal acting as the dielectric.

Since the crystal acts as an electrical resonant circuit, we would expect it to be frequency selective; that is, it will oscillate more vigorously at its natural resonant frequency than at any other frequency. This is true. When an ac voltage is applied to its electrodes, the crystal generates an alternating potential of its own.

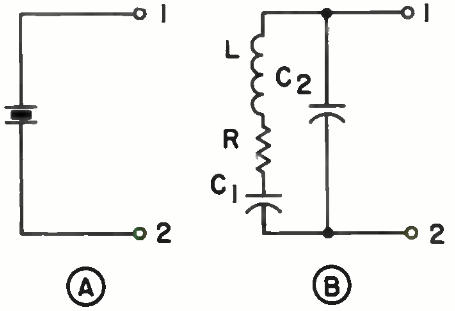

Fig. 21. The schematic symbol for a quartz crystal in its holder is shown at A. The equivalent electrical circuit of a quartz crystal is above at B.

Because of its electrical characteristics, the crystal can be used in an oscillator circuit. The electrical properties of the crystal are somewhat different from those of a typical coil and capacitor. The mechanical properties of the crystal produce a very high apparent inductance, L. Also, since the mechanical losses during vibration are small, the electrical equivalent resistance is also very small. When we have an L-C circuit containing a large inductance and a very low resistance, the Q of the circuit will be very high. This is the case with the crystal used in oscillator circuits.

Practical crystals have effective Q values which are about 100 times as great as that ordinarily obtainable with the usual inductance coil and tuning capacitor. Crystals, therefore, have extremely good frequency selectivity. The higher the Q, the better the frequency stability. Thus, if we substitute a crystal for the ordinary L-C tank circuit, we can make an oscillator that has good frequency stability.

CRYSTAL OVENS

The purpose of a crystal oven is to maintain the crystal at a constant temperature to prevent frequency drift. Some time ago, it was common practice to put the crystal, the entire master oscillator of the transmitter, and often even the buffer stage in a heat-controlled chamber. This prevented temperature variations from affecting the physical dimensions of the coil and capacitor in the plate circuit, and

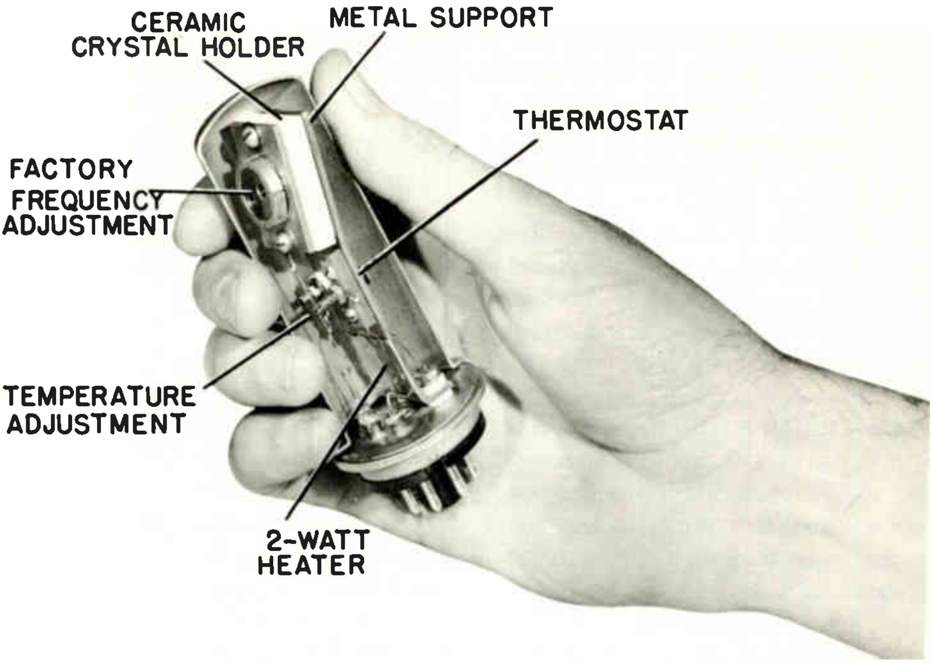

Fig. 22. A cut-away view of a crystal oven.

thus changing the oscillator frequency. This is seldom done in modern transmitters; generally only the crystal is temperature-controlled.

A typical modern crystal oven is shown in Fig. 22. The overall unit is about the size of a metal receiving tube -- about 4 inches high and 1-1/4 inches wide. Smaller units are also available. The crystal oven unit fits into an octal tube socket. The unit in Fig. 22 is guaranteed to hold the transmitter frequency within 10 Hertz at any point on the broadcast band.

The crystal is contained in a ceramic holder attached to a copper support. The heater is also wrapped around this support. Thus, the metal support conducts the heat to the crystal and maintains it at a constant temperature.

The heat is controlled by a bimetallic thermostat attached to the metal support. When the temperature of the support drops a very small amount, the thermostat contacts close, and current is applied to the heater. When the support reaches a certain temperature, the thermostat contacts open. The difference between the on and off temperatures of the thermostat is very small; that is, the temperature must drop only a small amount before current is again applied to the heater coil.

The crystal frequency and thermostat temperature adjustments shown in Fig. 22 are set at the factory when the unit is assembled. It is impossible to change the adjustments because the unit is hermetically sealed. Thus, when ordering such a crystal unit, you must specify the exact crystal frequency you want and the circuit in which the crystal will be used. Crystal manufacturers will not guarantee the operating frequency of a crystal unless the crystal is adjusted in the circuit in which it will be used.

CRYSTAL OSCILLATOR CIRCUITS

To help see how the crystal oscillator works, let's look at another L-C oscillator. This oscillator is shown in Fig. 23, and is called a tuned-grid, tuned-plate oscillator. It is easy to see where this oscillator gets its name, since there are resonant circuits in both the grid circuit and the plate circuit of the tube.

The tuned-grid, tuned-plate oscillator works because of the capacity between the plate and grid of the triode tube. When the resonant circuit in the plate circuit of the tube is tuned to a frequency slightly lower than the operating frequency, it will act like an inductance. Under these conditions, the phase of the signal voltage fed from the plate of the tube back to the grid of the tube is correct to aid the ac grid voltage, and oscillation occurs.

The crystal oscillator shown in Fig. 24 is simply a modification of the tuned-grid tuned-plate oscillator shown in Fig. 23. Here a crystal has been substituted for the resonant circuit in the grid circuit of the oscillator and a milliameter is shown in the plate circuit of the stage to measure plate current. Actually almost all oscillators have some provision made for measuring plate current.

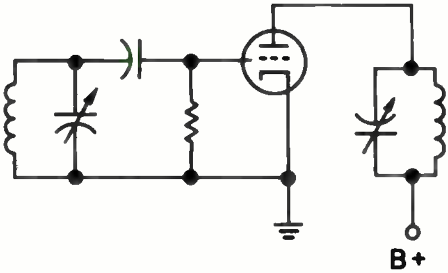

Fig. 23. A tuned-grid, tuned-plate oscillator.

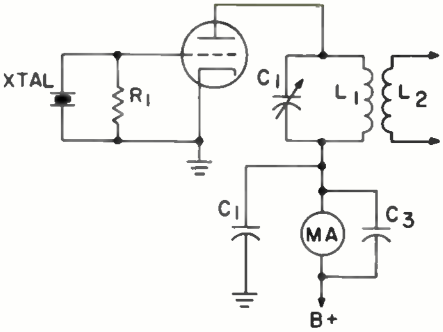

Fig. 24. A simple crystal-oscillator circuit.

Since the crystal is the equivalent of the circuit that has been removed, the crystal oscillator operates in exactly the same way as the resonant circuit in the grid of the tuned-grid, tuned-plate oscillator. The plate circuit must be tuned so that it presents an inductive load, and energy will be fed from the plate of the tube back to the grid in the correct phase to aid the ac grid voltage so oscillation will occur.

In the input circuit, the rf current flowing through the crystal itself is limited only by the resistance of R_1. This resistance is usually low enough to result in a fairly high crystal current. If the resistance is made too high, the crystal may be somewhat erratic as it starts to oscillate when power is applied to the stage. On the other hand, if the current becomes higher than about 100 milliamperes, the crystal vibrations may be so violent that the crystal may shatter, and thus destroy itself. Of course, the thinner the crystal and the higher its resonant frequency, the lower the safe current limit becomes.

Many transmitters have an rf current

meter in series with the crystal to indicate this current. To prevent possible damage to the crystal, the amplitude of oscillation in a crystal oscillator circuit must be kept at a safe level. Usually this is accomplished by keeping the plate voltage on the oscillator tube low. This low plate voltage reduces the maximum output power that can be obtained from such oscillators.

Pierce Oscillator. It is possible to place the crystal between the plate and grid circuits, as shown in Fig. 25, instead of between the grid and cathode. In this case the circuit is similar to the ultra-audion circuit. This circuit is called the *Pierce* oscillator.

Notice that the circuit contains no tank inductance or tuning capacity. The amount of feedback and the grid excitation can be controlled to some extent by adjusting the capacity of C_1. The larger this capacity, the less the feedback. The exact capacity of C_1 in most cases is not critical. Usually, when the best value is determined, crystals of slightly different frequency can be switched into the circuit without further adjustment. Again the plate voltage must be low to prevent damaging the crystal.

Crystal Oscillators Using Multi-Grid Tubes. Tetrode and pentode tubes also may be used in crystal-oscillator circuits. These tubes have less plate-to-grid capacity than do triodes, and therefore, there is less feedback current to the grid when they are used as crystal oscillators. The lower feedback means that these tubes can be operated at a higher output power than a triode without excessive rf crystal current.

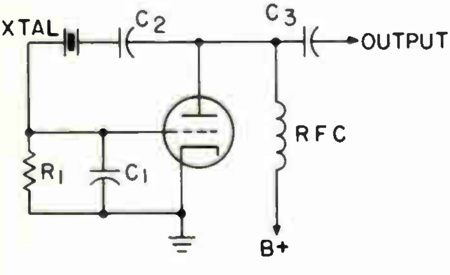

Fig. 25. The basic Pierce oscillator.

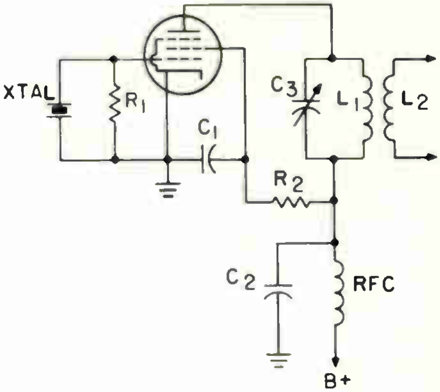

Fig. 26. Crystal oscillator using a pentode tube.

A crystal oscillator using a pentode tube is shown in the diagram of Fig. 26. Because of the limited amount of plate-grid feedback, the plate voltage can be considerably higher than for the triode oscillator. This, of course, increases the output power. The circuit may also be used for high-frequency crystals having fundamental resonant frequencies of about 10 MHz. The output in this case can be high, but the small amount of current through the crystal protects it from excessive vibration. Sometimes extra feedback is needed to produce oscillation in the circuit. This is done by connecting a small capacitance between the plate and the control grid.

Crystal Control Transistor Oscillators. A transistor tickler coil oscillator using a crystal to control feedback is shown in Fig. 27. Positive feedback from collector to base is provided through the mutual

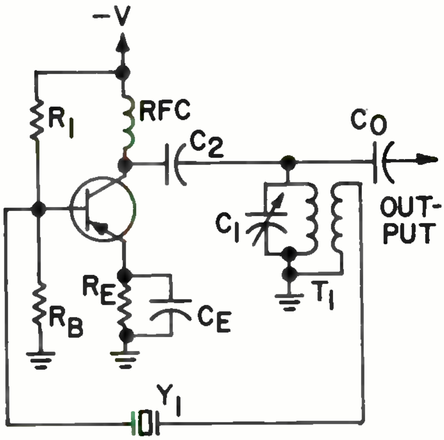

Fig. 27. Crystal tickler coil oscillator.

inductance between the windings of T_1. This provides the 180° phase shift necessary to sustain oscillation. In this circuit, the crystal acts as a series resonant circuit. At frequencies other than the resonant frequency the crystal acts as a high impedance, blocking the feedback path. At the resonant frequency the crystal offers minimum impedance to the feedback signal. The operating frequency may be varied by the use of different crystals and tuning the tank to the frequency of the crystal with C_1.

The crystal oscillator shown in Fig. 28 is a variation of the Colpitts oscillator. In this circuit the crystal acts as a parallel tuned circuit and replaces the L-C tank. Operating frequency is determined by the crystal and the capacitance in series with it. At the resonant frequency, the crystal and capacitors in parallel with it form a high impedance tank circuit. Capacitors C_1 and C_2 form a voltage divider that is center-tapped to ground. The voltage developed across C_1 is applied between the base and ground providing a 180° phase shift in the feedback path.

OVERTONE OPERATION

Most crystals will oscillate not only at their fundamental resonant frequencies, but also at odd overtones of the fundamental. A crystal with a fundamental of 4 MHz, for example, will oscillate also at frequencies near 12 MHz, 20 MHz, 28 MHz, etc. The oscillation frequency will not be an exact multiple of the fundamental oscillation frequency. Exact multiples would mean harmonic operation rather than overtone operation. Thus, if you use a crystal designed for fundamental operation as an overtone crystal, you can use the frequency markings on the crystal holder only to get an approximate idea of the actual frequency at which the oscillator is working. To determine the exact frequency, you will have to measure it with a frequency meter.

Although any crystal can be used in overtone operation, it is best to use one that has been ground specifically for this purpose. The ordinary fundamental type of crystal is somewhat unstable and hard to adjust when operated on an overtone. Most of the overtone crystals are designed

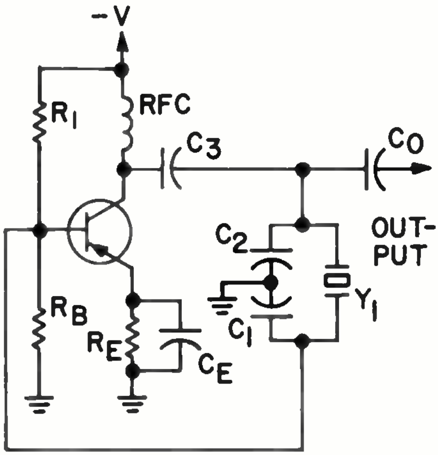

Fig. 28. Colpitts crystal oscillator.

to operate on the third overtone; operation at higher overtones is possible, but the stability and ease of adjustment becomes more critical at the higher overtones.

The chief advantage of overtone operation is that we can generate frequencies in the vhf range without the use of doubler stages. The highest fundamental oscillation frequency of a crystal is about 10 MHz. If one is ground to operate on a higher frequency then it is so thin that it breaks easily. Thus, by operating it on the third or fifth harmonic, we get a much higher frequency than we could on the fundamental. Another advantage of overtone operation is that no frequencies are generated that can cause interference with other channels. Because the number of frequency multiplier stages is reduced or completely eliminated, overtone crystals are used often in mobile, marine, and aircraft transmitters in which compactness is important.

The oscillator circuit using an overtone crystal is similar to an ordinary crystal oscillator circuit of the type you will study later. The overtone at which the crystal will operate is determined by the plate circuit resonant frequency. The circuit of an overtone oscillator is shown in Fig. 29. The oscillator uses a crystal having a fundamental frequency of about 8 MHz to give a 24 MHz output when operated on the third overtone.

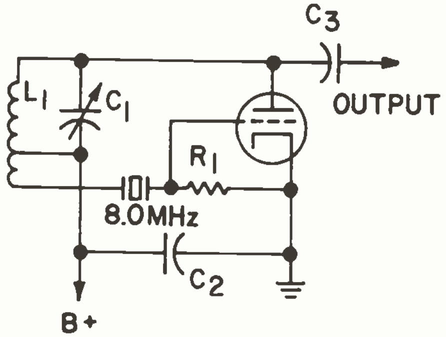

Fig. 29. An overtone oscillator circuit.

In Fig. 29, the circuit made up of C_1 and the upper end of L_1 is resonant at 24 MHz. The tap on L_1 is held at rf ground potential by C_2. The lower end of L_1 is inductively coupled to the upper end (usually this is a simple one-tapped coil) so energy is fed from the plate circuit back to the grid circuit to sustain oscillations. The rf signal fed back to the grid circuit will cause the crystal to oscillate on its third overtone frequency. Output from the oscillator is taken from the plate circuit through C_3.

Modern overtone crystals are capable of oscillating as high as 100 MHz on higher order harmonics, so the output of a crystal oscillator could be up in this region. However, when such high frequency signals are needed, you will often find a crystal oscillator operating at 50 MHz followed by a doubler to increase the frequency to 100 MHz, or an oscillator operating at about 33.3 MHz followed by a tripler.

An oscillator circuit that can be used to generate both even and odd harmonic frequencies of the fundamental is the tri-tet circuit shown in Fig. 30. The output signals are harmonics rather than overtones.

The tri-tet circuit is actually the crystal version of the electron-coupled circuit described earlier in this lesson. The crystal and the resonant tank L_1-C_1 are connected to the control grid, the cathode, and through C_4 to the screen grid (which acts as the oscillator plate), to form a modified tuned-plate, tuned-grid oscillator. The cathode tank circuit L_1-C_1, therefore, must be tuned to a frequency slightly lower than that of the crystal in order to be inductive.

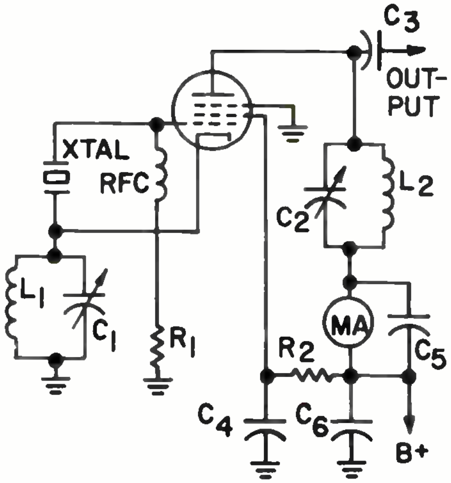

Fig. 30. The tri-tet oscillator circuit.

Since the screen grid is bypassed to ground by capacitor C_4, there is very little direct coupling between the actual tube plate and the oscillator portion of the circuit. The electron stream reaching the plate, however, arrives in the form of pulses that contain relatively large amounts of harmonic energy. If we tune the plate tank circuit L_2-C_2 to a frequency twice that of the crystal, a considerable amount of output power at the second harmonic frequency will be obtained. Even if the plate is tuned to a frequency three times that of the crystal we will get a fair amount of third harmonic output power.

Therefore, the tri-tet circuit not only behaves as a crystal-controlled oscillator, but also performs as a frequency doubler or tripler at the same time. The additional feature of the electron coupling prevents load variations from reaching the crystal and influencing the oscillator frequency. A disadvantage of this circuit is that both sides of the crystal are above rf ground potential. Another is the fact that a cathode coil is needed.

CRYSTAL-OSCILLATOR ADJUSTMENT

The tuning procedures for crystal oscillator circuits of all types are similar. The curves in Fig. 31 show how the plate current of an oscillator tube varies with changes in the tuning capacity. The solid curve is for an unloaded oscillator circuit, and the dashed curve represents the circuit loaded.

When you adjust a triode or Pierce oscillator like those shown in Figs. 24 and 26, begin first with the plate tank capacitor in the minimum capacity position. Then rotate the capacitor toward the maximum capacity position. As soon as oscillation begins, the plate current will begin to decrease. It will decrease more and more, going through points 3 and 2 in Fig. 31 as oscillation becomes stronger. If the plate capacitor is turned too far, however, oscillations will stop abruptly as at point 1 in Fig. 31. In practice, it is best not to approach point 1 too closely because minor voltage or current variations may stop the oscillator. Instead, adjust the plate tuning capacitor so that operation will be somewhere in the stable region between points 2 and 3.

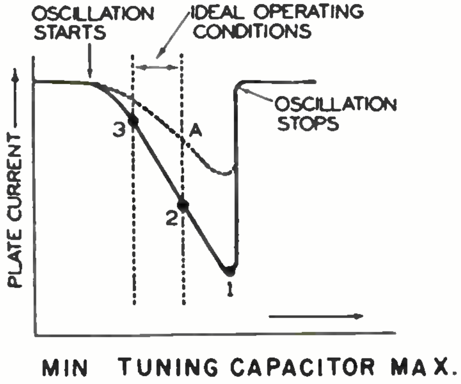

Fig. 31. Curves showing how the plate current in a crystal-oscillator circuit varies with tuning.

When a load is placed on the oscillator circuit, the plate current dip of the oscillator will not be as pronounced. It will follow the dashed curve in the diagram. As before, however, too much capacity will cause the oscillator to stop. The operating point again should be somewhere between points 2 and 3.

The transistor oscillator in Fig. 27 would be adjusted in a similar manner, C_1 being tuned to a point where the current through the tank is between points 2 and 3 in Fig. 31. C_1 is first tuned for minimum capacitance. Then the capacitance is increased until current is between the stable points of operation.

When adjusting the tri-tet circuit in Fig. 30, first set the cathode tank capacitor C_1 to a frequency higher than resonance (minimum capacity) so that oscillations will occur. In this circuit, the usual parts values are such that oscillation will be maintained over a fairly wide range of C_1 adjustment. However, the crystal current increases very rapidly as the capacity is increased. Start tuning C_1 for the minimum capacity position and progress only to the point of normal crystal current. Usually an rf milliammeter is placed in series with the crystal to measure this current. The current should be kept below 100 milliamperes.

With no load connected, the plate tank capacitor C_2 should be adjusted for a minimum value of plate current as indicated by a sharp dip in the meter reading. Now, connect the load to the circuit. This is usually the grid of the following buffer amplifier stage. With the load attached, capacitor C_2 may need readjustment to bring the plate current back to minimum. This time, however, the current value will be somewhat higher because of the loading.

Finally adjust the cathode tank capacitor C_1 for maximum harmonic power output which will be indicated by a maximum current flow in the following amplifier grid current. Also watch the crystal current to be sure that it does not rise above the safe limit.

FREQUENCY SYNTHESIZERS

In order for a transmitter to be versatile, it must be capable of operating on more than one frequency. In the crystal oscillators discussed previously we have to change the crystal each time the frequency is changed. Thus for each channel the equipment is operated on, we need a separate crystal. Transmitters that are operated on only a few channels use separate crystals for each channel. However, this arrangement is not completely satisfactory when the transmitter must be capable of operating on a large number of channels. The frequency synthesizer is one solution to this problem.

A frequency synthesizer is basically a circuit in which harmonics and subharmonics of one or more crystals are combined to provide a variety of output signals. The same principle is used that you studied earlier in the basic superheterodyne receiver. You will recall that in the mixer stage of that receiver the incoming signal was beat with the local oscillator to form two new frequencies. These new frequencies were equivalent to the sum and the difference of the incoming signal frequency and the local oscillator frequency.

Fig. 32 shows one type of frequency synthesizer. Circuit details have been omitted for simplicity. Two oscillator circuits are used with a mixer which will beat the outputs of the oscillators together and produce an output equal to

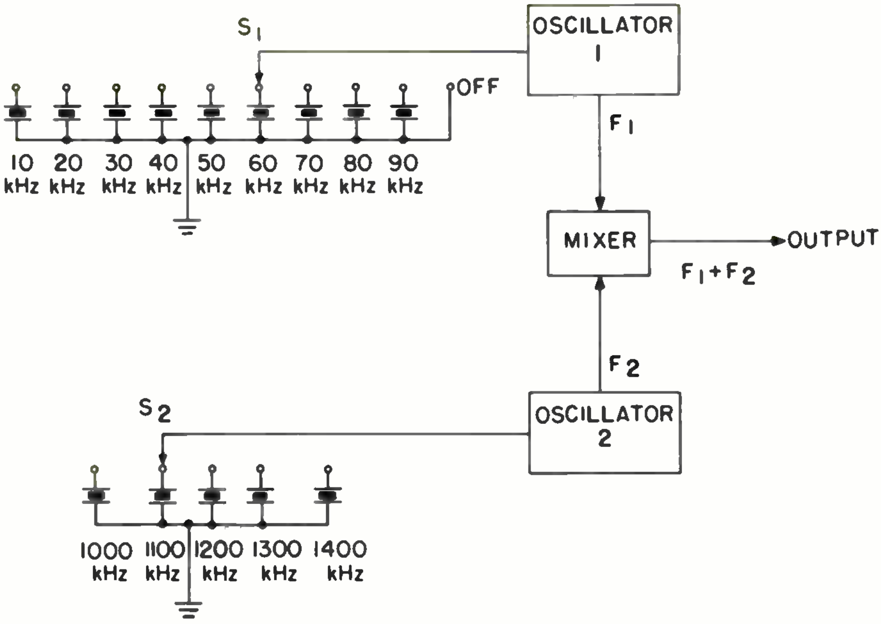

Fig. 32. Multiple crystal frequency synthesizer.

the sum of the two frequencies. Each of the oscillators is tunable to different frequencies of a selected band by switching the crystals in the oscillator circuit.

Oscillator number 1 has 9 crystals in the input. Each crystal is resonant at a different frequency, enabling the output of oscillator number 1 to be varied in 10 kHz steps from zero to 90 kHz. The tenth position of switch S_1 disables the oscillator. Oscillator number 2 has 5 crystals which vary its frequency over a 500 kHz band in 100 kHz steps.

With S_1 and S_2 in the positions shown, oscillator 1 is operating at 60 kHz and oscillator 2 at 1100 kHz. The mixer receives both outputs and beats them to form a 1160 kHz output. If S_2 was left in this position and S_1 moved, the output of the mixer could be varied from 1100 kHz (when S_1 is in the off position) to 1190 kHz in 10 kHz steps. By moving both switches, the output can be varied from 1000 kHz to 1490 kHz in 10 kHz steps. In this manner, a total of 50 different frequencies can be generated from only 14 different crystals.

This type of synthesizer has the advantage of less crystals than a conventional oscillator with similar frequency coverage.

Let's look at a block diagram of a transceiver and see another use for frequency synthesizers.

The transceiver is a compact radio station that uses some of the components for both transmitting and receiving. These units usually transmit and receive on the same frequency.

Fig. 33 is a block diagram of a transceiver. The upper channel is the receiver section while the lower channel is the transmit section.

Incoming rf is coupled from the an-

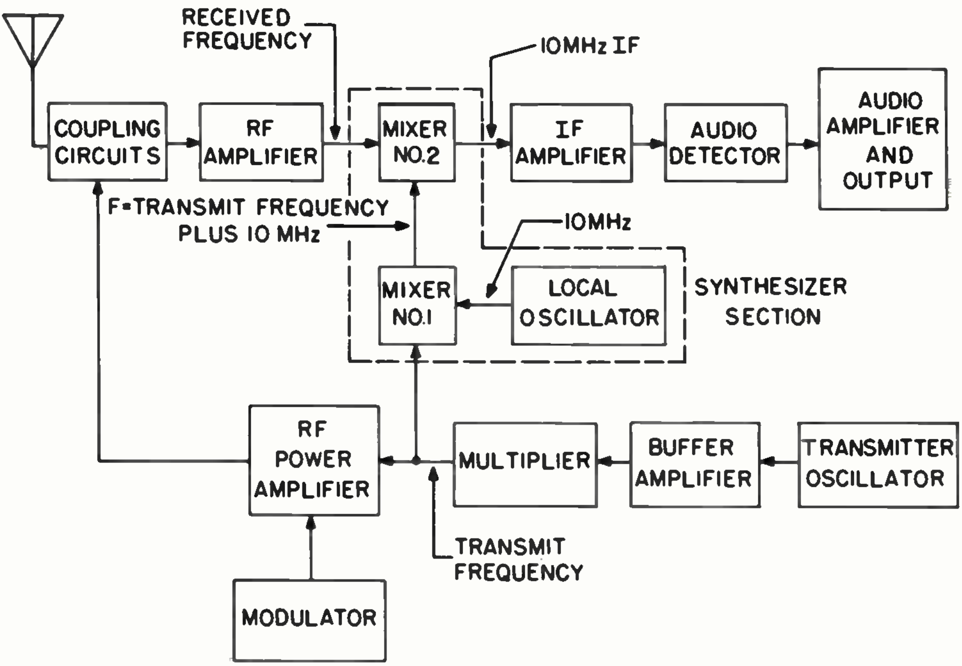

Fig. 33. Block diagram of a basic transceiver.

tenna to the rf amplifier. This amplified rf is then heterodyned in mixer number 2 with a signal from mixer number 1. We will discuss the signal from mixer number 1 shortly. The difference frequency is detected and sent through the i-f amplifiers to the audio detectors and output section.

The transmit channel gets its frequency from the transmitter oscillator. After being multiplied to the proper frequency, the rf is fed to the power amplifier. In the power amplifier the modulating signal is applied to the rf. The rf, now containing the intelligence, is coupled from the power amplifier to the antenna.

Notice that between the multiplier and the power amplifier, the transmitter frequency is fed to mixer number 1. This is part of the frequency synthesizer.

You recall that the i-f is the difference between the local oscillator and the incoming rf. Let's assume in this example that we desire a 10 MHz i-f. In that case our local oscillator frequency to mixer number 2 must be 10 MHz above the incoming rf. Since the transmitted rf and received rf must be the same frequency for stations to communicate with each other, a separate oscillator is required to generate the local oscillator frequency.

If a synthesizer were not used, the local oscillator crystal would have to be changed each time the transmitter oscillator crystal was changed in order to keep the local oscillator 10 MHz above the transmitter frequency. The synthesizer however, uses a very stable constant frequency oscillator operating at the 10 MHz i-f. The transmitted rf is fed to mixer number 1 of the synthesizer where it is mixed with the 10 MHz signal. The sum of these two frequencies is then used as the local oscillator frequency. In mixer number 2 the local oscillator frequency is mixed with the incoming rf and the difference (10 MHz) is used as the i-f.

In this manner the local oscillator frequency to the receiver is changed each time the transmitter frequency is changed. Therefore the local oscillator frequency is always 10 MHz above the received frequency. This eliminates the need to use a different crystal in the receiver local oscillator each time the transmitter frequency is changed.

There are many types of frequency synthesizer circuits in modern communication equipment. They all operate on the same principle of combining two or more frequencies to generate an output frequency. From this discussion you should be able to understand the basic fundamentals of any frequency synthesizer you encounter.

SELF-TEST QUESTIONS

(o) Why is plate voltage kept low in the Pierce oscillator?

(p) Describe how frequency is controlled in the oscillator in Fig. 27.

(q) What is the advantage of overtone operation?

(r) In the multiple crystal frequency synthesizer in Fig. 32, what is the output of the mixer if S_1 is in the 80 kHz position and S_2 is in the 1300 kHz position?

(s) In addition to performing as an oscillator, what other function is accomplished by the tri-tet oscillator?

Nonsinusoidal Oscillators

The oscillators you have studied up to this point have all been sine wave oscillators; that is, their output is a sine wave. In this section we will look at nonsinusoidal oscillators. There are many circuits that can be classed with this group of oscillators but we are primarily interested in only two; the multivibrator and the blocking oscillator. After we complete our study of the basic circuits, we will see how these circuits are used in communication equipment.

An oscillator circuit in which the output is a nonsinusoidal waveform is generally classified as a relaxation oscillator. The relaxation oscillator uses a regenerative circuit in conjunction with an R-C circuit to provide a switching action. The charge and discharge time constants of the R-C components are used to control the shape and frequency of the output waveforms.

THE MULTIVIBRATOR

The multivibrator is essentially a nonsinusoidal two-stage oscillator in which one stage conducts while the other is cut off until a point is reached at which the stages reverse their conditions. This oscillating process is normally used to produce a square wave output. A multivibrator that operates continuously with first one stage conducting and then the other is called a free running or astable multivibrator.

The multivibrator in Fig. 34 is a two stage R-C coupled, common-emitter amplifier with the output of the first stage coupled to the input of the second stage and the output of the second stage coupled to the input of the first stage. Since the signal in the collector circuit of a common-emitter amplifier is reversed in phase with respect to the input signal, a portion of the output of each stage is fed to the other stage in-phase with the signal at the base. This regenerative feedback with amplification is required for oscillation. The output of this multivibrator is a square wave whose frequency is determined by the R-C time constant in the feedback loops.

Forward bias for the base of Q_1 is obtained through the low resistance emitter-to-base junction in series with R_2 across the power supply. In a similar manner, bias for the base of Q_2 is obtained through the emitter-to-base junction and R_3. When the power supply is first energized the current that flows through each collector load resistor, R_1 and R_4, is determined by the effective resistance of Q_1 and Q_2 for a given value of base bias voltage. Due to slight differences in the transistors, more current will flow in one transistor than in the other.

For the purpose of this explanation,

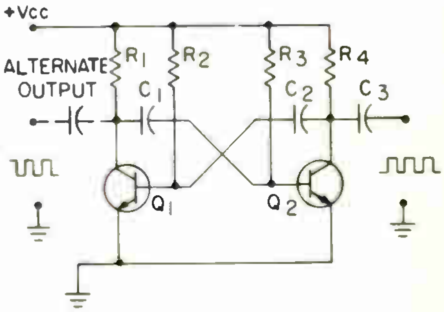

Fig. 34. Astable multivibrator.

assume that initially more collector current flows through Q_1 than Q_2. Thus as collector current in Q_1 increases, the voltage at the junction of R_1 and C_1 decreases. In other words, the collector of Q_1 becomes less positive. This negative going pulse is coupled through capacitor C_1 to the base of Q_2. As the collector current in Q_1 continues to increase, the signal coupled to the base of Q_2 continues to become more negative. As this negative signal overcomes the positive bias established by the emitter-to-base junction and R_3, collector current in Q_2 starts to decrease.

With collector current in Q_2 decreasing, the voltage at the junction of C_2 and R_4 starts to increase. This positive rise in voltage is coupled to the base of Q_1 through capacitor C_2. The positive going pulse at the base of Q_1 aids the foward bias already established by R_2 and the emitter-to-base junction of Q_1. This causes collector current in Q_1 to continue to increase. This regenerative process continues until Q_1 is driven into saturation and Q_2 is cut off.

When Q_1 is saturated, its collector current no longer increases but becomes a constant value, therefore, there is no further change in collector voltage to be coupled through C_1 to the base of Q_2. In a similar manner, Q_2 is cut off so there is no further change in its collector voltage to couple through C_2 to the base of Q_1.

With no positive pulse coupled from Q_2 to Q_1, the base of Q_1 is only a few tenths of a volt positive. C_2 quickly charges through the low resistance of the base to the emitter junction of Q_1 and R_4 to a potential approximately equal to the power supply voltage. The heavy conduction of Q_1 places its collector voltage at nearly ground potential. C_1, which was previously charged with a negative potential at the junction of C_1 and R_3, starts to discharge through R_3 at a time constant of R_3-C_1.

As C_1 discharges, the voltage at the base of Q_2 becomes less and less negative until a point is reached where reverse bias is no longer applied and Q_2 goes into conduction.

When Q_2 starts to conduct, collector current begins to flow through R_4, collector voltage at Q_2 decreases, and a negative going pulse is coupled through C_2 to the base of Q_1. As C_1 continues to discharge, collector current in Q_2 continues to increase and the pulse coupled to the base of Q_1 goes more negative. As this negative signal increases, Q_1 decreases its conduction. This results in a rise in collector voltage which is coupled to the base of Q_2, aiding the forward bias on Q_2.

This regeneration continues until Q_1 cuts off and Q_2 saturates. When Q_1 cuts off, C_1 no longer couples a positive signal to the base of Q_2. C_2 starts to discharge through R_2 at a rate equal to R_2-C_2. When C_2 is sufficiently discharged to remove the reverse bias on the base of Q_1, the transistor again starts to conduct.

This action will continue as long as the power supply voltage is present; the discharge of C_1 controlling the time that Q_2 remains cut off and C_2 controlling the time that Q_1 is cut off. In this manner, C_1 and C_2 control the width of the output pulses.

While we explained the various things happening that caused one transistor to switch from saturation to cutoff, you might have thought this action takes quite some time. Actually, the switching action is very fast. For example, with Q_1 conducting and Q_2 cut off, once the reverse bias on Q_2 disappears and Q_2 begins conduction, current rises to saturation in Q_2, and Q_1 is cut off almost instantly. The result is the output from the multivibrator is essentially a square wave. The square wave output is taken from the collector of Q_2 through C_3. A second output, reversed in phase, is available at the collector of Q_1.

The output of the multivibrator will be symmetrical, that is the two half cycles will be the same if the time constant of C_1 and R_3 is equal to the time constant of C_2 and R_2. However, if we change the time constant of either R-C circuit, the output will no longer be symmetrical. In other words, if we shorten the time constant of the C_1-R_3 network by reducing the value of C_1, it will take C_1 less time to discharge through R_3. As a result, Q_2 will be cut off for a shorter period than Q_1 and the two halves of the square wave will no longer be equal.

There are two major variations of the astable multivibrator, the monostable and the bistable. The bistable is a modification of the astable and can be used as a switching circuit. Basically it is the same circuit as the astable but provision has been made to control the change of the condition of the transistors with an input signal. Upon receipt of an input the transistors in the bistable multivibrator will change state and remain in their new condition until another input pulse is received.

The monostable multivibrator, like the bistable, is a modified astable circuit. Monostable multivibrators have only one stable state and the transistors remain in their respective states (saturated and cut off) until an input pulse is received. At that time the transistors change states and remain in their new state a length of time determined by the R-C components in the circuit. At the end of this R-C time they return to their stable condition.

THE BLOCKING OSCILLATOR

Blocking oscillators are a type of oscillator used for generating pulse waveforms of short time duration followed by a period of no output. Similar to multivibrators, blocking oscillators may be either free running or driven. Let's first look at a free running blocking oscillator, then we will examine a practical application of the circuit.

Fig. 35 shows the basic free-running blocking oscillator. Transformer T_1 provides the necessary regenerative feedback from the collector to the base of Q_1. Terminals 1 and 2 are the primary winding and connect the collector to the power supply. Terminals 3 and 4 are the secondary and furnish feedback to the base. The output is taken across the third winding at terminals 5 and 6. Notice the phase inversion between the different windings.

When the power supply is first energized, a small amount of collector current will flow through the primary of T_1. This current flow induces a voltage in the base winding (terminals 3 and 4). The induced voltage causes C_1 to charge through the low forward resistance of the base-to-

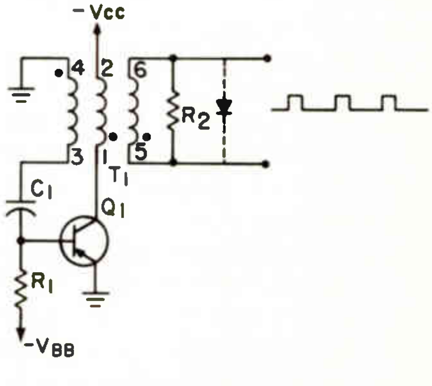

Fig. 35. Free running blocking oscillator.

emitter junction. This couples the induced voltage to the base of Q_1.

Since collector current flow is increasing, the voltage at terminal 1 will be less negative or going in a positive direction. The induced voltage in the base winding is of opposite polarity; therefore, a negative going signal is coupled to the base of Q_1. This increase in forward bias aids collector current and regeneration continues rapidly until the transistor becomes saturated.

When Q_1 reaches saturation, the current is no longer changing; therefore, there is no voltage induced in the base winding. C_1 begins to discharge through the resistor R_1, holding the base-to-emitter junction forward biased. As the charge on C_1 bleeds off, the forward bias on Q_1 decreases.

As the forward bias of Q_1 decreases and collector current is reduced, the magnetic field about the primary winding (terminals 1 and 2) collapses. The collapsing magnetic field induces a voltage in the secondary (terminals 3 and 4) which is positive at terminal 3. This induced voltage, coupled through C_1 drives Q_1 to cutoff.

Due to the reverse bias, Q_1 remains cut off until C_1 discharges through R_1 and T_1 to a point where the base of Q_1 is returned to a forward bias condition. When the forward biased condition is reached, conduction begins and the cycle repeats.

The output pulse width depends mostly on the inductance of T_1. The smaller the inductance, the more rapidly the collector current must increase to maintain a magnetizing current in T_1, the faster the collector current will reach saturation, and the shorter the pulse width. Usually, C_1 has little effect on the pulse width. However, if C_1 is small enough so that the capacitor can charge rapidly during pulse time, there will be a decrease in pulse width.

The frequency of the blocking oscillator in Fig. 35 is determined by the value of R_1-C_1. Compared to R_1, the resistance of the base winding has little effect on the discharge time of C_1.

Resistor R_2 is a damping resistor connected across the output winding of T_1 to reduce the amplitude of the reverse voltage, sometimes called the overswing, caused by the collapsing magnetic field about T_1 at the end of the output pulse. If it were not for R_2, the amplitude of the reverse voltage pulse could exceed the breakdown voltage of Q_1 and damage the transistor. In another type of damping circuit a clamping diode is placed across the collector winding or across the output winding. The diode would then shunt any reverse voltage present in these windings.

Tube type multivibrators and blocking oscillators were once widely used, but in modern equipment they are generally being replaced by transistors. The operation of the older vacuum tube units is essentially the same as the modern transistor units.

Both oscillators with a sine wave output and those with a pulse type output are widely used in communications equipment. Be sure you understand how both types work before leaving this lesson.

SELF-TEST QUESTIONS

(t) In the astable multivibrator shown in Fig. 34, what components control the length of time Q_2 is cut off?

(u) What type output is obtained from the blocking oscillator?

Answers to Self-Test Questions

(a) Regenerative or positive feedback. If positive feedback is not present, oscillations will be damped.

(b) Decrease. Frequency is equal to:

$$\frac{1}{2\pi \sqrt{LC}}$$

Therefore: if inductance increases, the frequency will decrease.

(c) There will be more cycles in the wave train. Losses in the coil of a high Q circuit are low so more cycles occur before the wave train is damped.

(d) .0000005 seconds or .5 microseconds. The formula is:

$$P = 1/F$$

$$P = \frac{1}{2{,}000{,}000}$$

$$P = .0000005 \text{ seconds.}$$

(e) They are in-phase. The voltage developed across L_2 is the feedback voltage and must aid plate current.

(f) The bias voltage developed across R_1. If the oscillator output increased, C_2 would be charged to a higher potential on positive peaks and would produce a larger bias voltage across R_1. The larger bias would reduce the amplitude of the oscillator output.

(g) 1. Oscillator remains energized at all times.
2. Oscillator coil and capacitor are placed in an oven.
3. Temperature compensating capacitors are placed across the tank.

(h) A swamping capacitor is placed across collector-to-emitter junction.

(i) R_1 and C_2 develop the negative bias. L_2 develops the signal.

(j) It goes positive. The reactance of C_2 is small at the resonant frequency of the tank; therefore, the positive voltage induced in the tank by L_2 (voltage across C_1) is coupled to the grid.

(k) C_1 develops the feedback voltage. It is applied to the base through C_3 and across R_1.

(l) The ultra-audion oscillator is a modification of the Colpitts circuit.

(m) Through the R-C phase shift network in the grid. Each pair of R-C components shift the phase a definite number of degrees. Total shift through all stages must equal 180°.

(n) R_2 and C_2 develop the feedback voltage.

(o) To prevent damage to the crystal.

(p) Frequency is controlled by the crystal, Y_1. At the resonant frequency, Y_1 offers minimum impedance to the feedback voltage. At other frequencies, impedance increases.

(q) A higher frequency can be obtained without the use of frequency multipliers.

(r) 1380 kHz.

(s) The tri-tet oscillator functions as an oscillator and a frequency multiplier.

(t) C_1 and R_3. Q_2 remains cut off until the charge on C_1 leaks off enough for Q_2 to become forward biased.

(u) A pulse output followed by a period of no output.

Lesson Questions

Be sure to number your Answer Sheet C206.

Place your Student Number on every Answer Sheet.

Most students want to know their grades as soon as possible, so they mail their set of answers immediately. Others, knowing they will finish the next lesson within a few days, send in two sets of answers at a time. Either practice is acceptable to us. However, don't hold your answers too long; you may lose them. Don't hold answers to send in more than two sets at a time or you may run out of lessons before new ones can reach you.

1. If the operating voltage on an oscillator tube is changed so that the plate resistance of the tube increases, what will happen to the oscillator frequency?

2. When adjusting the capacitance of the tank circuit in a crystal oscillator, what happens to the tank current as oscillations start?

3. What component of the blocking oscillator has the most effect on the output pulse width?

4. For what part of the cycle does current flow through the oscillator tube in an L-C oscillator circuit?

5. What is the advantage of a frequency synthesizer over the normal local oscillator circuit in a transceiver?

6. What will the frequency be at 65°C of a crystal oscillator using an X-cut crystal that operates at 5250 kHz at 50°C, if the temperature coefficient is −20 Hz per degree centigrade per MHz?

7. What controls the amount of feedback applied to the base of the transistor in a transistor Colpitts oscillator?

8. In a tuned L-C circuit, if capacitance is increased while inductance is held constant, what will happen to the output frequency?

9. How is positive feedback attained in the Wien-bridge oscillator?

10. How is frequency multiplication obtained in the tri-tet oscillator?

Take The Middle Course

Most of us realize the necessity for moderation in eating and drinking, but we often overlook the fact that moderation in all things is essential to happiness.

Consider, for example, the simple matter of opinions. If a man can see only his own opinions, and is unwilling to recognize that other people may also have good ideas, he is opinionated. A man with this fault is often unhappy, because he doesn't get along very well with other people. On the other hand, if a man yields his ideas to another's too readily, he is weak-kneed - and also unhappy.

If you can give and take - if you are open to reason - if you steer a middle course, you will be liked, people will be comfortable in your company, and you will be following one rule of happiness.

Let "moderation in all things" be one of the guiding principles of your life.

LINEAR RF POWER AMPLIFIERS

21CC

STUDY SCHEDULE NO. 21

☐ **1. Introduction** . . . . **Pages 1-2**

A brief discussion of why linear amplifiers are used to amplify the modulated signal at the transmitter.

☐ **2. The Class B Linear Amplifier** . . . . **Pages 2-9**

You learn how linearity is achieved and study the requirements for the driver stage and the plate circuit, and the power considerations for a linear class B amplifier.

☐ **3. Adjusting a Linear Amplifier** . . . . **Pages 9-12**

You learn how to interpret meter readings and study step-by-step adjustment procedures.

☐ **4. Variations in Linear Amplifiers** . . . . **Pages 13-20**

You study push-pull, multi-grid and grounded-grid amplifiers, and the high-efficiency Doherty amplifier.

☐ **5. Outphasing Modulation System** . . . . **Pages 21-28**

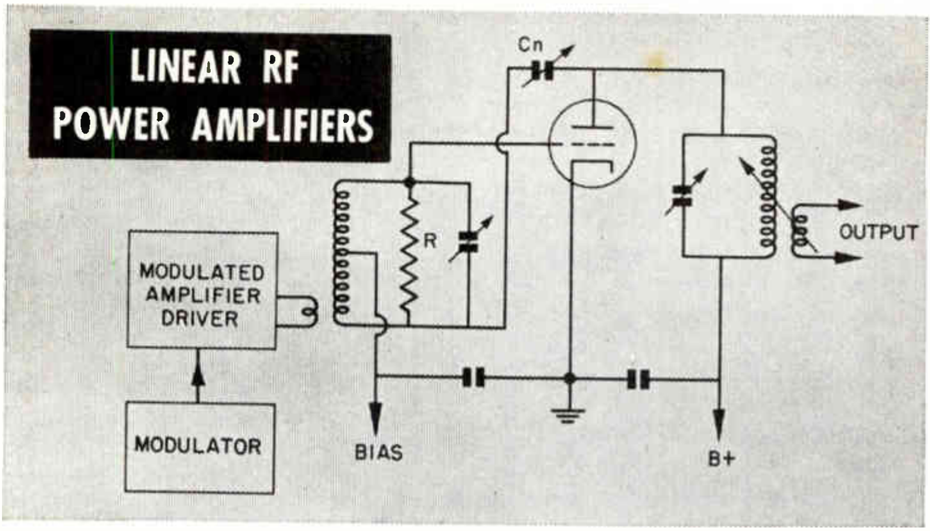
Here we take up a system of modulation, which by using phase differences, eliminates the necessity of operating the amplifiers following the modulator in a linear manner.

☐ **6. Answer Lesson Questions.**

☐ **7. Start Studying the Next Lesson.**

MP3M269 **1969 EDITION** Printed in U.S.A.

LINEAR RF POWER AMPLIFIERS



As you have learned, in amplitude modulation, the amplitude of the carrier signal is made to vary according to the amplitude variations of the intelligence signal. In some AM transmitters, the modulation takes place in the plate circuit of the final power amplifier stage where the power level is high, so the modulated signal is fed directly to the transmitting antenna. This is called "high-level" modulation. The modulation can also take place in an intermediate class C power amplifier stage. Then, the power of the modulated signal is increased by additional power amplifiers. This is called "low-level" modulation, because it takes place at a lower power level. The modulated signal must not be distorted by stages following the modulated stage. The signal that is fed to the transmitting antenna must be a faithful copy of the output signal from the modulator, or the demodulated signal from the receiver will also be distorted.

The stages that amplify the modulated signal cannot be operated in class C, because a class C stage is driven to saturation at the peak of each positive alternation of the input signal, which would distort the modulated signal waveform. They could be operated in class A, in which case, the output signal would be an exact duplicate of the input signal. However, we want high power output from a transmitter as well as an undistorted signal. A stage operated in class A has very low efficiency and very low power output.

It is most satisfactory to operate the power-amplifier stages following the modulated stage in class B. This gives an undistorted output signal, and more power output than for class A. The class B amplifier stage is operated on the straightest part of its transfer characteristic curve, so that there is a linear relationship between the amplified output voltage and the exciting voltage applied to the input. That is, the output voltage developed across the load is proportional to the grid voltage. An increase or decrease in the excitation voltage will produce a corresponding increase or decrease in the output voltage.

As you will learn in the following section, linearity is obtained by proper adjustment of the grid bias and the load impedance. All the stages following the modulated stage must be operated as class B linear amplifiers.

There is an exception to this, and that is in a system of modulation called "outphasing modulation." With this system of modulation, the rf power amplifiers following the modulator do not need to be linear. You will see why in the last section of the lesson.

First, you will find out how high-power linear amplifiers work, how they are adjusted, and what their advantages and disadvantages are. One of the chief disadvantages of the class B linear amplifier is that its efficiency is lower than that of a class C amplifier. However, it is possible to get higher efficiency by redesigning the stage. An example of a high-efficiency amplifier is the Doherty linear amplifier, which we will discuss.

Linearity in a transmitter can be improved by using feedback between the final linear amplifier output and the speech amplifier section. Feedback will also reduce distortion and improve frequency response and stability in the transmitter stages. We will also take up feedback circuits. First let us find out how the class B linear amplifier works.

The Class B Linear Amplifier

A schematic diagram of a class B linear amplifier stage is shown in Fig. 1. This stage has tuned resonant circuits in the input and output, and is neutralized in the same way as a class C power amplifier.

The basic difference is that the linear amplifier is biased as a class B stage. The tube, however, is not biased exactly to plate-current cut-off. The transfer characteristic curve of a vacuum tube is shown in Fig. 2. Notice that the lower end of the curve bends and is very non-linear before the plate-current cut-off point is reached. If the stage were biased exactly at cut-off, the non-linearity in this part of the curve would cause the signal to be distorted. Therefore, the bias is set a little above the actual cut-off point on the curve, so that the tube will operate only on the straight or linear part. This point is called "extended cut-off," and is shown in Fig. 2. The extended "cut-off" point is found by extending the straight part of the transfer curve until it crosses the current axis. This is the point at which plate-current cut-off would occur if the lower end of the curve were linear.

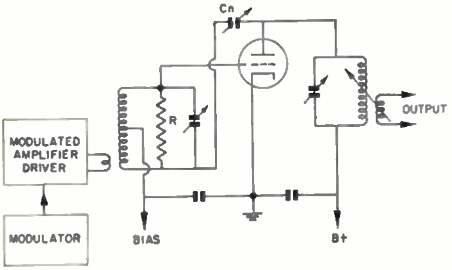


FIG. 1. Basic class B linear amplifier system.

With the grid bias set to the extended cut-off point, the plate current flows for slightly more than 180° of the input signal cycle. In class C, as you learned, the plate current flows for 120° to 150° of the cycle.

The linear power amplifier can be operated in class AB$_1$ or class AB$_2$ instead of in class B. You will remember that a class AB stage is a stage that is biased between class A and class B conditions. In class AB$_1$ operation, the input signal never

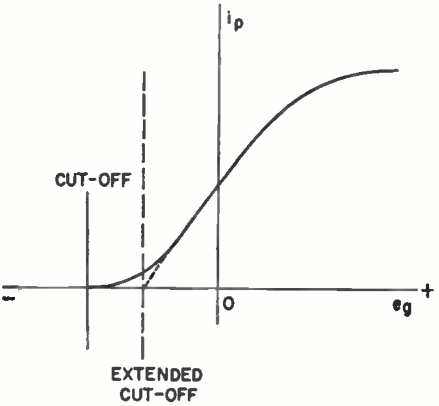

FIG. 2. A tube's e_g-i_p curve, showing the extended cut-off point.

drives the grid positive. In class AB_2 operation, the signal voltage on the grid drives the grid slightly positive on a part of the positive cycle. Class AB_2 operation delivers more power than class AB_1 but less power than class B.

The operation of the linear amplifier can be demonstrated by using the waveform illustrations in Fig. 3. With the grid bias set at the extended cut-off point, a small plate current will flow when no excitation is applied to the input. When a signal is applied to the grid, on the negative alternations the grid is driven below plate current cut-off, so no plate current flows. On the positive alternations, the input signal voltage subtracts from the grid bias, reducing the negative bias on the tube, and the plate current flows for slightly more than the entire positive half cycle. The plate current is in the form of pulses as shown in the diagram.

For distortionless output, the amplifier must operate over the straight portion of the characteristic curve. In other words, the highest peak grid voltage must not swing the plate current beyond point A. As you have learned, on 100% modulation, the

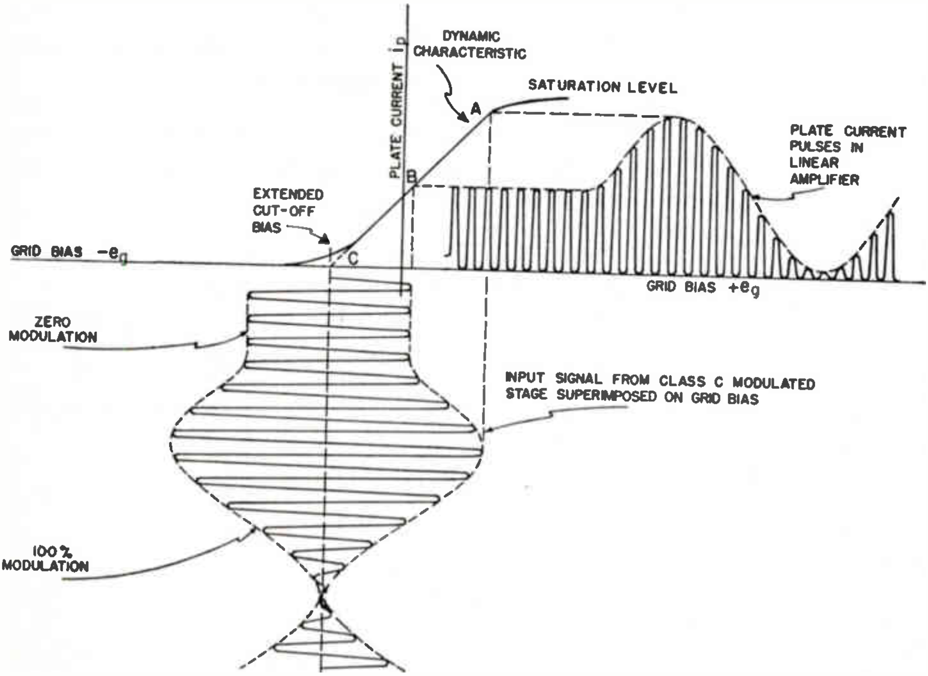

FIG. 3. Class B operation of an amplifier.

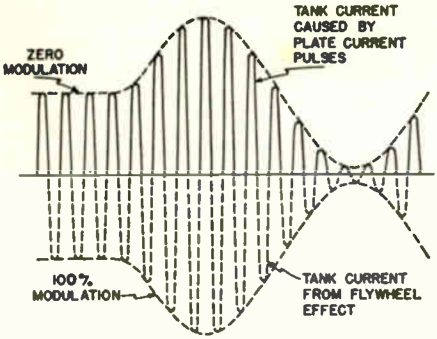

FIG. 4. The flywheel effect of the plate tank circuit in a class B amplifier supplies the missing half-cycles of plate current.

peaks are twice the unmodulated carrier value. In the diagram, the current value at point B is slightly more than half the current value at point A. Thus, if the unmodulated carrier excitation is set at point B, the positive peak at 100% modulation will swing the rf excitation to point A. During the modulation troughs when the modulation amplitude is least, the plate current will be driven near point C. For most efficient linear operation of the amplifier, the grid bias must be set properly so that point B is midway between points A and C, and the input signal must have a high enough amplitude to swing the plate current over the entire linear portion of the characteristic curve between points A and C.

The plate current pulses supply energy to the plate tank on the positive half cycles, just as in a class C amplifier. Then, on the negative half cycles when the plate current is cut off, the energy stored in the tank is fed back into the circuit to form the negative alternations of the output signal. This is shown in Fig. 4. The upper half of the output signal waveform, shown in solid lines, is the part contributed by the plate current pulses. The lower half, produced by the energy-storing (flywheel) action of the tank circuit is shown in dashed lines.

Thus, the output signal fed to the antenna or load circuit is a completely modulated signal, even though the class B rf amplifier tube feeds power to the load for only half of the input signal cycle.

The circuit shown in Fig. 1 is a single-ended stage. In your study of audio stages, you learned that for audio frequencies a class B stage must be operated in push-pull, or the sound will be highly distorted and contain many harmonics. However, this is not true at rf frequencies; a class B stage using a resonant circuit in the plate circuit can be single-ended because the resonant circuit restores the missing parts of the modulated signal wave-form. The resonant circuit also eliminates many of the undesired harmonics.

HOW LINEARITY IS ACHIEVED

The proper operation of a class B linear stage is determined by its grid bias, grid drive, plate voltage, load impedance, plate and grid currents, and the power relationships in the

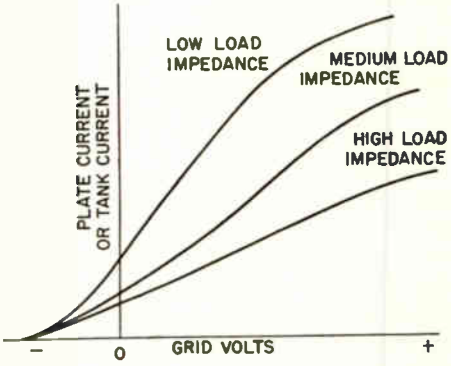

FIG. 5. Linearity curves for a class B amplifier using various values of load impedance.

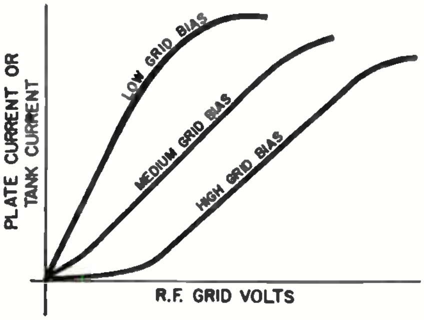

FIG. 6. The effect of various grid bias values upon the linearity of a class B amplifier.

input and output circuits. The linearity in the stage depends primarily on the grid bias and the load impedance.

The plate load impedance must be chosen to get high power output and efficiency as well as good linearity.

Load Impedance. Fig. 5 shows the effect of various load impedances on a tube operating in class B. The instantaneous grid voltage, made up of the bias voltage and the rf excitation signal, is plotted along the horizontal axis. The plate current, or proportional tank current, is plotted along the vertical axis. As you can see, the curve is not linear for low impedance but is quite linear for high impedance. The low impedance is not satisfactory, because the output would be distorted, although it is ideal for class C operation because it has high power output. The high impedance is not satisfactory either, because the plate current swing would be small and the power output very low.

Proper loading of a linear amplifier must be a compromise between linearity and power output. The medium load impedance curve in Fig. 5 is the one that is usually chosen. For a triode tube, the best value of the load impedance is equal to about twice the plate resistance of the tube.

Grid Bias. Now let us see how the grid bias affects the linearity of the stage. Fig. 6 shows the dynamic characteristic curves for various values of grid bias. With a low grid bias, the lower part of the curve is linear, but it soon folds over. If a modulated signal were applied to the input, the peak of the modulation envelope would be compressed, and the signal would be distorted.

With high grid bias, the curve is flat or compressed at the bottom, and a modulated signal would again be distorted. A medium value of bias is best for linear operation. There is a slight bend near the bottom of the medium bias curve which is kept at a minimum by operating the tube at the extended cut-off bias as discussed previously.

The grid bias for the linear amplifier must be supplied from a separate low-impedance power supply. Grid-leak bias, which is used in class C stages, cannot be used in a class B linear stage, because the excitation to the linear amplifier is not constant; the grid current flow is small for low modulation and very high for 100% modulation. Thus, the grid-leak bias itself would vary over the modulation cycle and cause distortion.

Sometimes a cathode bias resistor is used, because the average cathode current in a linear amplifier is constant and does not vary during the modulation cycle. However, a cathode bias resistor wastes too much power for use in a stage other than a low power stage, so fixed bias is more often used.

The power supply that provides the bias voltage must be a low-impedance supply, because if the impedance is low, the variation in the grid current due to the input signal will have little effect on the dc bias voltage. Also, by using a separate bias source, the bias can be easily adjusted to get the exact value required for the most linear operation of the stage.

Excitation. The excitation must be carefully set to prevent distortion during modulation peaks, because regardless of what load impedance or grid bias is used, an excessive grid excitation will cause the plate current to swing into the curved portion of the characteristic curve. At the same time, the excitation must be high enough to operate the class B stage with reasonable efficiency. Thus, the driver stage must be operated properly to get undistorted linear output.

REQUIREMENTS OF THE DRIVER STAGE

Now let's consider the requirements of the stage that drives the class B amplifier. Because grid current flows in the class B amplifier during the part of the cycle that the grid is driven positive, power is being dissipated in the grid circuit. This power must be supplied by the driver stage. The higher the grid current, the lower the impedance presented by the amplifier, and the more power the driver stage must supply.

During an rf cycle, the grid impedance of the amplifier may change from an infinite value for negative grid potential to only a few hundred ohms for a high positive potential. This varying impedance places a varying load on the driver with the result that the driver output voltage, which is fed to the amplifier to drive it, will vary. For no grid current and a light load, the driver voltage will be high; for high grid current and a heavy load, the driver voltage will be reduced. If the output impedance of the driver is too high, this effect becomes worse and the driver output voltage may become so low when the amplifier grid is drawing current, that the grid is not driven far enough positive to drive the stage.

The positive peaks of excitation will be flattened out as shown in Fig. 7. When this happens, we say the driver has poor regulation. In Fig. 7, the excitation of the grid of the class B amplifier from a poorly regulated driver is shown in heavy lines. For comparison, a perfect sinusoidal excitation voltage is shown in dashed lines. Obviously, even though the amplifier is operating over a perfectly linear dynamic characteristic curve, excitation such as that in Fig. 7 will cause serious distortion.

To minimize this grid-loading effect, the driver regulation must be made as good as possible. This is usually done by designing the driver stage so that it is capable of delivering two or three times as much power as that required to drive the grid of the amplifier. This keeps the impedance of the driver down. In addition, the input tank of the amplifier is shunted by a relatively low resistance. This resistance, shown as R in Fig. 1, absorbs considerable driver power, but reduces the wide fluctuations in grid circuit impedance. With this resistor, the input circuit impedance can change from a few hundred ohms only up to the value of the shunting resistance. Thus, the driver works into a more nearly constant load.

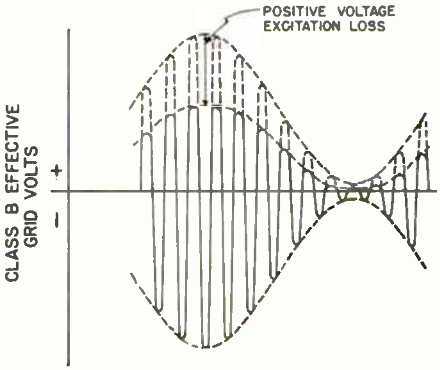

FIG. 7. How poor voltage regulation of the driver stage causes distortion of the class B amplifier excitation.

The grid-loading resistor may not be required if a special zero-bias tube is used in the class B stage. The operating bias for these tubes is very low, usually from 5 to 10 volts. The grid loads the circuit at all times, during the positive half of the input cycle so the impedance remains nearly constant during this half of the cycle. Since this is the only half of the input cycle we are interested in, it does not matter that the impedance changes during the negative half cycle.

Another way of assuring proper drive to the linear amplifier is to operate the amplifier as a class AB amplifier. If the amplifier is operated in class AB_1, the grid is not driven positive, so no grid current flows. The grid circuit impedance remains constant, and furthermore the driver needs to supply only an exciting voltage—it does not have to supply any power because no grid current flows.

Since the efficiency of a class AB_1 stage is low, a compromise arrangement is to operate the stage as a class AB_2 amplifier. Here the grid is driven positive during only part of the positive half cycle, and the power requirements are less than for class B operation. This enables us to get better driver regulation and hence a more linear output. Some modern linear amplifiers using tetrode tubes are operated as class AB amplifiers, usually class AB_2. Reasonably good efficiency can be obtained from these stages and the driving power requirements are low. Good efficiency can be obtained from class AB_2 tetrode stages because tetrode tubes have a high power sensitivity, that is, they can develop a high power output in the plate circuit with a low power input in the grid circuit.

PLATE CIRCUIT REQUIREMENTS

As in class C operation, the plate voltage in a class B or class AB linear amplifier has a decided influence on the power output. It must be high enough for maximum linear output without causing excessive plate dissipation. Naturally, the maximum rf peak voltage that can be developed across the load impedance is somewhat less than the B supply voltage.

With 100% modulation, during the negative half of the cycle of the rf exciting voltage, the tube is driven beyond cut-off, and the voltage developed across the load impedance is equal to the B supply voltage. During the positive half of the input cycle, when the tube is driven up close to the saturation point, maximum plate current flows, the tube plate resistance drops to a low value, and the plate voltage is very low. The maximum change in plate voltage is between this low value and the actual value of the B supply voltage. This maximum change occurs only during 100% modulation; for lower percentages of modulation, the plate voltage change is not as great.

The changes in the grid excitation voltage and in the output voltage are linear. In other words, a variation in the rf voltage applied to the grid will cause a corresponding variation in the plate voltage. This linear relationship depends upon the grid bias value. In a class C stage, the plate is driven to saturation in order to get a higher plate efficiency. In the saturation region, the excitation voltage and the plate voltage are no longer linear. To avoid the distortion that would result from this non-linearity, a linear amplifier is never driven into the saturation region.

If the amplifier has a truly linear characteristic, the plate current increase during the modulation crest is equal to the plate current decline during the trough. Hence, the average plate current read on a dc plate current meter is constant and should not change from no-modulation to 100% modulation. The average plate current will be equal to the peak plate current with no modulation when a linear amplifier is used to amplify a carrier and two modulation sidebands. In a later lesson you will see that in some applications of linear amplifiers the plate current does change with modulation.

POWER CONSIDERATIONS

In an earlier lesson you learned that the output power from a class C stage is proportional to the square of the plate voltage; in other words, if you double the plate voltage, the output power will increase four times. This relationship exists because the signal applied to the grid drives the tube from cut-off all the way to plate current saturation on every cycle. In a class B or a class AB linear amplifier, the output power is proportional to the square of the *exciting signal voltage*. With a constant load resistance, if the input signal voltage is doubled, the output power will increase four times because both the signal voltage and signal current developed in the output will double. Thus, the input signal has direct control over the output power.

The linear amplifier has a constant plate voltage and, when operating correctly, functions with a constant average plate current. Hence, it draws a constant amount of power from the high-voltage supply.

In your study of amplitude modulation, you learned that with 100% modulation, at the peak of the modulation the power of the carrier is four times the power without modulation. You have also learned that the plate input power of a linear stage remains constant whether or not modulation is applied. Therefore, the amplifier must have higher efficiency during modulation. (The higher the efficiency of an amplifier, the higher the power output.) When the stage is fed with an unmodulated carrier, its efficiency is 30% to 35%. For full 100% modulation its efficiency increases to 60% to 70%. The plate input power divides between the tube and the output load. With no modulation, two-thirds of the input power must be dissipated by the tube plate; at 100% modulation, only one-third must be dissipated by the tube plate. This shows that the linear amplifier tube runs cooler when it is delivering the most power output (high modulation percentage).

Since the modulation peaks of speech and music are often 10 to 20 times as great as the average signal level, the average grid excitation must be kept low. The average efficiency of a typical linear amplifier is usually not over 40%.

The power gain, which is the ratio of the output power to the driving power, of a linear amplifier is usually between 5 and 10 with triode tubes, and between 20 and 50 with tetrode and pentode tubes. The gain is low when triode tubes are used because triode tubes require a substantial driving power because of their low power sensitivity and also because the losses in the grid circuit are often quite high.

If a stage has a power sensitivity of 10, we will need a driving power equal to 1/10 of the power output. For example, if the power output of a linear amplifier with no modulation is 10 kw (10,000 watts) and the stage has a power sensitivity of 10, the driving power needed would be 10 kw ÷ 10 = 1 kw. If the efficiency of the linear amplifier is 33 1/3%, the input power to the stage would be 30 kw; 10 kw would be useful output and the other 20 kw would be dissipated as heat by the tube. If the driver is a plate-modulated class C amplifier with an efficiency of

66 2/3%, the plate input to the driver would be 1.5 kw (1500 watts). To plate modulate the driver we would need approximately 750 watts of audio power. Thus, we can 100% modulate the 10 kw output of the linear amplifier with only 750 watts of audio power.

On the other hand, if we tried to plate modulate an amplifier with an output of 10 kw we would need much more audio power. If the efficiency of the stage is 66 2/3% (a class C stage), the power input would be 15 kw and to 100% modulate the stage would require 7.5 kw of audio power. This is ten times the power needed for 100% modulation when we modulated the driver and operated the power output stage as a linear amplifier. Thus, the poor efficiency of the linear amplifier is compensated for by the lower audio power needed for 100% modulation. In high-power transmitters it is more economical to modulate one of the low power driver stages and then amplify the signal with linear amplifiers than it is to try to plate modulate a high power class C amplifier.

Adjusting a Linear Amplifier

Fig. 8 shows the schematic diagram of a typical single-ended class B linear stage. Notice the similarity between this circuit and the conventional class C amplifier stage. The plate and grid resonant circuits and neutralizing method are identical to those used for class C. The modulated rf signal is link-coupled to the grid of the amplifier from the plate circuit of the modulated stage. Thus, the modulated stage acts as the driver.

Resistor R1 connected across tuning capacitor C2 and part of coil L2 is the grid-loading resistor. It is used to prevent wide impedance variations

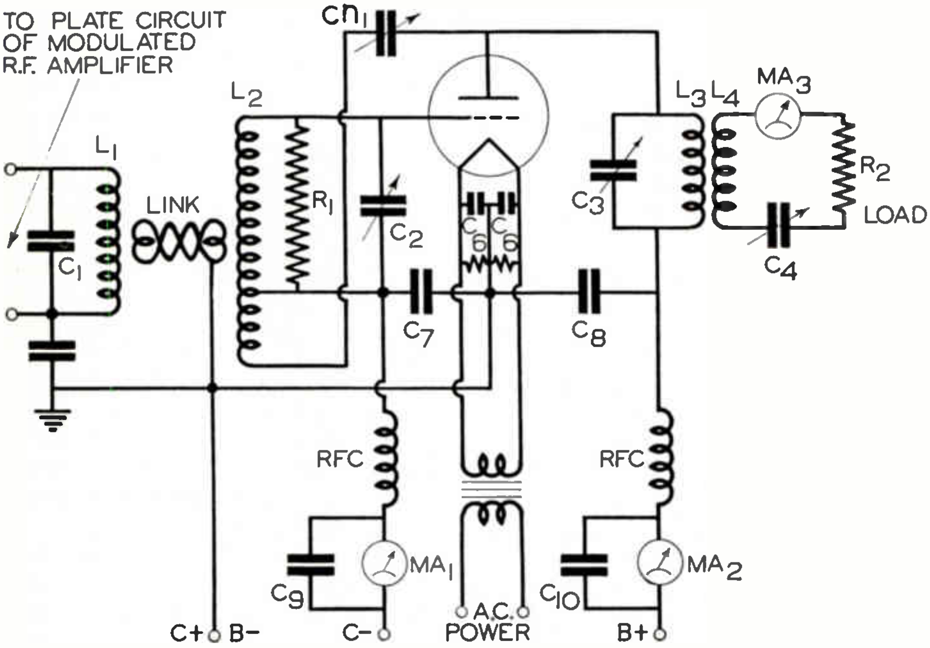

FIG. 8. A typical single-ended class B linear rf amplifier.

in the amplifier grid circuit, and thus present a more constant load to the driver stage. The bias voltage for the grid is obtained from a separate low-impedance supply.

As shown in Fig. 8 there are current meters in the circuit to indicate the operation of the amplifier. Meter MA_1 indicates the grid current, meter MA_2 indicates the plate current, and meter MA_3 indicates the load current. The meters in the grid and plate circuit are shunted by capacitors to prevent rf currents from damaging them.

INTERPRETING METER READINGS

From the readings on the grid current, plate current, and output current meters you can determine whether or not the amplifier is operating correctly. If the amplifier has been adjusted correctly and is being driven by a well regulated driver, the meter readings should be as follows:

With no modulation on the carrier, the grid current will be small and steady. The plate current will also be constant and its value should be that recommended for the rated power output. The reading on an antenna current meter should be constant. Its exact value of course will depend on the power output of the stage, the type of transmission line used to connect the amplifier to the load, and on how well the line is matched to the load. For the present, all you need be concerned about is that with no modulation the meter reading should be constant.

On 100% sine-wave modulation, the grid current reading should rise sharply to a maximum value. The plate current, however, should not change and will not if the amplifier is truly linear. Any change in the plate current reading is an indication of nonlinearity. The output load current in MA_3 should increase 22.5% with 100% sine-wave modulation.

With voice or music modulation, the grid current reading will rise and fall with the peaks of the modulation. The antenna current meter will also fluctuate, but the plate current should never vary from its normal steady reading.

Since the average power contained in voice and music is low, the antenna or load current will rise only a few percent higher than with no modulation. There will be a sharp rise in the load current value only on loud sustained passages.

The grid, plate, and output meter readings can also be used to localize defects and causes of distortion. The modulated signal fed to the linear amplifier stage must be free from distortion. Therefore, when checking any linear amplifier circuit, almost the first test to make is to see that the input signal itself is linear and undistorted. If it is distorted, check the modulated amplifier and the modulator stages. Be sure that their operating voltages and drive are correct, that the class C amplifier is not being over-modulated, and that the tuning and loading are correct for the stages.

If the input signal is not distorted, incorrect meter readings may indicate defects in the linear amplifier itself. Suppose the plate current reading increases and the pointer on the antenna current meter "kicks up" sharply when modulation is applied. A rise in antenna current is normal; the meter pointer, however, should not swing up or down sharply. (You may not notice abrupt changes in meter readings if a thermocouple meter is used.) This indicates a positive carrier shift (upward modulation). The plate and antenna current increase can be due to excess bias on the grid, which causes the tube to operate further down on the knee of the characteristic curve. This will cut off the trough of the modulated signal, causing the average plate current to rise. Parasitic oscillations, incomplete neutralization of the amplifier, and improper tuning and loading of the stage can also cause positive carrier shift.

Negative carrier shift (downward modulation) occurs when the average plate current and the antenna (output) current decrease with modulation. This is due to a defect that cuts off or distorts the peaks of the modulated signal. If an excess amount of excitation is applied to the grid, the tube will be driven to saturation, and the positive peaks will be distorted. Poor regulation in the bias or high-voltage power supplies can also cause negative carrier shift because the grid or plate voltages are not high enough to provide the peak values of the amplified waveform.

Also, if the load that the linear amplifier presents to the driver stage varies widely during the input signal cycle, the peaks of the modulated waveform at high modulation levels will be cut off. The output signal will be distorted, as indicated by a decrease in the antenna meter reading. The purpose of the shunt resistor across the coil in the grid circuit is to prevent the load on the driver stage from varying. A higher than normal load impedance for the class B linear stage or incorrect tank circuit tuning will also cause the modulation peaks to be cut off, and cause the readings on the plate and antenna current meters to decrease.

A decrease in the grid and plate current meter readings over a period of time could indicate a loss of efficiency in the driver amplifier or some defect earlier in the transmitter, causing a loss of excitation power to the linear amplifier. Also, a gradual decrease in the grid and plate current meter readings is often an indication of a weakening linear amplifier tube.

Thus, to get an undistorted output signal from a class B linear amplifier stage, the operating voltages, grid drive, and loading must be correct. Also, the stages preceding the linear amplifier must be operating properly to produce an undistorted signal of the correct amplitude to the stage. Usually the recommended operating voltages are applied to the stage and then the grid bias and the load are varied slightly on either side of the recommended values to get the greatest undistorted power output at the best efficiency. This is a part of the adjustment procedure; let us go through the complete procedure now.

ADJUSTMENT PROCEDURES

Before the class B stage itself can be adjusted, the preceding stage must be adjusted, and the class C modulated stage and the class B stage itself must be neutralized. During adjustment the grid bias and plate voltages are not set to their full final values to be sure tubes and other parts are not damaged, and to prevent the possibility of interfering with other broadcast stations. The procedure for adjusting a class B stage using triode tubes is as follows:

1. Apply grid bias of one-half its final intended value.
2. Apply a low-amplitude unmodulated rf signal to the input.
3. Increase the level of the unmodulated rf signal by tightening the coupling between the driver and the amplifier until there is grid current flow.
4. Readjust the plate tank circuit of the driver stage, and the grid tank circuit of the amplifier stage to resonance by tuning each for maximum grid current.
5. Apply plate voltage of one-half the final intended amplitude.
6. Quickly tune the plate tank to resonance as indicated by a dip to

minimum in the plate current.

7. Couple the load circuit to the amplifier by increasing the coupling between the output tank circuit and the coupling network to the antenna or the next stage; as coupling is increased, readjust the tank capacitor to resonance. Continue increasing the coupling until the plate current minimum is approximately three times the minimum without a load.

8. Apply normal plate voltage and extended cut-off grid bias to the stage.

9. Check the plate current and the output current readings. If they are both too high, reduce the excitation to the stage. If the plate current is high and the output current is low, reduce the excitation and increase the load coupling; then, increase the excitation again. If the plate current is still too high, the grid bias may be too low. In this case, to get the best possible linearity, it may be necessary to vary the bias slightly above or below the value recommended by the transmitter manufacturer.

If you get good linearity for a bias voltage near the recommended value, and the input and output power are correct with full excitation, the amplifier is properly adjusted.

If the plate current is still too high or the plate input power and the output power are below normal, the load impedance is too high. Readjust the load coupling and make a new set of linearity checks.

10. Make a final check of all meter readings with modulation applied. The grid current meter reading should change rapidly with modulation, and the plate current meter should remain steady. The load current meter reading will increase very slightly with normal modulation. However, with sustained 100% sine-wave modulation, the load current reading should rise 22.5%.

You can also use an oscilloscope to check the linearity of a linear amplifier system. To do so, you first observe the modulation envelope at the output of the driver to make certain that an undistorted signal is being applied to the linear amplifier. Then, you use the oscilloscope to check the performance of the linear amplifier itself, with 100% sinusoidal modulation applied. The major advantages of oscilloscopic checks are that they are instantaneous and do not require a tedious step-by-step measurement procedure. The oscilloscope can be used to monitor the output of the transmitter during normal operation, to provide an immediate indication of any non-linearity. You will receive detailed instructions on how to use the oscilloscope in a later lesson.

The adjustment procedure for a class B linear amplifier using pentode or tetrode tubes is the same as for triode tubes, except that some load should be connected to the stage before plate and screen voltages are applied to the stage. If you attempt to tune a pentode or tetrode rf stage without a load connected to it you may destroy the tube.

Variations in Linear Amplifiers

So far, we have been discussing single-ended linear amplifiers. Linear amplifiers may also be operated in push-pull and can use multi-grid tubes as well as triodes. There are differences in the operation of single-ended and push-pull stages, but the basic characteristics and the purposes for which they are designed are the same. We will show several examples.

PUSH-PULL LINEAR AMPLIFIERS

A class B push-pull stage using triode tubes is shown in Fig. 9. Resistors R1 and R2 load the grid and establish proper driver regulation. The two radio-frequency chokes shunting the loading resistors provide low resistance dc paths for the grid current so there will not be any unwanted grid-leak bias. Regular push-pull cross neutralization is used, and the metering arrangements are similar to those for a single-ended stage.

Advantages. The push-pull class B linear amplifier in Fig. 9 has some advantages over the single-ended type. Twice as much power can be obtained from a push-pull stage, and the Q of the tank circuit can be lower than in a single-ended stage, if the push-pull tubes are properly balanced. The Q of the tank circuit of the single-ended stage must be higher, because the single-ended class B stage depends upon flywheel effect in its plate tank circuit to establish one alternation of the rf output cycle. If the Q is too low, the flywheel effect is inadequate and the modulation envelope is distorted. This means that the second harmonic content becomes high and filters must be used to reduce second harmonic radiation. Hence, a compromise must be made in a single-ended stage between power output (which depends on the circuit loading) and the tank circuit Q.

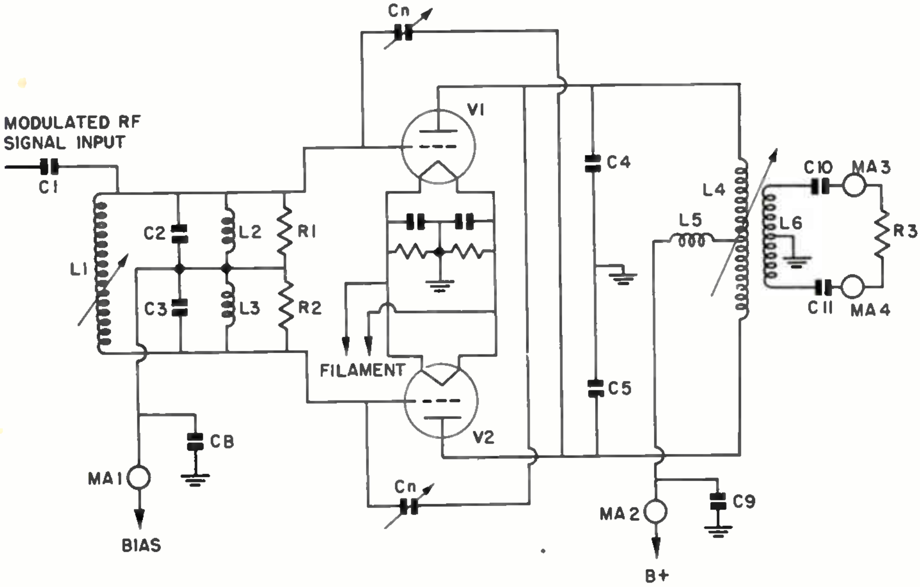

FIG. 9. Push-pull class B linear amplifier.

In a push-pull class B stage, one tube supplies energy during the positive half-cycle. Its plate current then falls to zero, and the other tube supplies energy for the negative half-cycle. Consequently, each tube contributes one-half or 180° of the complete rf cycle. Since the tubes supply energy to the tank circuit for the entire signal cycle, the tank circuit flywheel effect is not essential. The load can be coupled into the tank circuit for optimum power output and efficiency and for the best linearity. Thus, the power output is higher and the harmonic distortion is less for push-pull class B operation.

The circuit Q is still important in a push-pull stage. A low Q tank circuit will pass a considerable amount of harmonics, but by balancing the tubes properly, much of the even-harmonic energy can be eliminated. A low Q circuit will reduce the tank circuit losses and raise the efficiency. In a high power transmitter even a 5% loss in output power is a considerable amount, when it just heats the coil.

There is also less sideband clipping in a push-pull stage than in a single-ended stage. In a single-ended stage, to maintain an adequate flywheel effect, the Q of the tank circuit must be quite high and sharp. Thus, some of the higher frequency sidebands may be clipped off. With push-pull operation, the Q can be considerably less, and therefore, the tank circuit response is broad and sideband clipping is less likely to occur.

The load impedance in the push-pull stage must be chosen correctly to get the best linearity, power output, and efficiency. For a stage using triode tubes, the load impedance is about twice the plate resistance of one of the amplifier tubes. This is considerably less than the load impedance required for a push-pull class B audio amplifier in which the load impedance is four times the plate resistance of one of the tubes.

Adjustments. The adjustment procedure for the push-pull class B linear stage is similar to that described for the single-ended stage. The preliminary adjustments are made, as described previously, and then the grid and plate voltages are set to half their normal values. After the class B stage adjustments are completed, full normal operating voltages are applied. Usually small touch-up adjustments are required for best operation.

LINEAR AMPLIFIERS USING MULTI-GRID TUBES

Tetrode, pentode, and beam-power tubes are also used in linear amplifiers. Multi-grid tubes give better power gain, and less driving excitation is required for a given power output. Also, the additional electrodes give better shielding, so neutralization is not as much of a problem.

However, to prevent non-linearity, the voltage applied to the screen grid must be very well regulated. Variations in screen voltage as the modulation changed would have the same effect as variations in grid bias in a triode linear amplifier. Variations in screen voltage would cause the plate current and power output of the amplifier to change in a non-linear manner, causing a distorted modulation envelope. In low-powered amplifiers, it is common to use small voltage-regulator tubes, and in higher-powered amplifiers, the screen voltage is obtained from an extremely well-regulated power supply.

The multi-element tubes are often operated in class AB_1 or AB_2. An advantage of AB_1 operation is that no driving power is needed because the tubes will not draw grid current. Driver regulation is much less of a problem because the grid circuit in-

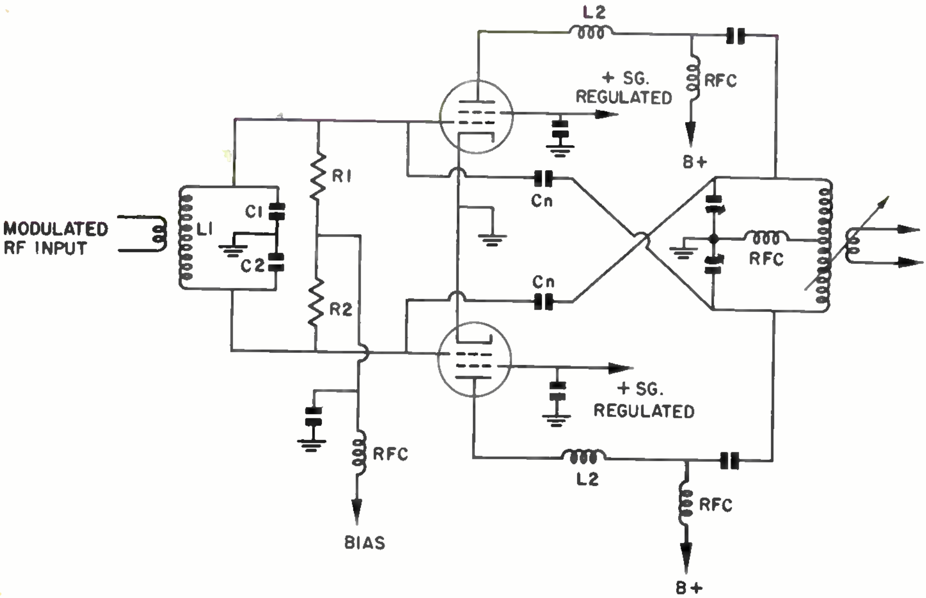

FIG. 10. A class AB_1 linear amplifier using tetrodes.

put impedance does not vary as in a class B linear amplifier, which draws a very high grid current. A class AB_2 amplifier draws some grid current, but not as much as class B.

The class AB_1 linear amplifier may have two tubes in push-pull, or four or eight tubes in a push-pull parallel combination. Fig. 10 shows a linear amplifier with two tubes in push-pull operated in class AB_1. Resistors R1 and R2 in the grid circuit load the input, increase the circuit bandwidth, and broaden the response of the input resonant circuit so that the input does not have to be tuned. Thus, capacitors C1 and C2 can be fixed rather than variable capacitors.

Neutralization of the multi-grid tubes is not exacting, and two small fixed capacitors, such as those labeled C_n in Fig. 10, are often used.

The output circuit has parasitic chokes and a split-stator tuning capacitor, making it similar to most push-pull class C amplifier output circuits. The class AB_1 operation depends upon the loading, biasing, and excitation.

The screen voltage is obtained from a voltage-regulated supply.

GROUNDED-GRID AMPLIFIER

A linear rf amplifier may also use a grounded-grid circuit, as shown in Fig. 11. The grounded-grid circuit gives somewhat better linearity than a grounded-cathode circuit.

The exciting voltage is applied between the cathode and ground. The input of the grounded-grid amplifier presents a low impedance load for the driver. Thus, it is not necessary to

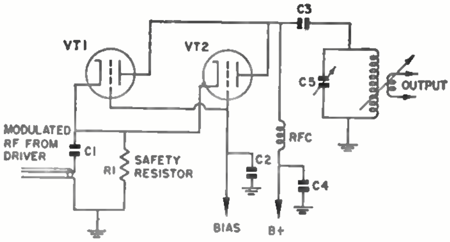

FIG. 11. A grounded-grid linear amplifier.

use a tuned circuit in the input. The driver can be connected directly between the cathode and ground, if a capacitor is used for proper dc isolation between the driver and the linear amplifier. The cathode resistor is inserted to prevent a high voltage from appearing between the cathode and ground in case an open develops between the driver and the cathode circuit of the amplifier.

A grounded-grid amplifier is very stable; much more stable than a conventional grounded-cathode amplifier. The control grid is at rf ground potential and acts as both a control element and a screen between the cathode and plate. Therefore, the stage usually does not have to be neutralized. This stage also operates better at frequencies above 50 mc than the grounded-cathode amplifier does. If it is used at these high frequencies, the inductance of the leads in the input and output circuit and the grid-to-plate capacity can provide enough feedback to cause instability and perhaps oscillation. In this case, the stage must be neutralized.

When filament-type tubes are used, the grounded-grid amplifier requires a special filament transformer that has a very low capacity between the primary and secondary windings. The capacity between the windings will shunt the signal to ground.

The stage requires more power from the driver than does a grounded-cathode stage. This additional power, however, does not represent a loss, because the extra power actually appears in the plate circuit of the stage. Thus, the output power comes partly from the driver and partly from the amplifier itself.

DOHERTY AMPLIFIER

We have learned that the average efficiency of a conventional linear amplifier is seldom better than 40%. With 100% modulation, we can get an efficiency of about 70% on modulation peaks, because then the amplifier is operated near saturation. If we could operate the amplifier near saturation at all times, its efficiency would be high, but then, on modulation peaks, the output would be distorted, because the peaks would be flattened out—the amplifier would not be able to supply the additional power demanded of it on peaks.

It is possible to get an average efficiency of from 60% to 65% by using a two-tube circuit like that shown in Fig. 12. This amplifier is called the Doherty amplifier. The circuit is arranged so that the unmodulated signal from the driver drives

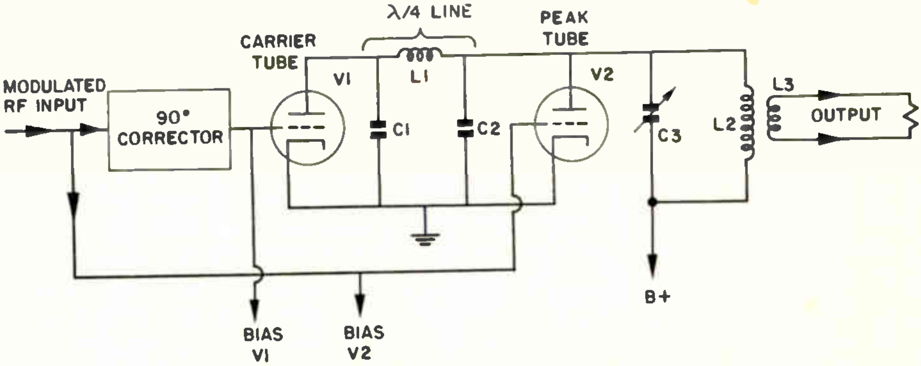

FIG. 12. A basic Doherty system.

one tube, called the carrier tube, to saturation while the other tube, called the peak tube, passes little or no plate current. Thus we have one tube operating at peak efficiency and the other tube wasting little or no power.

The two tubes are of the same types, and therefore will have almost identical characteristics. The carrier tube is biased at the extended cut-off value as a true class B linear amplifier. The peak tube has about twice as much bias applied to it so that it operates more as a class C amplifier than a class B amplifier. When the unmodulated signal from the driver is fed to this tube it barely drives it into the conducting region.

The load on both tubes is the parallel resonant circuit made up of C_3 and L_2 and the load connected to it through L_3. The output of the peak tube, V2, is connected directly to this load. The parallel resonant circuit is designed so that the load impedance will be about half what would normally be used for one of the tubes operated in the normal way as a Class B amplifier. Thus, if the load should be Z_L, the load impedance that V2 will see will be $Z_L/2$.

The load the carrier tube, V1, will see will be quite different. V1 is connected to the load through a network consisting of C_1, L_1, and C_2. This network is called an artificial transmission line because it acts like a transmission line. By selecting the values of C_1, L_1, and C_2, we can make the network act like a transmission line one quarter of a wavelength long. (The symbol λ that you see on the diagram is the Greek letter Lambda, and is used as an abbreviation for wavelength.) You will study transmission lines in detail later; for the present you need know only a few things about them.

Transmission lines have a characteristic which is known as the "surge impedance" or "characteristic impedance." It depends on the size of wire used, the spacing between the wires, and the material between the wires. The characteristic impedance is represented by the symbol Z_o. When a load Z_1 is connected across one end of a quarter-wave line, the impedance that is seen at the other end, which we will call Z_s is given by the formula:

$$Z_s = \frac{Z_o^2}{Z_1}$$

If we make the characteristic impedance of this line equal to the load that the tube should work into for normal class B operation (Z_L), and the actual load equal to half the normal class B load, then the impedance looking into the line from V1 becomes

$$\begin{aligned} Z_s &= \frac{Z_L^2}{\frac{1}{2}Z_L} \\ &= \frac{2Z_L^2}{Z_L} \\ &= 2Z_L \end{aligned}$$

Thus, the load impedance into which V1 is working is equal to twice the normal load for class B operation.

Another characteristic of a transmission line is that it delays a signal traveling through it. With a quarter-wave line between V1 and the load there will be a one-quarter cycle delay. We refer to this as a 90° delay or a 90° phase shift. One other characteristic of a quarter-wave line is that it inverts any change in the load connected across the output. If the impedance of the load is increased, at the input the line acts as if the impedance had been reduced, and if the impedance of the load at the output is reduced, at the input it acts as if it had been increased. Now let's go ahead and see exactly how this amplifier works.

When an unmodulated signal is fed from the driver to the amplifier, the signal does not drive the grid of V2 hard enough to cause this tube to conduct any appreciable amount of plate current. The signal from the driver is fed to the grid of V1 through a phase-shifting network that advances the signal phase so that the signal applied to the grid of V1 leads the signal fed to the grid of V2 by 90°. This signal drives the grid of V1 hard enough to drive this tube to plate-current saturation. Thus the tube operates with good efficiency. However, because the load impedance is twice the normal class B load impedance, the power output will be only about half of what would be obtained with the correct load impedance. The output from V1 is fed through the artificial line, which delays it 90°, to the load. Since the signal has been advanced 90° and then retarded 90°, the two phase shifts cancel, so the signal reaching the load from V1 will be in phase with any signal reaching it from V2.

When the driving signal is modulated and its amplitude starts to increase, V2 begins to conduct. This results in an increase in the signal voltage across the load because the load current increases. The quarter-wave transmission line, which is also connected to the load, sees this higher voltage. Since the extra current is not coming from this line, the higher voltage across the load has the same effect on the line as an increase in load impedance. The quarter-wave transmission line inverts this change so that at its input the impedance decreases. This means that the impedance of the load that V1 is working into goes down, and V1 supplies more power to the load.

With 100% modulation, the amplitude of the driving signal will drive V2 to saturation. Since its load impedance is only ½ the normal value of Z_L, it will supply twice the power it would if it were operated at saturation with the normal load impedance. This power supplied to the load causes the voltage across it to increase so that the value of the load impedance connected at the end of the quarter-wave transmission line appears to have doubled. This means that it is now equal to Z_L. The impedance at the other end of the line, to which V1 is connected, becomes:

$$Z_s = \frac{Z_L^2}{Z_L} = Z_L$$

Therefore V1 is now working into the load impedance it should work into for normal class B operation, and the power output from it will be twice the value with no modulation. Thus both V1 and V2 are supplying twice the power to the load that V1 supplied to it with no modulation, so the power output has increased four times, as it should with 100% modulation.

You might wonder how we can say that the efficiency of this amplifier is good when with no modulation one tube is supplying only half the normal class B power to the load and the other tube none at all. You must remember that efficiency is not a measure of the amount of power output. If the ratio of the power output to the power input is high, the stage is efficient regardless of how much power it actually delivers to the load. The efficiency simply tells you how much of the power that the stages take from the power supply is converted into a useful output signal. If the efficiency is 75% then 75% of the power input is converted to useful output and only 25% wasted. If an amplifier with 75% efficiency has a power input of 100 watts, the output will be 75 watts; the wasted power 25 watts. On the other hand, a 1000-watt amplifier with an efficiency of 30% would put out 300 watts of useful power, which is more than the preceding example, but in doing so would waste 700 watts.

Although the efficiency of the Doherty circuit is high, it has some important disadvantages. At high frequencies, the capacity in the phase-correcting circuit and the quarter-wave line is so small that even the stray capacity in the wiring and the tube capacities can affect the operation of the stage. Also, as the operating frequency increases, it becomes more and more difficult to maintain the proper phase relationships in the circuits.

Distortion will occur when a signal with a low modulation percentage is amplified by the Doherty system, because the peak tube then operates near cut-off where the characteristic of the tube is the most non-linear. Operating the carrier tube near saturation can also produce distortion. Other disadvantages of the Doherty circuit are that it presents a varying load to the preceding amplifier, and the circuit is very difficult to adjust. For these reasons, the Doherty amplifier is no longer being manufactured. However, you may find them still in use in some broadcast stations.

The class B linear circuits that we have discussed in this section are typical of those found in both low-power and high-power transmitters. The power output, of course, depends on the tube type, the component rating, and the operating voltages and currents used in the stage.

FEEDBACK SYSTEMS

You have already studied both regenerative and degenerative feedback. You will remember that when a signal is fed from the output of one stage back to the input of the stage, or to a preceding stage, we have feedback. If the polarity of the signal that is fed back is such that it aids the original signal, we have regenera-

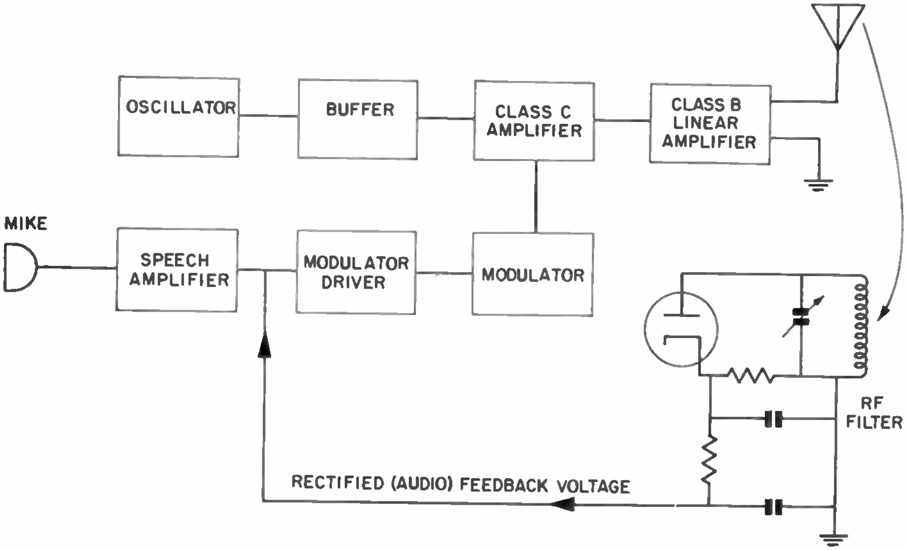

FIG. 13. Over-all rf to af feedback that reduces distortion, hum, and noise in the modulated class C and class B amplifier stages as well as in the audio-frequency amplifiers on the modulator.

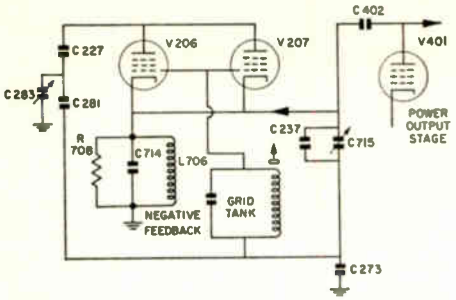

FIG. 14. The Collins rf feedback arrangement.

tive feedback, and if it opposes the original signal we have degenerative feedback, which we usually call inverse feedback. Regenerative feedback is used in oscillators. Inverse feedback is used to help reduce noise, hum, or distortion produced in amplifiers.

Inverse feedback systems are used in transmitters to reduce noise and distortion. A feedback system used in a transmitter is shown in Fig. 13. This feedback will reduce noise and distortion produced in the modulator driver, the modulator, the modulated class C stage and in the linear amplifier.

In this system there is a small resonant circuit that is tuned to the output frequency of the transmitter and loosely coupled to some portion of the output system such as the final tank circuit, or the transmission line, or picks up radiation directly from the antenna. It picks up the modulated signal, demodulates it, and filters out the rf. The demodulated signal, which is made up of the original audio signal plus any noise or distortion that has been added is then fed back to the speech amplifier or modulator of the audio system. It is reinserted 180° out of phase with the original signal.

In this system, noise or distortion originating in the modulator and its associated driver and amplifier stages, and distortion components contributed by the modulation process can be reduced to very low values.

Fig. 14 shows a system in which rf or carrier feedback is used. This is the Collins KWS-1 transmitter.

RF energy is fed back through capacitor C402 to the cathode circuit of the driver. Notice that the driver consists of two tubes, V206 and V207, connected in parallel. The feedback voltage developed between the cathodes of the driver and ground is 180° out-of-phase with the driver input signal. Hence, the feedback link includes the driver and the linear amplifier output stage. The feedback not only corrects distortion, but also improves the driver regulation, insuring a more linear operation.

The amount of feedback depends on the relative reactance of capacitors C402 and C714. Coil L706 is a radio frequency choke that provides a dc return for the cathodes. It is loaded by resistor R708 to prevent oscillation.

Outphasing Modulation System

A system of modulation in which linear amplifiers are not required has recently become more widely used. It is called the "outphasing" system or "phase-to-amplitude" modulation system.

As you have learned, in low-level modulation systems, the rf power amplifier stages must be operated linearly or the output will be distorted. However this is not the most efficient form of operation. In high-level modulation systems, the carrier is amplified before it is modulated, which eliminates the need for linear amplifiers, but much more audio power must be supplied to the class C stage to modulate it. Therefore, in low-level systems it costs more to amplify the carrier; in high-level systems it costs more to develop the high audio power required. The outphasing system combines some of the advantages of each. Let us see how.

BASIC SYSTEMS

Fig. 15A shows two ac generators connected in series across a load. If the two generators are exactly in phase, the two voltages they produce, E_1 and E_2, will add. For example, if each one is 10 volts, the total output will be 20 volts. This is shown by the vector diagram in Fig. 15B. The Greek letter phi (ϕ) is used to mean phase angle. Here it is shown as 0°.

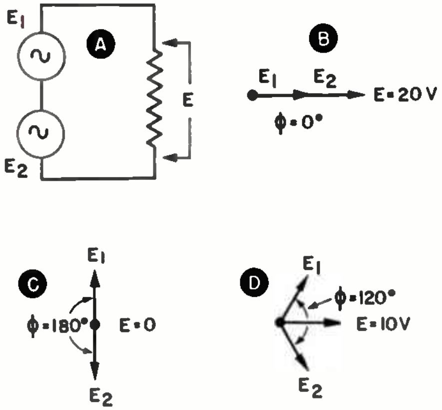

FIG. 15. Two generators connected in series across a load as in A, will produce varying voltages across the load, depending upon their phase relationship. B shows the output if they are in phase; C shows them 180° out of phase; and D shows them 120° out of phase.

If E_1 and E_2 are exactly opposite in phase, the voltages will cancel as shown in Fig. 15C. The phase angle is 180°, and the output voltage E is 0.

If the phase angle is anywhere between 0 and 180°, the output voltage will be somewhere between 0 and 20 volts. For example, if the phase angle is 120° as shown in Fig. 15D, the output voltage will be the vector sum of E_1 and E_2, or 10 volts. If the phase angle is varied, the output will also

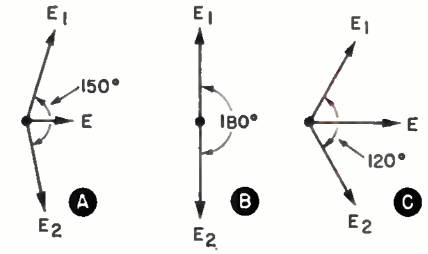

FIG. 16. Vector diagram showing how the combined output of two amplifiers depends upon the phase relationship between them.

vary in the same manner.

The generators in Fig. 15A can be replaced by vacuum tube amplifiers operating on the same frequency but out of phase by some value between 90° and 180°. If the amplifiers are then modulated with an audio signal that increases and decreases this phase difference between them in proportion to the amplitude of the audio signal, and if their outputs are then combined, the signal obtained across the output of the two amplifiers will be proportional to the modulating voltage. We will have 100% modulation if the modulating signal varies the phase of the carrier by the amount of the original phase shift away from 180°.

For example, if the amplifiers are operated with a phase difference of 150° without modulation (30° away from 180°), and 100% modulation is applied, the output will vary as shown in Fig. 16. The length of E indicates the amplitude of the output. When no modulation is applied, the carriers are 150° out of phase, and the output is equal to their vector sum, as shown in Fig. 16A.

On one half of the audio cycle, the phase difference will increase 30°, or up to 180°. The two carriers will cancel, and the output will be zero, as shown in Fig. 16B. On the other half of the audio cycle, the phase difference is decreased by 30°. This approximately doubles the output as shown in Fig. 16C.

Fig. 17 shows a block diagram of such a system. The output of an rf source is split between two amplifier branches. A phase shift of less than 180° is introduced into one branch so that the carrier will not be completely cancelled. The first tube in each string is a phase modulator. It is designed so that when an audio voltage is applied, the phase of its output will vary in step with the amplitude variations of the audio voltage. You will

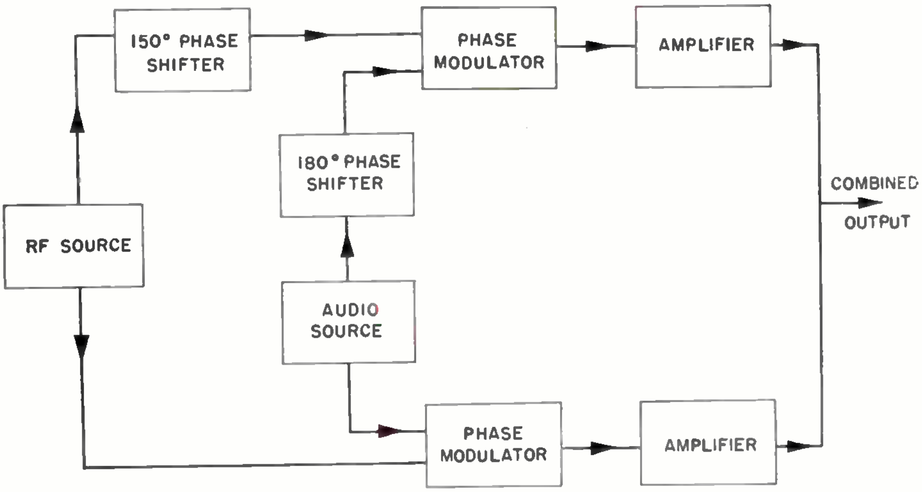

FIG. 17. Block diagram of basic outphasing modulation systems.

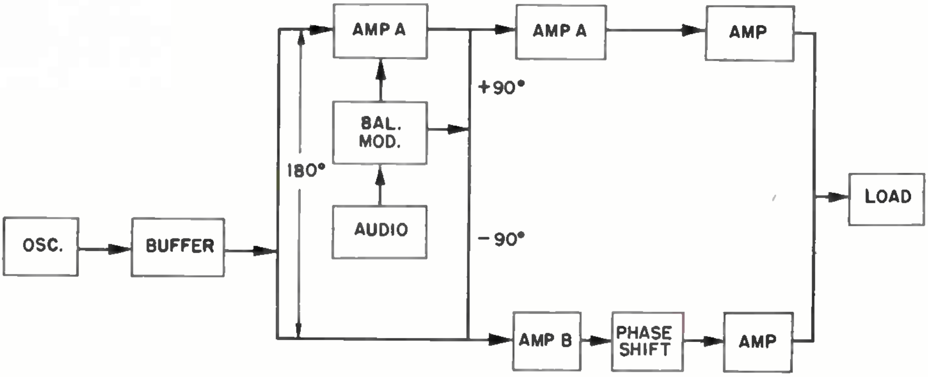

FIG. 18. Another basic outphasing modulation system.

learn how this is done in a later lesson on phase modulation. The audio voltages fed to the two phase modulators must be 180° out of phase with each other, or their effects would cancel.

The outputs of the two phase modulators are amplified, and the amplified outputs are combined.

The modulation envelope will not be distorted, regardless of whether the amplifiers are linear or not, because it is the phase not the amplitude of the signal that is varying in accordance with the audio, and the linearity of an amplifier does not affect the phase of the output.

Fig. 18 shows another arrangement for outphasing modulation. Here we have an rf source consisting of an oscillator and buffer stage. The output is fed to two amplifier strings, 180° out of phase. The audio signal is fed to a balanced modulator, which produces a double-sideband signal that is substantially free of carrier. The output of the modulator is divided between the two amplifier branches. One part is shifted +90° in phase and combined with the output of amplifier A, and the other part is shifted —90° in phase and combined with the output of amplifier B.

A small phase shift is introduced in the lower branch so that the carriers in the two branches will not cancel each other. After amplification, the two carriers are combined in the output. Since they are almost 180° out of phase with each other, the resultant carrier will be almost 90° out of phase with the carrier in each branch. Since the modulation sidebands were shifted 90° in phase at the output of the balanced modulator, they will be practically in phase in the output of the amplifier. Thus the original modulation appears in the

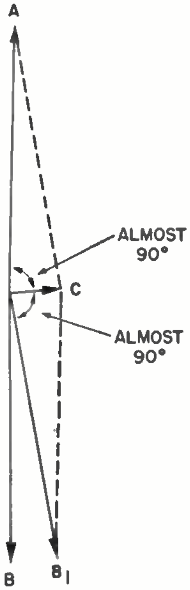

FIG. 19. Relationship of carriers in Fig. 18.

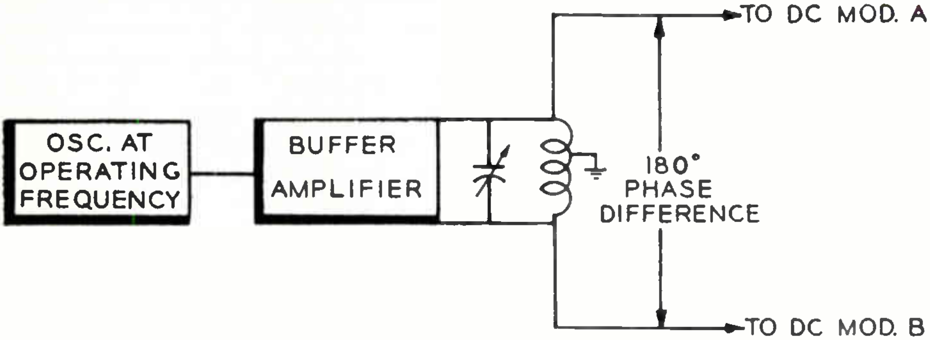
FIG. 20. Block diagram of RCA Ampliphase transmitter.



Courtesy RCA

FIG. 21. Exciter-modulator circuit of Fig. 20.

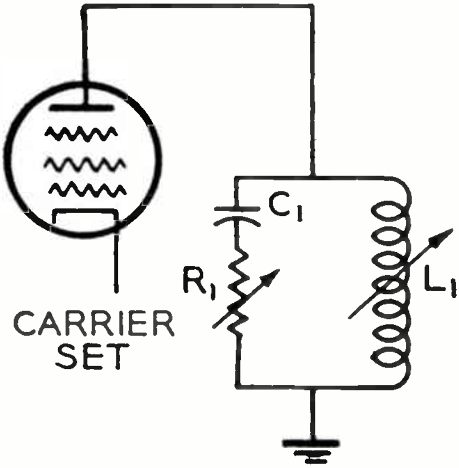
output. Fig. 19 shows the vector diagram for the carriers. A is the original carrier fed to amplifier A. B is the original carrier fed to amplifier B. B_1 is the carrier in the lower branch after being shifted slightly in phase. C is the resultant carrier in the output. As you can see, it is almost 90° different in phase from the carriers in the two amplifier branches.

THE RCA AMPLIPHASE TRANSMITTER

A modern commercial transmitter that uses this "phase-to-amplitude" system of modulation is the RCA 50-kw "Ampliphase" transmitter. A block diagram of this transmitter is shown in Fig. 20. Its operation is essentially similar to that of the circuits we have studied..

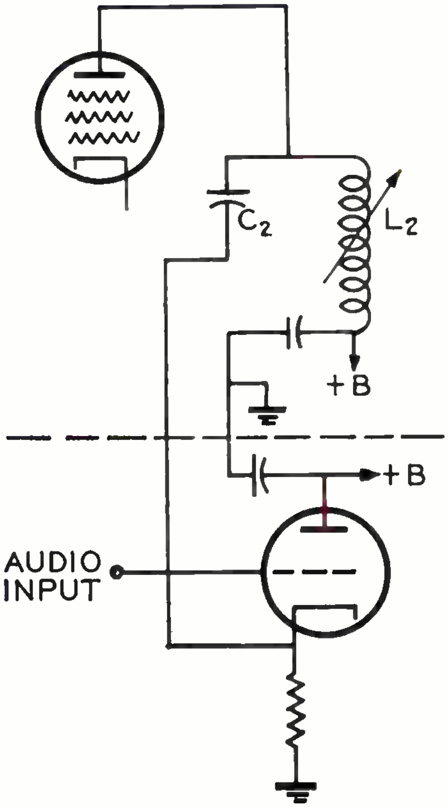
The output of a single crystal oscillator is fed to a buffer amplifier with a push-pull output tank, as shown in Fig. 21. Thus, the carrier wave is split between two rf amplifier channels, and the signal supplied to one chain is 180° out of phase with that supplied to the other. Since these two signals are 180° out of phase, no output would be obtained if they were impressed on a common load. However, if the phase difference is made less than 180°, some output will be obtained, the amount depending upon the phase angle.

So that the phase difference will be less than 180°, the first stage in each amplifier is an adjustable phase-shift amplifier. These are dc modulator A and dc modulator B in Fig. 20. A simplified diagram of the circuit is shown in Fig. 22. The values of L_1, C_1, and R_1 are chosen so that when R_1 is set to one end of its range, there will be a phase shift of +25°, and when it is set to the other end of its range, there will be a phase shift of −25°. Setting the phase-shift amplifier in one chain for a +22.5° phase shift, and the phase-shift amplifier in the other chain for a −22.5° phase



Courtesy RCA

FIG. 22. Simplified diagram of the adjustable phase shifter.



Courtesy RCA

FIG. 23. Simplified diagram of the modulated amplifier and modulator.

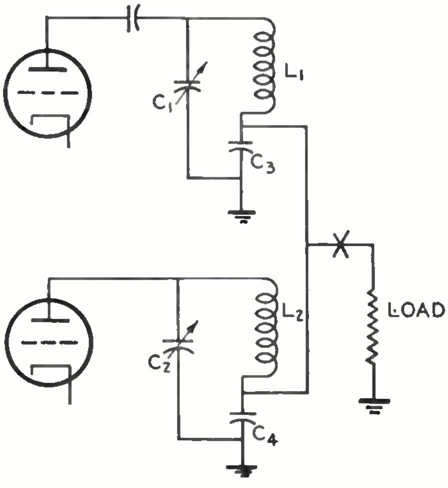
shift will give a total phase shift of 45°, and the two carriers will be 135° apart in phase instead of 180°.

The next three stages in each channel are called modulated amplifiers. They are quite similar to the adjustable phase-shift stages, except that instead of a variable resistor in the plate tank circuit there is a triode tube, as shown in Fig. 23. The triode tube acts as a variable resistance when an audio signal is applied to its grid. The audio signal applied to each modulator tube produces a phase-modulated signal in the tank circuit of its corresponding modulated amplifier.

Following the modulated amplifiers there is a conventional amplifier stage providing isolation and drive to the first intermediate power amplifiers. The signals are further amplified and then combined in the output to give an amplitude-modulated output. Fig. 24 shows a simplified diagram of the power amplifier output circuit.

The relationship between the carriers in the two channels is shown in vector form in Fig. 25. The two vectors A_1 and B_1 show the relationship of the carriers in the two branches without modulation. C_1 represents the output with no modulation. Vectors A and B show the carriers during the modulation troughs with 100% modulation, and A_2 and B_2 show the carriers on the peaks of 100% modulation. On the troughs the output is zero, and on the peaks, the output is doubled, as shown by C_2.

A very important consideration in designing transmitters is the amount of time a transmitter must be off the air if anything goes wrong. To minimize this time, the RCA Ampliphase transmitter is designed with two complete oscillators and two complete exciter-modulator sections. Either of these can be switched in with only a



Courtesy RCA

FIG. 24. Simplified diagram of the power amplifier output circuit.

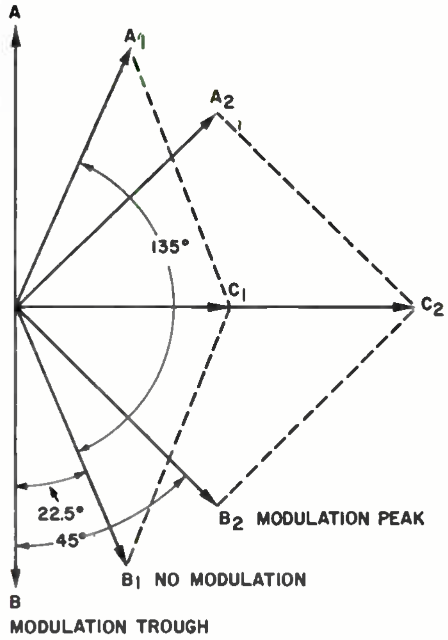


FIG. 25. Relationship of the carriers in the two amplifier channels of Fig. 20 for no modulation and 100% modulation.

momentary loss of carrier, and without cutting off the dc supply to the transmitter. Fig. 26 shows the switching arrangement.

Provision is also made for remote control of the transmitter. Because of the extra oscillator and exciter-modulator sections that can be switched in at a moment's notice, one of the big disadvantages of remote control operation is eliminated, that is, of having to lose time on the air while a maintenance man is sent to the transmitter.

Switching from local to remote control is accomplished with a single transfer switch. A safety feature is that this switch can be operated only at the transmitter. This eliminates the possibility that someone working on the equipment will be endangered by someone operating it from the remote point.

Meter readings for the total plate current, output plate voltage, driver plate voltage, carrier level, and both output cathode currents are repeated at the remote control point.

Broadly tuned band-pass coupling circuits are used to insure stability. A special transformer-type of neutralization circuit is used to make the final amplifiers completely broadband.

LOOKING AHEAD

Class B linear amplifiers are important because they are used in many AM radio broadcast stations. They are used because it is more economical to modulate a low-power class C stage and then amplify the modulated signal than it is to modulate a high power class C stage.

Remember that class B linear amplifiers are operated at extended cutoff bias. If the amplifier is properly adjusted, the plate current will not change when the amplifier is modulated. If there is a meter in the transmission connecting the transmitter to the antenna, the current reading on this meter should increase 22.5% with 100% modulation.

Distortion will be produced in a linear amplifier that is overdriven because the plate current is not able to follow the grid voltage variation if the tube is driven beyond saturation. Distortion may also be due to improper bias on the linear amplifier, or poor driver regulation.

Most linear amplifiers that you en-

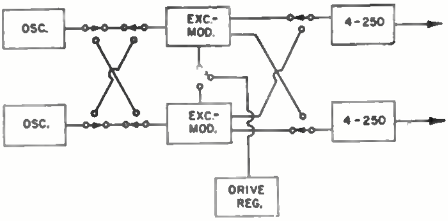

FIG. 26. Arrangement for switching in extra oscillator or exciter-modulator in Fig. 20.

counter in AM broadcast work will be class B amplifiers. However, class AB linear amplifiers are also used, particularly in single sideband applications. You will study these amplifiers later, and also class B amplifiers for TV. When you study these amplifiers, you will find that the plate current of these linear amplifiers does not remain constant when they are modulated.

One method of getting around the necessity of using linear amplifiers is to use a combination of phase and amplitude modulation, as in the Ampliphase system. You will learn more about phase modulation in a later lesson.

Lesson Questions

Be sure to number your Answer Sheet 21CC.

Place your Student Number on *every* Answer Sheet.

Most students want to know their grade as soon as possible, so they mail their set of answers immediately. Others, knowing they will finish the next lesson within a few days, send in two sets of answers at a time. Either practice is acceptable to us. However, don't hold your answers too long; you may lose them. Don't hold answers to send in more than two sets at a time or you may run out of lessons before new ones can reach you.

1. Why can't class C amplifiers be used to increase the power of the modulated signal from an AM transmitter?

2. What TWO operating adjustments on a properly tuned linear stage have most effect on the linearity?

3. What makes it possible to use a single tube in a class B rf linear amplifier, when two tubes in push-pull are needed in a class B audio amplifier?

4. How does the plate current meter reading in a class B linear amplifier in an AM broadcast station react when modulation is applied?

5. In which of the following operating conditions is less power dissipated in the class B linear tube: (a) *with modulation* (b) *without modulation?*

6. If the final class B linear amplifier stage in a transmitter has an output of 50 kw and an efficiency of 40%, how much power must be dissipated by the tubes?

7. List three causes of positive carrier shift in a linear amplifier stage.

8. Why are the grid and plate voltages in a linear amplifier set to one-half their normal values during adjustment?

9. What is the output voltage when two generators generating equal voltages 180° out of phase are connected in series?

10. When the output of an Ampliphase system is at its maximum, will the phase difference between the two amplifier signals be (a) *maximum* or (b) *minimum?*

THOROUGHNESS

Whatever you do, do well if you would stay on the straight road to success. The habits of carelessness and slipshod work are all too easy to acquire; beware of them as you would the plague. Men who are thorough in their work cannot remain undiscovered for long, because the demand for such men is greater than the supply.

Thoroughness is just as important in study as it is in work; what you get out of a lesson depends upon how completely you master the material presented in it. Some books, as fiction, are read hurriedly and only once, then cast away; the enduring works of literature are carefully read and reread many times but always essentially for the pleasure they give; textbooks, however, must be read quickly to get the basic ideas, then carefully many times until every important principle has been mastered.

Thoroughness in study habits leads to thoroughness in work habits, and eventually to a thorough success.

CURRENT, VOLTAGE, AND RESISTANCE MEASUREMENTS

22CC

STUDY SCHEDULE NO. 22

☐ 1. **Introduction** ....**Pages 1-3**

Here you get a general idea of how meters are used, meter accuracy, and why meters are shielded.

☐ 2. **Basic Meter Movements** ....**Pages 3-8**

You study the three basic types of meter, the d'Arsonval, the moving vane, and the dynamometer.

☐ 3. **DC Measurements** ....**Pages 8-18**

First we take up direct current measurements then dc voltage measurements.

☐ 4. **AC Measurements** ....**Pages 19-25**

We take up alternating current measurements then ac voltage measurements.

☐ 5. **Resistance Measurements** ....**Pages 25-32**

We discuss series and shunt ohmmeters, meggers, and multimeters.

☐ 6. **Power Measurements** ....**Pages 32-36**

Here you learn how dc power, 60-cycle power, and af and rf power are measured.

☐ 7. **Answer Lesson Questions.**

☐ 8. **Start Studying the Next Lesson.**

MP2M469 **1969 EDITION** Printed in U.S.A.

CURRENT, VOLTAGE, & RESISTANCE MEASUREMENTS

METERS play an important part in all phases of electronics. They are used to find out what is going on in an electronic circuit, for making operating adjustments, in checking performance, and in troubleshooting. In communications work you will deal with meters that are wired right into transmitter circuits to indicate operating conditions, and also with portable test instruments. Sometimes, you may want only a general indication of current, voltage, or resistance; sometimes you may have to take very accurate measurements, but whether the measurement is general or very exact, its usefulness depends on how well you understand your instrument. If you misuse a meter, you will get inaccurate readings, and may damage the meter.

In this lesson, we will discuss meters used to measure current, voltage, resistance, and power. You will learn that the same types of meter are used in all measuring circuits. It is the arrangement of the meter circuit and the way in which the meter is connected that determines the type of measurement that will be made.

We will discuss only meters that do not use vacuum tubes as part of their circuits here. In a later lesson we will take up vacuum-tube voltmeters and other instruments using vacuum tubes.

Most meters used in electronics rely on the principles of electromagnetism. That is, when current flows through a coil of wire, a magnetic field is produced around the coil that is proportional to the amount of current flowing. This principle is used in the three most common types of meters: the d'Arsonval, the magnetic vane, and the dynamometer. We will discuss these three types. No matter which type it is, the moving element is made as light as possible. Because the moving element is light it will move quickly and have a tendency to oscillate somewhat back and forth through the correct reading. There must be some means of bringing the pointer to rest quickly without oscillation after the meter has been energized, and to keep it from swinging back and forth after it is brought back to zero. This is called "damping." It can be accomplished either electrically or mechanically. You will see examples of both systems.

ACCURACY

Although it is possible to make highly accurate meters (within one-quarter of 1% or better) by hand-calibrating them with a standard meter, they are large and very expensive. For general communications work, meters having an accuracy of 2% are satisfactory. These meters are mass-produced, with printed scales, and are adjusted internally at the time they are manufactured to the required accuracy.

The accuracy of a meter movement is generally expressed as a percentage of the full-scale reading. For example, if a meter with 50 scale divisions has 2% accuracy, it is accurate within one scale division at the *full-scale* reading. This does not indicate the per cent of accuracy on the rest of the scale, because it may be off as much as one scale division at any other part of the scale also. For example, when the meter pointer is at the tenth division (1/5 of full scale), the reading may still be in error by one division; this would be an error of 10%. Most instruments used in communications work have a 2% accuracy at full scale, but not as much error as 10% at the low end of the scale.

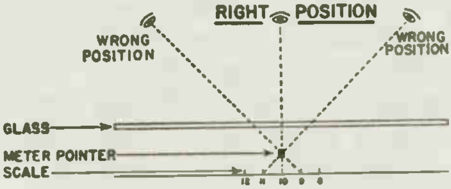

FIG. 1. When reading a meter, always look at it directly to get an accurate reading.

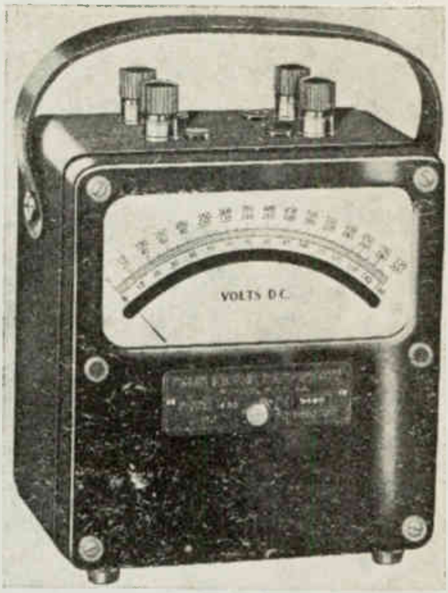

Courtesy Weston Electrical Instrument Co.

FIG. 2. A portable dc voltmeter. The dark arc below the scale is a mirror to make it easier to read the meter accurately.

Reading the Meter. In order to get an accurate reading from a meter, you must look at it squarely, not from an angle, because in order to swing freely, the pointer must be a little bit above the scale. As shown in Fig. 1, if you look directly down on the meter you will get one reading, for example, 10. However, if you look at it from one side, you might think the reading was 9, and from the other, you might think the reading was 11.

To help avoid this, many meters have a mirror under the pointer. The dark area under the scale in the meter shown in Fig. 2 is such a mirror. When you read the meter, you move your eye until the reflected image of the pointer disappears, and you know you are looking directly at it.

Shielding. It is sometimes desirable to shield the meter elements, because external magnetic fields produced by nearby current-carrying conductors or by the earth itself can react with them and affect the readings. There is no known insulator for magnetic lines of force, so the undesirable stray fields must be bypassed around the meter elements by a shield made of iron, which is a good conductor of magnetic lines of force. Such an arrangement is shown in Fig. 3.

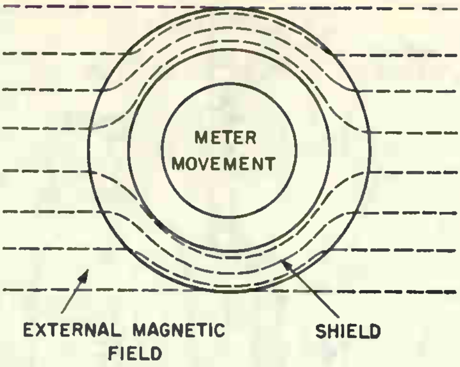

FIG. 3. A meter can be shielded from an external magnetic field by encasing it in iron, which bypasses the field around the meter movement.

Now, let's take a look at the basic types of meters, and then see how they are used to measure current, voltage, resistance, and power.

Basic Meter Movements

The three types of meters we will discuss in this section are the d'Arsonval, the magnetic vane, and the dynamometer. All three types can be used for both ac and dc measurements; however, the d'Arsonval is by far the most common for dc. When the d'Arsonval is used to measure ac, it must be used with a rectifier to change the ac to dc. Since the d'Arsonval is the most common type, let's discuss it first.

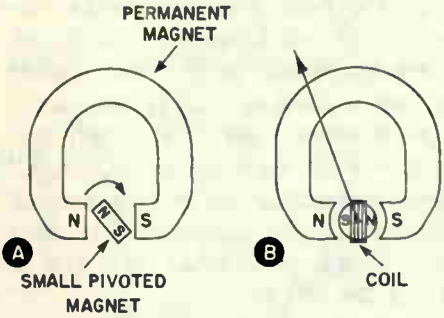

FIG. 4. A small pivoted magnet placed between the poles of a large magnet as at A, will rotate until the unlike poles are opposite each other. A pivoted coil through which current is passed will act in the same way, as shown at B.

THE D'ARSONVAL METER

In an earlier lesson, we had a quick look at the d'Arsonval meter. Let's review its action now. As you will remember, it works on the principle that like magnetic poles repel each other and unlike magnetic poles attract. If a small pivoted magnet is placed between the poles of a permanent magnet, as shown in Fig. 4A, it will move in the direction of the curved arrow.

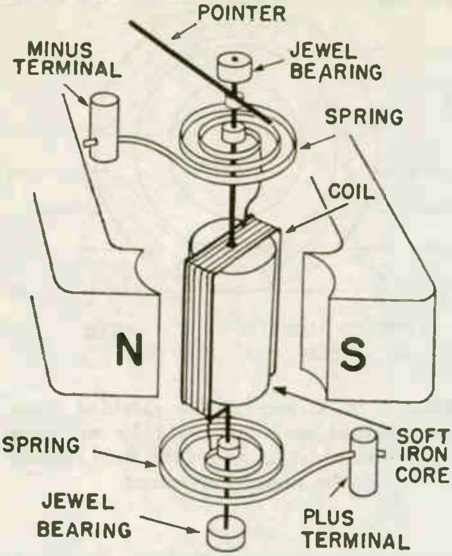

FIG. 5. How a d'Arsonval type of meter is made.

Now, suppose instead of the small magnet we put a coil between the poles of the larger magnet. As you know, when current flows through a coil it becomes magnetized. Therefore, if we send current through this coil, it will act just like the small permanent magnet in Fig. 4A. This is the way the d'Arsonval meter is made, as shown in Fig. 4B. The coil is wound on a soft iron core, and placed on a pivot, and a pointer is attached to the coil. When no current is applied, the coil and the pointer are in the position shown. When current is applied to the coil, it becomes magnetized and starts to rotate, moving the pointer.

The coil would continue to rotate until its south pole was opposite the north pole of the permanent magnet, except for the fact that springs are attached to the ends of the coil, as shown in Fig. 5, which oppose the coil movement. Therefore, the coil turns only to the point where the magnetic force caused by the current is exactly equal to the retarding force of the springs, and remains there as long as the current causing the magnetic force is applied. When current stops, the magnetic field of the coil disappears, and the springs move the coil back to its original position.

Since the magnetic force causing rotation of the coil is proportional to the amount of current flowing through the coil, one particular value of current will make the coil rotate to one particular place. A greater current will rotate the coil further, and a smaller one will rotate it less. A scale that is marked to show the amount of current that will cause any particular amount of movement is placed under the pointer.

The permanent magnet is made from a special steel or metal alloy, chosen for strong magnetic qualities and long magnetic life. The stronger the field of the permanent magnet, the more the coil will rotate for a particular current; in other words, the more sensitive the meter will be. The magnet is especially treated and aged until the field strength remains constant. The pole pieces are of soft iron, carefully shaped to give the desired magnetic distribution. If the meter scale is to be linear (that is, adjusted so that equal increases in current will produce equal increases in meter coil movement), the magnetic field must be uniform throughout the gap in which the coil turns.

So that it will turn easily, the coil is wound on a very light-weight metal form, and the coil and the form are suspended between almost frictionless pivots with jewel bearings. The number of turns used in the coil depends on the range and sensitivity desired for the meter.

The coil starts to rotate from the same position each time. When the coil rotates, one spring is wound while the other is unwound. The springs thus oppose the coil movement in either direction away from the starting position.

Naturally, these springs will not always remain perfectly balanced. Most meters have a zero adjustment to compensate for this. It is a small screw that usually protrudes through the case of the meter just above or below the meter coil. Turning this screw moves the upper spring enough to balance the springs and bring the meter pointer back to the zero position.

The springs are also used to make electrical connections to the coil. Of course, this means that they must be insulated from each other and from the meter frame.

Damping. In the d'Arsonval meter, the damping is done electrically by winding the coil on an aluminum frame. As the coil responds to the flow of current and starts to rotate, a voltage is induced in the aluminum frame as it cuts the lines of force of the permanent magnet. The induced voltage causes a current to flow in the frame, which in turn produces a magnetic field opposite to that of the permanent magnet. The opposing field produces a braking action which brings the pointer quickly to rest. When the coil comes to rest, no voltage is induced in the frame. Therefore, there is no field produced by the frame to interfere with the fields of the coil and of the permanent magnet. The same action takes place when the meter is de-energized and the pointer is returned to zero.

Another common method of creating damping is to place a resistor between the meter terminals. In this system, there is a voltage induced in the coil as it moves through the fixed field, which causes a current flow through the resistor and coil that sets up an opposing field similar to that produced by the current induced in the coil form. In both cases, damping action ceases as soon as the coil stops moving. The resistor value that will permit the most rapid coil movement without noticeable waving and still give full-scale meter reading is called the critical damping value. This value varies widely. Some meters require 10,000 ohms, others 100 ohms. Too small a resistor causes over-damping and a slow movement, whereas too large a resistor does not damp enough.

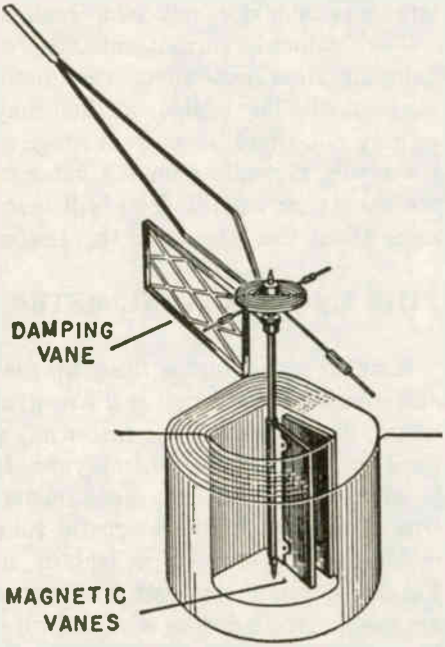
The induced current method of damping does not affect the meter range at all. The resistor method may or may not affect the current range of the meter, depending on the value of the resistance needed. You will learn more about this later on in this lesson.

THE MAGNETIC-VANE METER

Instead of having a fixed magnet and a moving coil like the d'Arsonval meter, the magnetic-vane meter has a fixed coil and a movable iron vane. It is often called an iron-vane meter. One of the best of the magnetic-vane meters is the book-type, shown in Fig. 6. In this meter, two iron vanes are used, surrounded by a coil of wire. When current flows through the coil, the vanes will be similarly magnetized so they will repel each other. It makes no difference whether the energizing current is dc or ac, the vanes will still repel each other. One vane is fixed, and the other is pivoted and attached to a pointer. The movement produced is shown on a scale under the pointer. Hair springs are used to control the motion and return the pointer to zero when no current is being applied to the coil.

The moving vane meter is not as widely used as the d'Arsonval meter for a number of reasons. The meter cannot be made as sensitive as the d'Arsonval meter and therefore cannot be used to measure very weak currents. Also the scale is not linear; the lower quarter of the scale is usually quite compressed.

Furthermore, when used on dc, the polarity of the current through the coil may have some effect on the reading, so it is best to take a reading, reverse the polarity, then take another reading, and average the two.



Courtesy Weston Electrical Instrument Co.

FIG. 6. A magnetic vane meter.

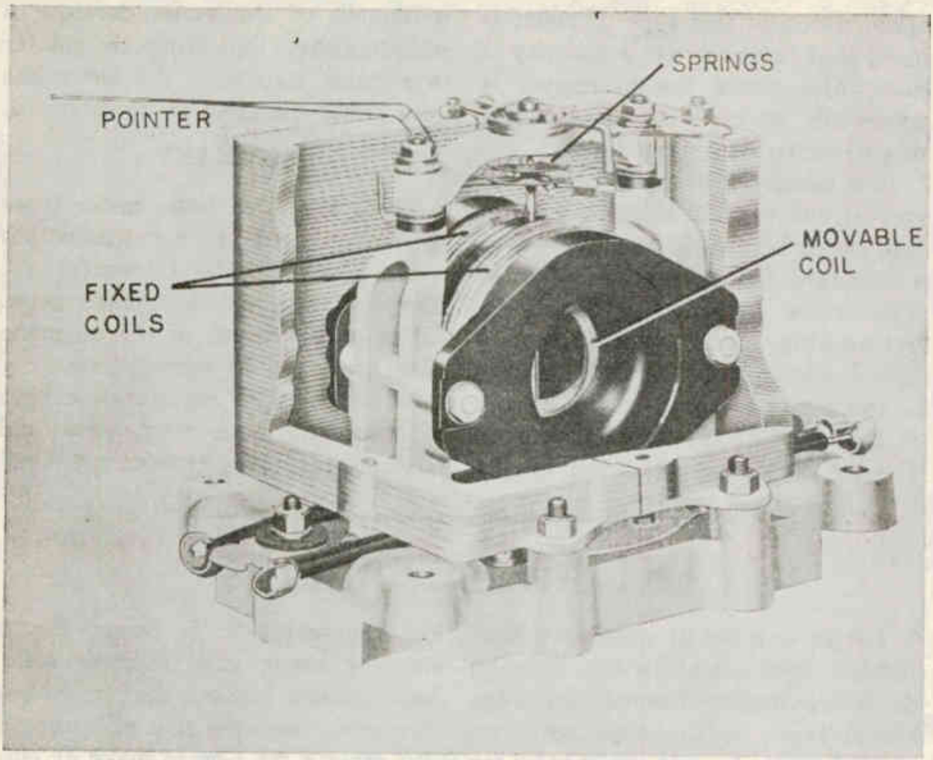
In addition, the meter cannot be used on high ac frequencies because of losses in the vanes. Both eddy current and hysteresis losses become appreciable as the frequency increases. In fact, these meters are usually calibrated for use at some specific frequency and if measurements are taken at another frequency, the percentage of accuracy of the measurements will be somewhat less than the rated accuracy of the meter.

Damping. A mechanical method of damping is used in this meter. The aluminum vane shown directly under the pointer is used to slow down the movement of the pointer. This vane fits quite snugly into the space inside of the coil. Both ends of the opening are closed, so the vane, in moving through the air in the enclosed space, is held back by the air pressure developed. This effectively damps any tendency of the vane and pointer to oscillate.

Several other types of magnetic vane movements have been developed, but the book type is the most sensitive and the most accurate. All have similar characteristics that restrict their use to dc and low-frequency ac measurements.

THE DYNAMOMETER

The dynamometer, or electrodynamometer as it is sometimes called, operates because of the reaction between the magnetic fields of a fixed coil and a movable coil when the same current flows through both of them.



Courtesy Weston Electrical Instrument Co.

FIG. 7. A dynamometer.

Actually, there are generally two fixed coils and one movable coil. Fig. 7 shows this type of meter.

The fixed and movable coils are in series, so the same current flows through them. When no current is flowing, the axis of the movable coil is at right angles to the axis of the fixed coils. This position is maintained by control springs.

When current flows through the coils, it sets up magnetic fields around them. Because of the physical position of the coils, the magnetic field of the movable coil is at right angles to the magnetic field of the stationary coils. As you know, like magnetic poles repel and unlike magnetic poles attract each other, so the two fields try to align themselves. This causes a turning force, or torque, which carries the pointer clockwise across the scale until the restraint of the springs equalizes the torque. The pointer then comes to rest. The deflection of the pointer is proportional to the square of the current. Therefore, the scale used with the dynamometer has nonlinear scale divisions.

It doesn't make any difference whether the current applied is ac or dc, because if it is ac it will change direction in the movable coil and the stationary coils at the same instant so that the two magnetic fields will still oppose each other.

Since there is no iron core to produce an economical flux, the power consumption of this type of meter is high; that is, the power sensitivity is poor. Also, since the movement is necessarily heavy, it is a slow-acting meter compared to other types.

It is usually calibrated with direct current and is often called a transfer instrument because it can be used as a standard for calibrating other ac instruments.

Damping. A mechanical method of damping is used in Fig. 7. It consists of two vanes attached to the bottom of the shaft of the moving element. The air turbulence produced by the movement of the vanes develops a retarding effect that brings the pointer to a quick stop after the meter has been either energized or de-energized.

SUMMARY

There are three basic meter types commonly used in communications work. These are the d'Arsonval, the magnetic vane, and the dynamometer. All operate because of the magnetic effect produced by current flow.

All three types require some kind of damping. Both mechanical and electrical damping systems are used

DC Measurements

The three types of meters we have just discussed can all be used to make dc measurements. However, the d'Arsonval meter is the most sensitive, and is itself a dc meter, so it is by far the most widely used for dc measurements. In fact, in communications work, you will probably use only d'Arsonval meters in making dc measurements.

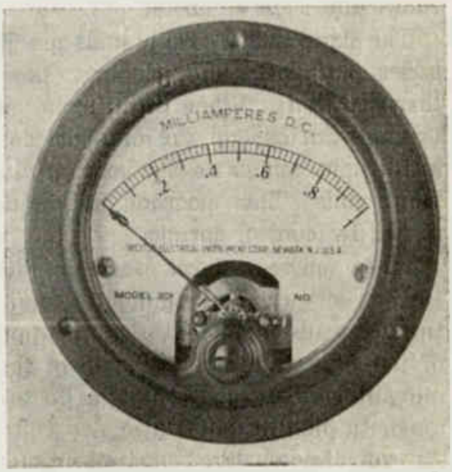
Practically all dc ammeters and voltmeters using d'Arsonval movements have linear scales. That is, the spacing between scale divisions is exactly the same over the whole scale. Let's see why.

The air gap in which the moving coil rotates is designed to give a uniform magnetic field in all of the space through which the coil moves. The torque or turning force exerted by the coil against the springs will be directly proportional to the current flowing through the coil. Since the springs allow the coil to turn by an amount proportional to the current, and the scale will be linear. Fig. 8 shows a meter with a linear scale. Each division between the longer lines represents one-tenth of a milliampere.

Now let's see how to make dc current measurements.

MEASURING DIRECT CURRENT

Current meters measure the flow of



Courtesy Weston Electrical Instrument Co.

FIG. 8. A milliammeter with a 1-milliampere linear scale.

electricity in a circuit. To make the measurement, the meter must be connected in series with the source and the load as shown in Fig. 9. Current meters that are used as operating indicators are wired into the circuit permanently. When a current meter is used as a temporary test instrument, the circuit must be broken so that the meter can be connected in series with the load.

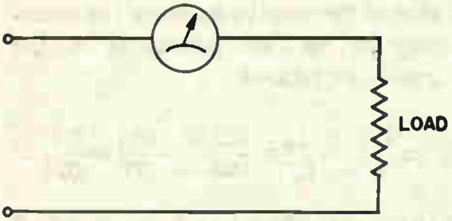


FIG. 9. A current meter is connected in series with the source and load as shown here.

When making temporary measurements, you must be sure to use a meter with a high enough range. If you are in doubt, use a very high range, and switch to a meter with a lower range if you find that the current is low enough to permit you to do so.

The amount of current flowing in transmitter and receiver circuits varies considerably, from a few milliamperes in some low-level stages to several hundred amperes in the filament circuits of the final amplifier in a high-power transmitter.

Meters are made in a wide variety of full-scale ranges, but it would not be practical to keep on hand meters for every conceivable range. However, it is possible to extend the range of a milliammeter to measure higher currents. Let's see how this is done.

EXTENDING METER RANGES

When currents up to 5 milliamperes are to be measured, usually a meter having a basic range that covers the range to be measured is used. For example, if the currents to be measured are under 1 ma, a 1-ma meter is used. If currents up to 3 ma are to be measured, a 3-ma meter is used. When currents over 5 ma are to be measured, resistors called "current shunts" are connected in parallel with the meter movement to extend the range.

Suppose we have a 1-milliampere meter and want to measure currents up to 10 milliamperes. We can do so by putting a resistor across the meter terminals. We choose the value of the resistor so that nine-tenths of the current (9 milliamperes) coming into the resistor-meter combination will flow through the resistor and one-tenth (one milliampere) through the meter. In other words, we use the resistor to bypass nine-tenths of the current. Fig. 10 shows how this is done. Since nine-tenths of the total current flows through the shunt, the shunt must have a resistance that is only one-ninth of the resistance of the meter.

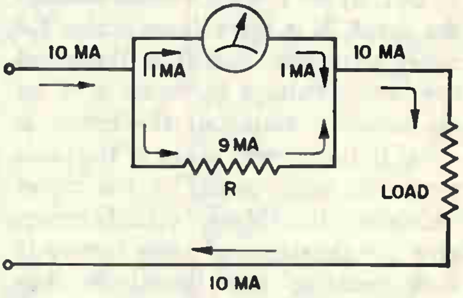

FIG. 10. How a shunt is used to increase the range of a milliammeter.

Since the meter is a 1-milliampere

meter, the scale will be calibrated like the meter scale shown in Fig. 8. However, by connecting the shunt across it we have converted the meter into a 10-milliampere meter. Therefore, to determine the current flowing in the circuit you must multiply the meter reading by 10. Thus a reading of .6 milliampere on the meter indicates a current of 6 milliamperes in the circuit.

Since the current bypass resistor R makes a parallel path around the meter, it is called a shunt. The ohmic value of R is calculated so that it will pass a current that is the difference between the total current being measured and the amount of current the meter needs for full-scale deflection.

It's easy to find the shunt resistance to change the current that can be measured by a meter. For example, if we have a 1-milliampere meter, and we want to measure currents up to 25 milliamperes, we must use a shunt that will pass 24 milliamperes. To find its value, we use Ohm's Law, $R = E/I$, where I is the current through the shunt, E is the voltage across the meter terminals, and R is the shunt resistance. Voltage E, which is called the millivolt rating of the meter, is equal to the current range of the basic meter, I_m, multiplied by the meter resistance R_m. Meter manufacturers give the resistance of their meters in their catalogs and sometimes they also mark it on the back of the meter. In a few cases they also give the millivolt rating of the meter. Current I through the shunt equals the total current, I_t, minus the basic meter current, I_m. Therefore, by substituting $R_m \times I_m$ for E, and $I_t - I_m$ for I, our Ohm's Law equation can be written:

$$R = \frac{R_m \times I_m}{I_t - I_m}$$

If we figure all the current values in the same unit (amperes, milliamperes, or microamperes), the answer will come out in ohms.

Now, suppose the resistance of our 1-ma meter is 100 ohms; to find the value of the shunt necessary for measuring 25 ma, we substitute in the formula as follows:

$$R = \frac{R_m \times I_m}{I_t - I_m} = \frac{100 \times .001}{.025 - .001} = \frac{0.1}{.024} =$$

4.166 ohms, which can be rounded off to 4.2 ohms with an error of less than 1%.

We could also have calculated the resistance from the fact that the shunt must pass 24 times as much current as the meter, and therefore must have a resistance that is 1/24 of the resistance of the meter. Therefore:

$$R = \frac{100}{24} = 4.166 \text{ ohms.}$$

To find the actual total current flowing, multiply the reading on the shunted meter by the ratio of the current range of the meter with shunt to the current range without shunt. In our example, a one-milliampere meter was made into a 25-milliampere meter so this ratio is 25/1. The meter readings must be multiplied by 25 to find the actual current flow. It is important to remember at this time that the meter itself is not passing 25 milliamperes; only 1 milliampere goes through the meter and 24 milliamperes go through the shunt.

You will remember that when we

spoke about damping we said that d'Arsonval meters are sometimes damped by connecting a resistance across the meter terminals. Also we mentioned that too low a resistance would result in over-damping, which causes the meter pointer to move very slowly. When we connect a shunt across the meter terminals we connect it in parallel with the damping resistor. Since the shunt resistance is usually less than the critical damping value of the meter we end up with an over-damped meter. This situation can be corrected to some extent by connecting a small resistance in series with the meter movement.

Let's consider the example we already have discussed where we converted a 1-milliampere meter with a resistance of 100 ohms to a 25-milliampere meter. We did this by connecting a 4.166-ohm shunt across the meter terminals. This shunt becomes the damping resistor. If the value of damping resistor required for critical damping is several hundred ohms, you can see the meter will be very badly over-damped.

Suppose we connect a 20-ohm resistor in series with the meter lead. Now the total resistance of the meter is 120 ohms. To shunt this combination so the meter will read full scale in a circuit when the current flow is 25 milliamperes, we need a shunt that has a resistance 1/24 of 120 ohms.

$$R = \frac{120}{24} = 5 \text{ ohms.}$$

Now with a five-ohm shunt connected across the meter and the 20-ohm resistor we added, the meter range will be 25 milliamperes as before. However, now the damping resistor is made up of the 20-ohm resistance we connected in series with the meter, plus the 5-ohm shunt. Thus, the total damping resistance is 25 ohms, which is over five times the value it was with the 4.166-ohm shunt. The meter will still be over-damped, but not nearly as much as before.

We mentioned before that meters designed to measure currents above 5 milliamperes are usually 5-milliampere meters with a shunt. Thus, a meter with a scale from 0-100 milliamperes consists of a 5-milliampere meter as the basic meter movement, with a shunt built inside the meter case. When the meter indicates a current of 100 milliamperes, 5 milliamperes will be flowing through the meter and 95 through the shunt. Similarly in the case of a 5-ampere meter, 5 milliamperes will flow through the meter and 4.995 amperes through the shunt.

You might wonder why meters are made this way. There are two reasons, it is more practical to build one basic meter movement and extend its range by shunts than to build a large number of basic meter movements. Another reason is that if high currents were used in the basic meter, the springs which conduct the current to the coil would be quite bulky. Also we would have to use a rather large wire size to wind the coil. This would make the moving coil assembly bulky and insensitive.

In small panel instruments having a range of about 20 amperes or less, the shunt is contained within the instrument. In portable instruments of high accuracy and in panel instruments having a rating of over 20 amperes, an external shunt is generally used with the meter.

Most meters designed for use with external shunts have a sensitivity of 50 millivolts. You will remember that we said the meter sensitivity in volts is equal to $I_m \times R_m$, where I_m is the full-scale meter current and R_m is the meter resistance. Thus, the meter sensitivity simply tells us the voltage across the meter terminals at full-scale deflection. If we have a number of meters that are all 5-milliampere meters and all have a 50-millivolt sensitivity, they must all have the same internal resistance. Thus, a shunt designed to work with one of these meters could be used with any of them. You will find shunts made for use with meters of this type. They are usually labeled 50 millivolts and are also labeled with the current range to which they extend the meter. For example, a shunt marked 50 millivolts-20 amps, is designed for use with any 5-milliampere meters that have a sensitivity of 50 millivolts. When it is connected across the meter terminals, the meter range will be extended to 20 amperes.

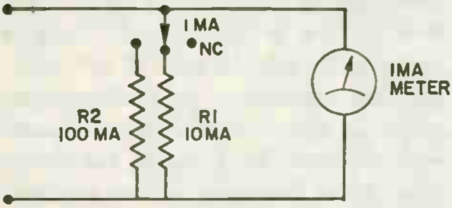

FIG. 11. A multi-range switch for connecting shunt resistances across a meter.

Many meters have several ranges, each with a separate shunt resistance. The shunts are connected into the circuit by means of a multi-range switch, as shown in Fig. 11.

Ring Shunts. Another arrangement of shunt resistors, called the "ring shunt" is shown in Fig. 12A. In this circuit, we have a meter with a 40-ohm, 5-milliampere movement, and a ring shunt arranged to extend the scale to 25 ma, 50 ma, and 250 ma.

The range switch is shown in the position for the 25-ma range. To find what the total resistance would be, we use our formula:

$$R = \frac{R_m \times I_m}{I_t - I_m}$$

The meter resistance is 40 ohms, the meter current is 5 ma (.005 ampere), and the total current is 25 ma (.025

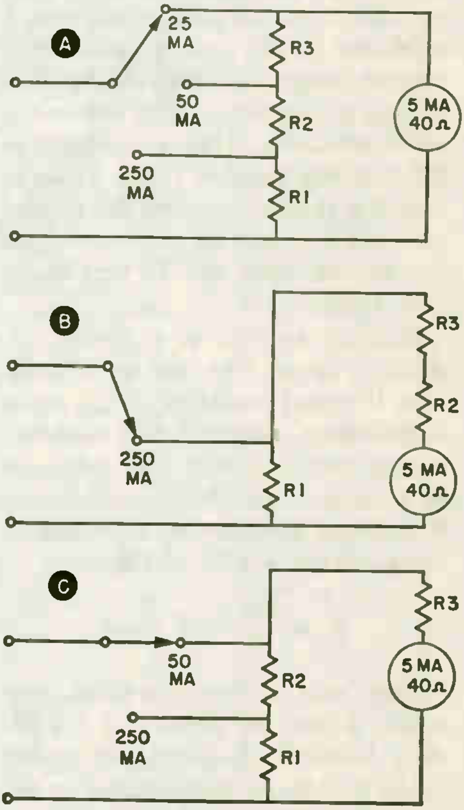

FIG. 12. How a ring shunt works.

ampere), so we have:

$$R = \frac{R_m \times I_m}{I_t - I_m} =$$

$$\frac{40 \times .005}{.025 - .005} = \frac{.2}{.02} = 10 \text{ ohms.}$$

We could also have determined the value of R using all currents in milliamperes. Thus it would work out:

$$R = \frac{40 \times 5}{25 - 5} = \frac{200}{20} = 10 \text{ ohms.}$$

Now we know that the total resistance of R1 + R2 + R3 is 10 ohms and the meter resistance is 40 ohms, so the total resistance in the circuit is 50 ohms, and we want to find the values of the individual resistances. Let's find the value of R1, first.

With the switch in the 250-ma position, the circuit could be redrawn as shown in Fig. 12B. Now the resistance of the meter is equal to 40 ohms *plus* the resistance of R2 and R3, or in other words, it is equal to 50 ohms *minus* the resistance of R1. The shunt is resistance R1 and its value can be calculated using the same formula as before. Now for R_m we substitute (50 — R1) which is equal to the total resistance in the meter circuit, 40 + R2 + R3. I_m, the current through the meter, is 5 milliamperes (.005 amps) as before, and I_t is 250 milliamperes (.250 amps). So in our formula, we have:

$$R1 = \frac{(50 - R1) \times .005}{.250 - .005} =$$

$$\frac{.25 - .005R1}{.245}$$

$$.245R1 = .25 - .005R1$$

$$.25R1 = .25$$

$$R1 = 1 \text{ ohm.}$$

The circuit with the switch in the 50-ma position can be redrawn as shown in Fig. 12C. Now the meter resistance R_m is equal to 40 ohms plus R3, which is equal to 50 ohms minus the resistance of R1 and R2, so we can find the combined resistance, R, of R1 and R2 as follows:

$$R = \frac{(50 - R) \times .005}{.05 - .005} =$$

$$\frac{.25 - .005R}{.045}$$

$$.045R = .25 - .005R$$

$$.05R = .25$$

$$R = 5 \text{ ohms.}$$

Now we know that R1 + R2 equals 5 ohms; since R1 equals 1 ohm, R2 must equal 4 ohms; and since the total of all three resistors equals 10 ohms, R3 must equal 5 ohms.

The ring shunt has two advantages over the circuit shown in Fig. 11. For one thing, the values of the resistors on the high ranges do not need to be as low. If we used the same basic 5-ma, 40-ohm meter in an arrangement like Fig. 11, we would have to have a resistor of only a fraction of an ohm on the 250-ma range. The other advantage is that the total resistance across the meter itself is the same on all ranges, and can therefore be used to provide damping.

MEASURING DC VOLTAGES

The meter in a voltmeter is actually a milliammeter or microammeter. The most commonly used meter in making dc voltage measurements is the d'Arsonval meter, which as you know, is a current-operated meter. Voltage is measured by sending current through a known resistance.

For example, if a 10,000-ohm resistor is connected across a source, and we connect a milliammeter in series with the resistance and it indicates that a current of 1 ma flows through it, you can calculate the voltage from Ohm's Law, $E = IR$. The voltage across the resistor must be $E = .001 \times 10{,}000 = 10$ volts. If we reduce the voltage, and the current drops to .5 milliamperes, (.0005 amps), we know the voltage must be

$$E = .0005 \times 10{,}000 = 5 \text{ volts}$$

Using this principle, a resistor, called a "multiplier resistor" is connected in series with a milliammeter and the combination is connected across the voltage source to be measured as shown in Fig. 13. The scale, of course, is calibrated to show the voltage rather than the current. We can do this because the current will depend directly on the voltage.

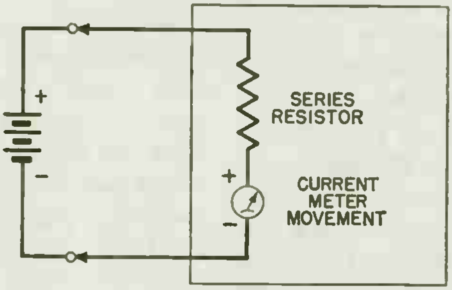

FIG. 13. How voltage can be measured by connecting a current meter and a series resistor across the source.

The value of resistance needed to be able to measure a certain voltage, depends upon the current range of the meter and the resistance of the meter itself, and upon the range of voltage to be measured. For example, suppose we have a 1-ma meter, and we want to use it to measure voltages from 0-1 volt. We find the value of resistance needed to limit the current flow in the meter circuit to 1 milliampere when the voltage across it is 1 volt by using Ohm's Law, $R = E/I$. The voltage range we want is 1 volt, and the current is 1 ma or .001 ampere, so we have $R = 1/.001 = 1000$ ohms. This is the total resistance in the circuit; it includes the resistance of the meter plus the resistance of the multiplier. In the example, if the meter has a resistance of 55 ohms, then the multiplier should have a resistance of 945 ohms.

Let's take another example, suppose we want to use a 50-microampere meter that has a resistance of 2000 ohms to measure voltage up to 10 volts. Using Ohm's Law to find the resistance we get:

$$R = \frac{10}{.00005} = 200{,}000 \text{ ohms.}$$

So the total resistance needed is 200,000 ohms. We can ignore the meter resistance in this example because it is so small, and simply connect a 200,000-ohm resistor in series with the meter. When 10 volts is applied to the series combination, the meter will read full scale. When 5 volts is applied, it will read half scale.

Voltmeter Loading. As we have said, the meter is always placed across the line to measure voltage, rather than in series with the line as when current is being measured. As you can see, a certain amount of current must flow through the meter and its series resistor. We say that the meter is loading the circuit. Because of this, in a low-current circuit, we must use a meter with high sensitivity, or it will not indicate circuit conditions accurately. For example, a 1-ma meter will draw 1 ma of current. If the normal circuit current is 1 ampere, the additional 1 ma, which is .001 amp, drawn by the meter will be an insignificant amount. However, if the normal circuit current is only half a milliampere, then the additional 1 milliampere that the meter draws represents an increase in the total circuit current of 200%. This increase in total current will upset a high-impedance circuit and the voltage indicated on the meter will be substantially less than the voltage that is normally present in the circuit.

An indication of how much a meter will load the circuit is given by the sensitivity of the meter. A meter with a high sensitivity requires less current to operate it than one with low sensitivity and hence loads the circuit less. For example, a 50-microampere meter is more sensitive than a 1-milliampere meter. It requires only 50 microamperes to give a full-scale deflection. A 1-milliampere meter, on the other hand, requires a current of 1 milliampere, which is 20 times 50 microamperes to give a full-scale reading. Thus, a voltmeter built with a 50-microampere meter and suitable multiplier resistors will be more sensitive and load the circuit only 1/20 as much as a similar voltmeter made with a 1-milliampere meter.

Instead of giving the sensitivity of meters in terms of the current needed for a full-scale meter deflection, manufacturer's rate them in ohms per volt. Let's see what this rating means.

A 1-milliampere meter requires a current of 1 milliampere to give a full-scale deflection. To convert this meter to a voltmeter with a full-scale range of 1 volt, we connect a multiplier resistor in series with the meter. The value of this resistor is

$$R = \frac{1}{.001} = 1000 \text{ ohms.}$$

If we wanted to make a 2-volt meter, we would need a resistor

$$R = \frac{2}{.001} = 2000 \text{ ohms.}$$

Notice that this is twice 1000 ohms. If we wanted a 10-volt meter we would need 10,000 ohms, which is ten times 1000 ohms, and if we wanted a 100-volt meter, we would need a 100,000-ohm multiplier, which is 100 times 1000 ohms. Thus we say the sensitivity of the meter is 1000 ohms per volt. From this figure we can immediately tell what the total resistance of the voltmeter is.

For example, if we have a 50-volt meter with a sensitivity of 1000 ohms per volt, we know that the total resistance of the meter plus its multiplier is 50 × 1000 ohms, which is 50,000 ohms. Notice that this figure is based on the full-scale range of the meter and not the voltage being measured. The resistance of the meter is 50,000 ohms whether the voltage being measured is 50 volts, 40 volts, 25 volts, or any other value.

You can determine the ohms-per-volt sensitivity of any meter if you know the current required for a full-scale deflection, or, if you know the ohms-per-volt sensitivity of a meter you can determine what current it draws at full scale.

For example, if we have a 50-microampere meter used in a voltmeter, its sensitivity is

$$R = \frac{1}{.00005} = 20{,}000 \text{ ohms.}$$

Thus its sensitivity is 20,000 ohms per volt. If the meter has a full-scale voltage of 150 volts, its total resistance will be 20,000 × 150 = 3,000,000 ohms.

If you have a meter rated at 10,000 ohms per volt and want to know what current is required for a full-scale deflection, you use Ohm's Law:

$$I = \frac{E}{R}$$

$$I = \frac{1}{10.000} = .0001 \text{ amps}$$
$$= 100 \text{ microamps.}$$

We can convert a one-milliampere full-scale d'Arsonval meter to a two-scale voltmeter by connecting the proper value multiplier resistors in series with the instrument, as shown in Fig. 14. Remember that to get an indication of 1 volt on a 1-milliampere meter, the series resistance must be 1000 ohms. If we wish to increase the full-scale reading to say 150 volts, we merely multiply 1000 by 150, which gives 150,000 ohms as the value of the series resistor between terminals A and B.

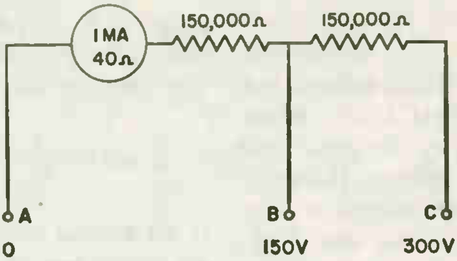

FIG. 14. How a 1-ma meter can be converted to a two-scale voltmeter.

To increase the full-scale reading to 300 volts, we add another 150,000-ohm resistor, giving a total of 300,000 ohms. In both cases, 1 milliampere of current flows through the meter, and the instrument has a sensitivity of 1000 ohms per volt on either scale.

In Fig. 14, the resistance of the 1-milliampere movement, 40 ohms, is negligible when compared with the value of the multiplier resistances. Thus, the meter resistance can be ignored. However, we would have to consider the meter resistance if we calculated the multiplier to make the meter read 1 volt full-scale deflection. The total meter circuit resistance would be 1000 ohms: 40 ohms in the meter, and 960 ohms in the multiplier.

Neglecting the meter resistance and using a 1000-ohm resistor would cause a 4% error in meter readings.

However, on the 150-volt range, neglecting the meter resistance and using a 150,000-ohm resistor would cause an error of only .02%. The percentage of error caused by neglecting the meter resistance will be approximately equal to the meter resistance divided by the multiplier resistance times 100. Although the percent of error decreases as the voltage range increases, the meter will always read low.

Meters with more sensitive movements will place less load on low-current circuits because of the much higher resistances used with them. For example, a .1-milliampere meter has a sensitivity of 10,000 ohms per volt. To extend its range to 150 volts, the resistor would be 10,000 × 150, or 1.5 megohms.

When measuring voltage, as when measuring current, if you are not sure what range to use, always use a high one, then switch to a lower one if the voltage to be measured is covered by the lower one.

Also, it would be very foolish to try to measure the output voltage of a power supply in a large transmitter or any other high-voltage source by holding the leads of a meter across it—you might even be electrocuted! If there is no permanent meter built in, and you must measure the voltage, first shut off the power. Then, discharge the filter capacitors, connect the meter across the output, turn on the power, and without touching the meter, read the voltage. Then, turn off the power, discharge the filter capacitors again, and disconnect the meter before turning the power back on.

PROTECTING THE METER

In communication circuits, special care must be taken to keep rf fields from affecting the meters. A strong field will induce rf currents in the meter wiring, which will affect the accuracy of the meter. High rf voltages may also cause the insulation to break down. This can be avoided in a dc meter in three ways: (1) connecting it so that it is at ground potential with respect to rf; (2) shunting it by an rf bypass capacitor; (3) putting an rf choke in series with it. Fig. 15A shows an example of the first method.

The meter is at the point of lowest rf potential in the cathode circuit. Although capacitor C1 does shunt rf currents to ground, it is not placed in the circuit specifically to protect the meter. Its primary function is to prevent degeneration in the circuit.

Fig. 15B shows the second method. This is used when a meter must be

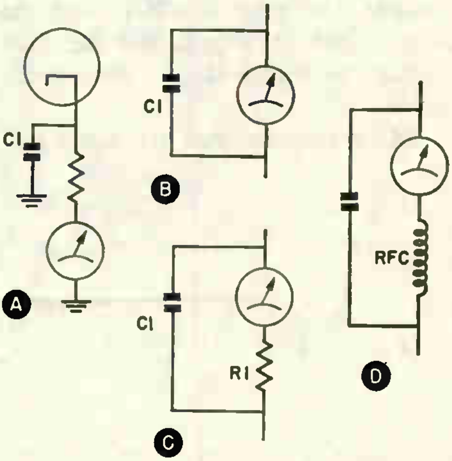

FIG. 15. How to protect a dc meter from strong rf fields.

placed in a lead that carries rf or af currents. A bypass capacitor having a low impedance compared to the meter impedance is used. The rf or af current follows the low-impedance path through the capacitor rather than the high-impedance path through the meter. This protection is sometimes increased by adding a resistor, as shown in Fig. 15C. The resistor, besides increasing the meter impedance, acts to damp out and prevent any resonance effects that might result from the parallel combination of the inductance of the meter coil and the capacitance of the bypass capacitor. Fig. 15D shows the third method. An rf choke is placed in series with the meter and within the circuit shunted by the bypass capacitor.

The bypass capacitor for rf circuits may be anywhere from .001 mfd to .01 mfd. For af circuits, the bypass capacitor should be .01 mfd to 1 mfd, depending upon the circuit. The size of the series resistor depends upon the current flowing in the circuit, but it is usually approximately equal to the meter resistance. The higher the resistor, the more it will protect the meter, but it should not be high enough to reduce the dc current too much.

DC voltmeters that are wired permanently into transmitter circuits are not put near rf fields. However, if you are making measurements with a portable instrument, you should be careful not to take your measurements where the meter can be affected by rf signals.

SUMMARY

Practically all meters used in communications work for measuring dc voltages and current have a basic d'Arsonval movement.

The range of a current meter can be extended by adding shunt resistors, the value depending upon the sensitivity of the meter and upon the current to be measured.

In a voltmeter, resistors called multipliers are added in series with the basic meter so the current through the resistor flows through the meter, and the combination is connected across the source to be measured. The meter scale is calibrated to show the voltage for the amount of current causing the pointer deflection.

For current measurements, the meter is always in series with the line; for voltage measurements, the meter is always across the line. When measuring either voltage or current always be sure to use a high enough range, or you may ruin the meter.

AC Measurements

The same basic meters can be used to measure alternating currents and voltages as are used to measure direct current and voltages. As you have learned, the magnetic vane meter and the dynamometer work on either ac or dc. Although they can be used with dc the d'Arsonval meter is so much superior for dc measurements that the magnetic vane type and the dynamometer are seldom used for dc measurements. The dynamometer is the most accurate of the meters for measuring alternating current and voltages, so it is often used as a standard for calibrating other instruments. The d'Arsonval meter can be used with copper oxide rectifiers to measure ac. This arrangement is primarily used in voltage measurements rather than current measurements. The d'Arsonval meter is used to measure alternating current by combining it with an arrangement called a thermocouple, which you will study in a minute.

MEASURING ALTERNATING CURRENT

In measuring alternating current, just as in measuring direct current, the meter is connected in series with the load. Again you must be careful to use a high enough range so you will not overload the meter.

AC meters are usually calibrated at some specific ac frequency. If the frequency at which you are taking measurements is too far removed from this, the readings will be somewhat inaccurate.

The range of an ac meter can be extended in the same way as that of a dc meter by adding a shunt resistance across the meter. The size resistance needed to extend a meter range to a given value is figured in the same way as the dc meters, using the same shunt formula.

The magnetic-vane meter and the dynamometer work directly on ac, but when the d'Arsonval meter is used, there must be some means of converting the ac to dc. One arrangement used particularly at rf frequencies is the thermocouple. Let's see how it works.

Thermocouples. The thermocouple works on the principle that when two dissimilar metals are joined and the junction is heated, there will be a dc voltage produced. The amplitude of this voltage depends upon the amount of temperature change at the junction. A sketch of a thermocouple junction is shown in Fig. 16A. Here two wires made of dissimilar metals are welded together to form a junction. The voltage produced at the junction can be measured between the other ends of the wires with a sensitive dc voltmeter.

Since current flowing through a resistance produces heat, we can get an indication of the amount of current flowing in a circuit by using a thermocouple junction along with a suitable meter as shown in Fig. 16B. The current to be measured is sent through a resistance wire or heater, producing heat. The junction of two dissimilar metal wires is brought near or actually welded to this heater. The other ends of the two wires are connected to a sensitive dc meter.

When current flows through the resistance, heat will be produced. The amount of heat produced will be proportional to the power dissipated in the resistance. Since the power dissipated in the resistance will be equal to I^2R, the heat will be proportional to the square of the current because the value of R remains constant. This heats the thermocouple junction, producing a dc voltage, which causes a dc current to flow through the thermocouple and through the meter.

Since the heat at the junction is proportional to the square of the current, and the generated dc is proportional to the heat, the meter will have what is called a square-law scale. Fig. 17 shows an example of a thermocouple meter with a square-law scale.

Square Law Meter Scales. Sometimes you'll have to use a standard dc milliammeter with a thermocouple or a square law meter. In this case the meter will be divided into equally squared divisions, and you can measure the current required for a full-scale deflection and then calculate the current for deflections less than full scale.

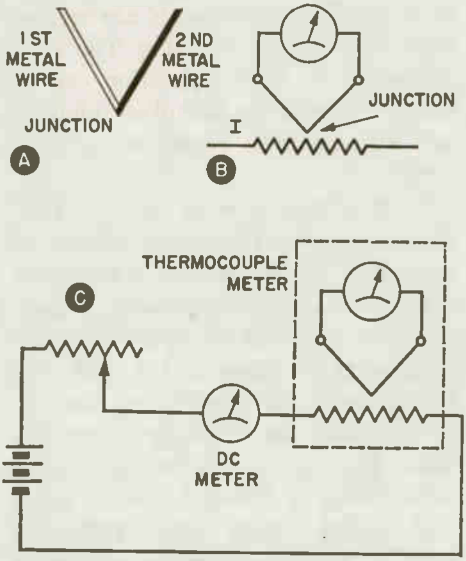

FIG. 16. How a thermocouple meter works.

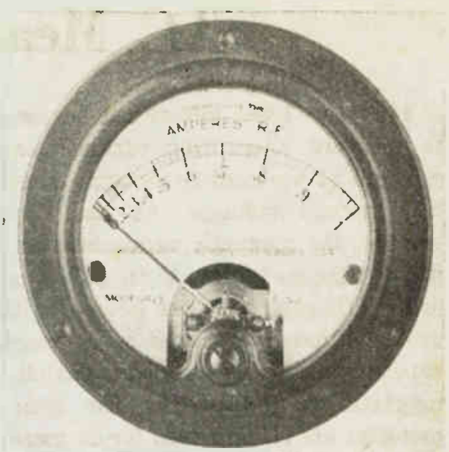


Courtesy Weston Electrical Instrument Co.

FIG. 17. A thermocouple meter with a square-law scale.

For example, assume that you have a square law meter with the scale divided into 100 equally spaced "divisions." If the full-scale reading (meter deflection of 100 divisions) is 10 ma, what is the current which corresponds to half-scale deflection (50 divisions)? To determine the unknown current, use the formula:

$$\frac{D_a}{D_b} = \frac{I_a^2}{I_b^2}$$

where I_a is the unknown current, D_a is the deflection corresponding to it, I_b is the known current and D_b is the deflection corresponding to the known current. Using values, we have:

$$\frac{50}{100} = \frac{I^2}{10^2} \text{ or } \frac{50}{100} = \frac{I_a^2}{100}$$

When transposed, we get:

$$I_a^2 = \frac{50}{100} \times 100 = 50$$

Then,

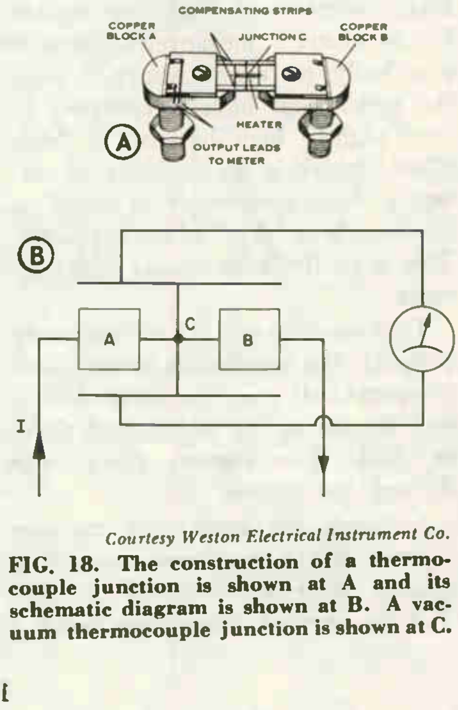
$$I = \sqrt{50}$$

which is approximately 7.1 ma.

You will remember that when we defined the ac ampere we said that an ac ampere is that ac current that will produce the same heating effect as one ampere of dc. Thus, since the relationship between ac and dc currents is based on the heating effect, we can calibrate a thermocouple-type meter with dc. A convenient circuit is shown in Fig. 16C. Here the dc current flow can be measured on a dc current meter and the reading on the meter connected across the thermocouple recorded. By adjusting the potentiometer the current can be varied so the entire thermocouple meter scale can be calibrated. Of course, thermocouple meters you buy come already calibrated, but this is how they are calibrated. Once they have been calibrated on dc they are quite accurate on ac even up into high radio frequencies. In fact, their accuracy is generally within 5% from dc up to 100 megacycles. In calibrating a thermocouple with dc, two sets of readings are usually taken, one with the current flowing in one direction and the other with it flowing in the opposite direction, and the readings are averaged.

The temperature difference between the hot junction and the free ends of the thermocouple element must not be influenced by surrounding temperature changes. To eliminate this possibility, the construction shown in Fig. 18A is used.

Fig. 18B shows the schematic diagram of this type of construction. There is a thin-walled tubular heater terminated in rather heavy copper blocks, A and B, which are so large they will not be heated by the heater. Current flowing through the heater will develop a temperature difference between the center of the heater and the blocks. The thermocouple junction C is on the center of the heater. The other ends of the wires are connected to two strips called "compensating strips." These strips are insulated from the blocks electrically by thin layers of mica, but connected to them thermally so the strips will be at the same temperature as the blocks. The heat capacity of the strips is such that the temperature difference between the ends of the thermocouple and the junction will always be the same as the temperature difference between the center of the heater and blocks A and B. Thus, if the temperature of the



Courtesy Weston Electrical Instrument Co.

FIG. 18. The construction of a thermocouple junction is shown at A and its schematic diagram is shown at B. A vacuum thermocouple junction is shown at C.

air surrounding the thermocouple changes, the temperature difference between the blocks and the center of the heater and between the junction and the ends of the thermocouple does not, so there will be no change in the potential developed by the thermocouple due to this change. Conductors are fastened to the ends of the compensating strips to conduct the potential developed by the thermocouple to the meter. If very small currents are to be measured, the thermocouple is enclosed in an evacuated glass envelope. This is designed to protect the elements from temperature changes which could be produced by warm air circulating around the thermocouple junction or the ends of the thermocouple.

Thermocouple meters are available in current ranges from less than 1 milliampere up to about 300 amperes. They are well suited for measuring radio frequency currents because of their accuracy at high frequencies. Up to about 2 megacycles, there is practically no error. Above 2 megs the meter does have a tendency to read slightly high because of "skin effect," which is the tendency of current at high frequencies to travel on the surface or "skin" of the conductor. This is particularly true at high currents.

To minimize skin effect and eddy currents, the conductors in the thermocouple unit are often made of thin-wall copper tubing plated with silver or gold. The current flows only through the plating.

Although the error may increase slightly as the frequency rises, it is usually below about 5% at 100 mc. The accuracy at frequencies below 2 mc may be as much as .5% at the temperature at which the meter was calibrated. Because of this accuracy at high frequencies, the thermocouple meter is often used as a standard for calibrating instruments at frequencies above those that can be measured on the dynamometer.

The meter used with a thermocouple must be very sensitive, because the output of the thermocouple unit may be only 15 millivolts.

Thermocouples in general must be handled with great care because they are delicate. You must avoid overloading a thermocouple because the heater is likely to burn out if subjected to more than a 40% overload.

MEASURING AC VOLTAGES

All three of the basic meter types can also be used to measure ac voltage. Just as for measuring dc voltage, a resistor is connected in series with the meter and the combination is connected across the source to be measured. The types of meters we have described in this lesson are seldom used to measure rf voltages. Such measurements will be discussed in a later lesson.

The magnetic vane meter is not suitable for most voltage measurements in communications circuits because it is difficult and costly to make a magnetic vane meter with a sensitivity better than about 5 ma. A voltmeter built around a milliammeter that required 5 ma for a full-scale deflection would have a sensitivity of only 200 ohms per volt. This would load many circuits to such an extent that the voltage reading on the meter would be much lower than the voltage normally present in the circuit.

A d'Arsonval meter can be used for ac voltage measurements by changing the current needed to operate the meter to dc. One common method of doing this is to use a copper oxide rectifier with the meter. We will study these now.

Using Rectifiers. The basic d'Arsonval meter can be used to measure ac voltages by connecting it to a single copper oxide rectifier as shown in Fig. 19A, or to a bridge circuit consisting of four copper-oxide rectifiers as shown in Fig. 19B. The rectifier consists of a number of copper discs. One side of each disc is covered with a film of copper oxide. Next to each disc is a lead washer, and the unit is held together under pressure in a clamp-like arrangement. Current will flow readily from the copper to the copper oxide, but will not flow readily in the opposite direction because the copper will readily give up its electrons but the copper oxide will not. The copper disc acts as the cathode of a rectifier, and the oxide acts as the anode. The lead disc is used as a means of contact with the copper oxide.

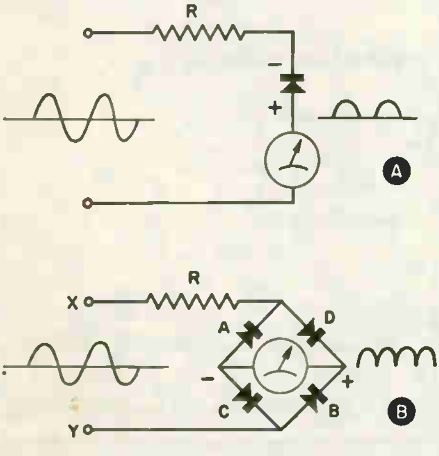


FIG. 19. A basic d'Arsonval meter can be used to measure ac voltages by connecting it to a single copper-oxide rectifier as at A, or to a bridge circuit at B.

The backward or reverse resistance of the unit to the flow of current in the opposite direction may be from 50 to 1500 times that of its forward resistance or rectifying direction.

Fig. 19A shows a single rectifier connected in series with the meter. This is a half-wave rectifier. Its output is a pulsating, direct current as shown by the waveform. The current flow is blocked during alternate half cycles.

In Fig. 19B, four copper-oxide rectifier units are connected in a full-wave bridge circuit. When point X is positive, current will flow from Y through rectifier C, through the meter from left to right, through rectifier D and resistor R to point X. When point Y is positive, current will flow from point X through resistor R and rectifier A, through the meter again from left to right, and through rectifier B to point Y.

The pointer of the meter cannot follow the pulsating direct current that appears at the input of the meter in either the full-wave or half-wave rectifier circuits. In the full-wave rectifier, the current that appears at the output of the rectifier is the average or .637 of the peak value. However, the scale is generally calibrated to read the rms or effective value of the voltage. In the half-wave rectifier the current at the output of the rectifier is only half of .637 or .318. Again the scale is calibrated to read the effective value of the voltage even though it is taken from the half cycle. The full-wave rectifier circuit is more commonly used than the half-wave circuit.

In the full-wave bridge circuit, both ac and dc are flowing simultaneously. The meter movement, however, is in that portion of the circuit where practically all the flow is in one direction. It is direct current resulting from having each alternate half of the sine wave flow through the meter element in the same direction.

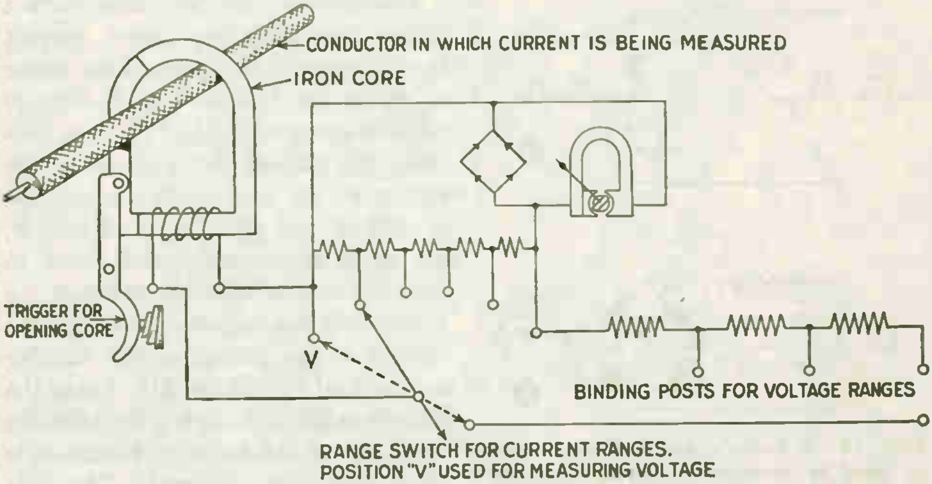
One of the advantages of the copper-oxide rectifier and d'Arsonval meter combinations for ac voltage measurements is that a very sensitive meter which takes little current from the source can be used. Another advantage is that the scale is linear. One disadvantage is known as frequency error. Because there is capacity between the oxide-coated sides and the non-oxide-coated sides of the discs in the rectifier unit, some current is bypassed, resulting in an error if the instrument is used at a frequency other than the one at which it was calibrated. Most instruments will read about 5% low for each 1000 cycles above the frequency for which the instrument is calibrated. The scale, for all practical purposes, is linear.

CLAMP-ON METER

We have mentioned several times that when current is being measured, the meter is connected in series with the line, and when voltage is being measured, the meter is connected across the line. However, there is a combination volt-ammeter that actually clamps around the line, so that the circuit need not be opened to take current measurements.

The diagram of a clamp-on meter is shown in Fig. 20. It consists of an iron-core that can be opened and clamped around the conductor carrying the current to be measured, with a coil wound around it connected to a d'Arsonval meter and bridge circuit.

The iron core and the coil form a transformer. The core is a one-turn



Courtesy Weston Electrical Instrument Co.

FIG. 20. A clamp-on meter.

primary, and the coil is the secondary.

The alternating current in the conductor produces a varying flux in the core. This in turn causes current to flow in the secondary, which is fed to the bridge circuit. The direct current output of the bridge actuates the meter movement. This type of meter is, of course, usable only with alternating current.

Both the current and the voltage range are usually wide, the current range may be as high as 1000 amperes, and the voltage range as high as 750 volts.

This instrument is a great aid in troubleshooting, especially to determine current flow taking place in a circuit in intermittent service, or to check running currents in motor circuits. It is also valuable in checking currents in three-phase circuits, which you will study later, to determine any unbalance that may exist between the phases, and in checking total input current against rated input current of a power supply. Care should be taken to see that the core laminations at the opening and hinged points are clean and sealed properly, otherwise possible obstruction at these points may cause erratic readings.

SUMMARY

The same basic meters are used for ac measurements as for dc measurements. When the d'Arsonval meter is used, the current fed to it must first be rectified. In current meters this is often done by means of a thermocouple. In voltage meters it is often done by means of copper-oxide rectifiers either singly or in a bridge circuit.

The meter is connected in series with the line to measure current and across the line to measure voltage.

When making measurements, it is always important to be sure to use a high enough range.

Resistance Measurements

Now let's see how the same basic current-operated meters can be used to measure resistance.

We know from Ohm's Law that $R = E/I$. Therefore, if we know the source voltage, and the current through a resistor, we can calculate the resistance. An ohmmeter does just this. It has its own source of dc voltage. When it is connected across a resistance, current flows through the resistance. The amount of current will be inversely proportional to the value of the resistance (the more resistance, the less current), and will determine the deflection of the pointer. The scale is calibrated to indicate directly the amount of resistance that will cause this amount of current flow. There are two general types of ohmmeter, the series type and the shunt type.

SERIES OHMMETER

The simplest type of direct-reading ohmmeter is shown in Fig. 21A. This ohmmeter is made up of a battery, a low-range milliammeter, and a combination of a fixed and a variable resistor, R1 and R2, in series.

The value of R1 plus R2 must be just enough so that with that particular battery voltage when the test leads of the instrument are touched together, making a complete circuit, the pointer of the current-operated meter movement will make a full-scale deflection. For example, if it is a 1-ma meter movement there must be 1 milliampere of current when the test leads are touched to each other. R2 is made adjustable because the battery voltage decreases with use and hence the resistance needed for a full-scale deflection will vary. Two resistors, one fixed and one variable are used to keep a minimum resistance in the circuit at all times. If you had only the variable resistance in the circuit and adjusted it so you had zero resistance in the circuit. such a high current would flow when you touched the test leads from the instrument together you could burn out the meter.

When an unknown resistance is to be measured, it is connected between the test probes as shown in Fig. 21B. Its resistance is added in series with R1 and R2, and the current will decrease accordingly, and there will be less deflection of the pointer. Since less deflection of the pointer means more resistance, the scale is printed with the zero at the right, which is the opposite of the current scale. A typical series-type ohmmeter scale is shown in Fig. 22.

To use this type of ohmmeter, the test leads are first shorted, and R2 is adjusted for a full-scale reading (zero on the Ohms scale). When the leads are connected across the unknown resistance, the current through the meter will be reduced because of the additional resistance. If the resistance being measured is equal to the resistance already in the meter circuit (the sum of the meter resistance and the resistance of R1 and R2), it will double the total resistance in the meter circuit, so the current will be cut in half, and the meter will read half scale. If the resistance being measured is less than the resistance in the meter circuit, the meter will read more than half scale. If the unknown resistance is greater than the resistance of the meter circuit, the meter will read less than half scale.

For example, the scale in Fig. 22 is for an ohmmeter with a 1-ma meter movement and a 3-volt battery. This means that the sum of R1 + R2 and the meter resistance will be 3000 ohms, because we need 3000 ohms in the circuit to limit the current to 1 ma with a 3-volt battery. We know this from Ohm's Law:

$$R = \frac{E}{I} = \frac{3}{.001} = 3000 \text{ ohms.}$$

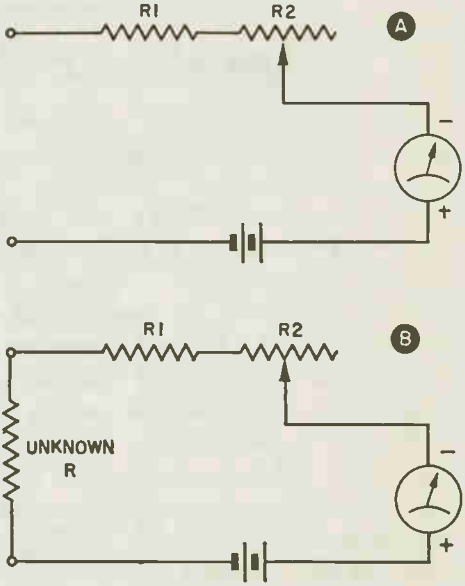


FIG. 21. A simple series-type ohmmeter.

This 3000 ohms might be made up of 100 ohms in the meter itself, a 1000-ohm potentiometer, R2, and a 1900-ohm resistor, R1. When the test leads are shorted so there is no additional resistance in the circuit, the meter will read full-scale (zero on the ohms scale). If a 3000-ohm resistor is connected between the leads, the total resistance will have doubled, the current will be cut in half, and the pointer will be at the center of the scale. As you can see, this is 3000 in Fig. 22. If the resistance being measured is 6000 ohms, the total resistance will have tripled, the current will be cut to one-third its full-scale value, and the pointer will be one-third of the way over. Thus, because of the relationship between the resistance and the current, zero resistance is at the right-hand end of the scale; 3000 ohms is represented by half the scale; the next 3000 ohms is represented by only one-sixth of the scale; the next 3000 ohms by only one-twelfth of the scale, etc.

FIG. 22. A scale for a series-type ohmmeter having a 3000-ohm center-scale value.

Higher resistance values can be measured with a series-type ohmmeter by using a higher battery voltage or a more sensitive meter. For example, if we used a 30-volt battery instead of a 3-volt battery with the 1-ma meter, then the resistance needed to limit the current to 1 ma when the test leads are shorted together would be

$$R = \frac{30}{.001} = 30{,}000 \text{ ohms.}$$

To reduce the current to .5 ma, we would need twice this resistance or 60,000 ohms. Thus, center scale on the meter would be 60,000 ohms minus 30,000 ohms (which is in the circuit at full scale) which is 30,000 ohms. The center of the scale on the ohmmeter would therefore be 30,000 ohms, ten times what it was with the 3-volt battery.

With a more sensitive meter we get the same results. Let's go back to the 3-volt battery and consider a 50-microamp meter. The resistance needed to limit the current will be:

$$R = \frac{3}{.00005} = 60{,}000 \text{ ohms.}$$

To reduce the current to half scale we would need an additional 60,000 ohms. Thus this meter would have a center scale resistance of 60,000 ohms.

Lower resistance values can be measured with a series-type meter by use of a shunt. Taking our original example of a 3-volt battery and a 1-ma meter, we can connect an additional resistor R3 in the circuit as shown in Fig. 23. Since R3 has a resistance of 333 ohms, which is 1/9 the resistance of $R1 + R2 + R_m$, nine times the current will flow through R3 that flows through the meter. Thus, with the test probes shorted together, the meter will read full scale, because 1 ma will flow through it and at the same time 9 ma will flow through R3. If we connect a resistance between the terminals that reduces the total current flow from 10 ma to 5 ma, we will get a half-scale reading on the meter, .5 ma of the current will

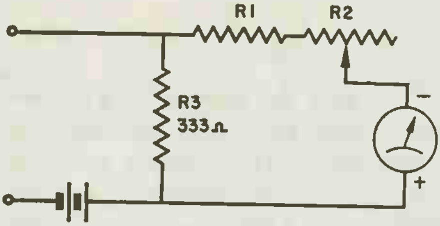

FIG. 23. Using a shunt with a series-type ohmmeter to measure lower resistances.

flow through the meter to give the half-scale reading, and the balance of the current, 4.5 ma, will flow through R3.

The resistance of R1 + R2 + R_m is 3000 ohms. This 3000 ohms is in parallel with 333 ohms. The resistance of the parallel combination is 300 ohms. With 300 ohms across the 3-volt battery, we get a total current of 10 ma which, as we said, gave us a full-scale meter reading. To cut the current in half, we need to double the resistance or add another 300 ohms between the test probes. Thus, with the shunt R3 added, center scale on the ohmmeter becomes 300 ohms. By adding a resistor that would permit still more current flow around the meter we could reduce the center scale resistance still further.

Some ohmmeters are arranged so that different values of shunt resistors can be switched into the circuit. The ohmmeter thus becomes a multi-range ohmmeter.

SHUNT OHMMETER

A different type of ohmmeter circuit is used when very low resistances are to be measured. This is the "shunt-type" shown in Fig. 24A. In this circuit, the milliammeter, the calibrating resistor R1, and the battery are connected in series and form a closed circuit even when the test leads are apart. The resistance of R1 must be just enough so that there will be enough current to cause a full-scale deflection of the meter pointer with the test leads apart (for a 1-ma meter, a 1-ma current). In actual practice R1 is made up of two resistors, a fixed resistor and a variable one to avoid the possibility of burning out the meter by setting the potentiometer so there is no resistance in series with the meter.

When the unknown resistance is connected between the test leads, it will be in parallel with the meter, as shown in Fig. 24B. This means that part of the current will flow through it, and part through the meter. If the

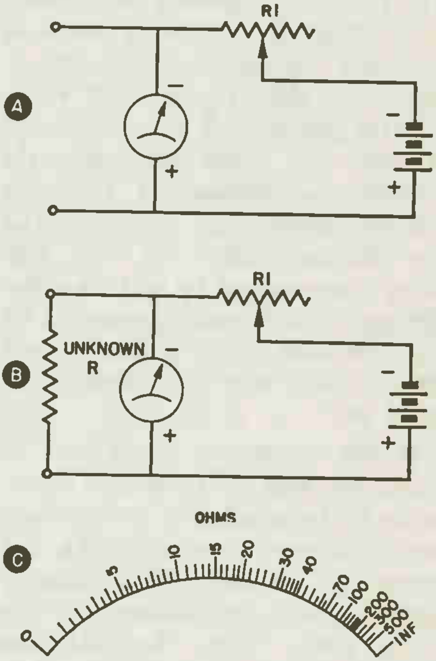

FIG. 24. A shunt-type ohmmeter circuit is shown at A and B, and the scale is shown at C.

resistance is high, most of the current will still flow through the meter, and the deflection will still be near full scale. If the resistance is low, most of the current will flow through it, not much will flow through the meter, and the deflection will be slight. If the resistance is exactly equal to the resistance of the meter itself, half the current will flow through it and half through the meter, and we will have a center-scale reading. As you can see, for low resistance values, the pointer would be at the left, and for high resistance values, it would be at the right. This means that zero would be at the left just as on a standard current scale.

A typical scale for a shunt-type ohmmeter is shown in Fig. 24C. The center-scale reading is 15, which means the resistance of the meter itself is 15 ohms. As you can see the scale is expanded at the low end just as the one for the series meter is.

The value of the resistance being measured would not appreciably affect the total resistance in the ohmmeter circuit, because the value of R1 would be so much larger than the value of the meter resistance, that for all practical purposes, it would determine the circuit current. For example, with a 1-ma meter and a 3-volt battery, the resistance of R1 plus the resistance of the meter would be 3000 ohms for full-scale deflection. Since the meter resistance is 15 ohms, R1 would be 2985 ohms. The resistance of the meter and the resistance being measured would vary from 0 to 15 ohms, depending upon the value of the resistance being measured. (Remember that the resistance of two resistors in parallel is always less than that of the smaller one). As you can see, this would not have any noticeable effect on the current drawn from the battery.

A word of caution about the use of this meter: Always turn it off when you are not using it, or you will drain the battery. You should get in the habit of switching it off after every measurement.

ACCURACY

The accuracy of any ohmmeter is limited by the stability of the battery terminal voltage. If the battery voltage is high, the meter will read low. If the battery voltage is low, the meter will read high. Practically all ohmmeters are designed to use batteries which are multiples of 1.5 volts; 1.5, 3.0, 4.5 volts, etc. Check the ohmmeter battery voltage occasionally to make sure your ohmmeter measurements will be reasonably accurate.

You can check the accuracy of the ohmmeter by measuring the value of a known resistance. A resistor with a tolerance of 1% is satisfactory. Choose a resistance value that will cause the ohmmeter pointer to indicate somewhere near the center of the ohmmeter scale.

The accuracy of most ohmmeters is only about 10% to 20%. That is, when the meter reads 100 ohms, the value of the resistance being measured may be anywhere between 80 and 120 ohms. However, this is usually as accurate as it needs to be for all practical purposes. If you must obtain a more accurate measurement, there are other instruments that can be used. You will study some of these instruments later.

THE MEGGER

Another resistance-measuring instrument you should become familiar with is the megohmmeter, or "megger," as it is called. As its name implies, it is used to measure very high resistance such as leakage in the insulation of cables, motor windings, transformers, and so forth.

Instead of a battery, it has a generator operated by a hand crank that generates about 500 volts. The meter is similar to a standard d'Arsonval meter, except it has two coils between the poles of the permanent magnet, wound on the same core, as shown in Fig. 25. Coil L1, which is called the *current coil*, is positioned so that when current flows through it, it will tend to move the pointer to the right (towards zero). Coil L2, which is called the *potential coil*, is positioned so that when current flows through it, it will move the pointer to the left (toward infinity).

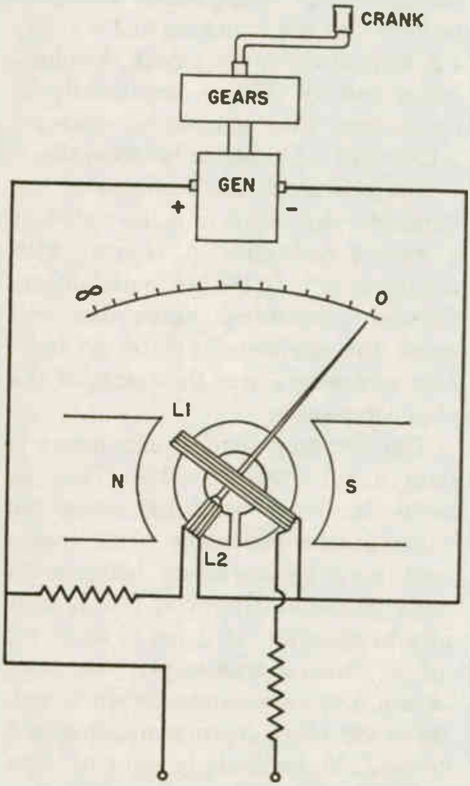

FIG. 25. How the "megger" is made.

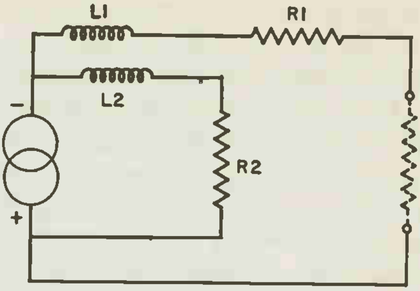

FIG. 26. Simplified schematic of the megger.

Fig. 26 shows a simplified schematic of the megger. The pointer on the megger is not restrained by springs so it is free to move to any position when the instrument is not in use. When you begin turning the hand crank the generator generates a voltage and as you can see, when nothing is connected across the terminals, the circuit will be open, and no current will flow through L1. However, current will flow through L2 and this current causes the pointer to swing to infinity. When a resistance is connected across the terminals, current will flow through L1, and this will tend to move the meter pointer towards zero. The current flowing through L1 will also tend to load the generator, which reduces the voltage and current through L2. This reduces the torque produced by L2 which has a further tendency to let the pointer move towards zero. How far it goes in this direction depends on how low the resistance is across the terminal. The lower the resistance, the more the pointer will move.

If there is any electrical path between the terminals, the meter will indicate it—up to hundreds of megohms.

For example, suppose you have a power transformer that has been subjected to undue moisture. Before placing it in operation you want to know if the moisture has caused leakage between the primary and the secondary. Connect the megger as shown in Fig. 27, and turn the crank. If there is any resistance between the primary and secondary it will be indicated on the meter scale. The design of the instrument is such that the speed of the crank has little effect on the reading as long as it is turned at a reasonable speed.

MULTIMETERS

Since the same basic meters can be used to measure current, voltage, and resistance, combination instruments, called multimeters can be designed that will measure all three. The same meter is used; it is connected in different ways by means of switches to measure current, voltage, and resistance. Multimeters are used for general maintenance and repair of electronic equipment. Fig. 28 shows the schematic diagram of such an instrument.

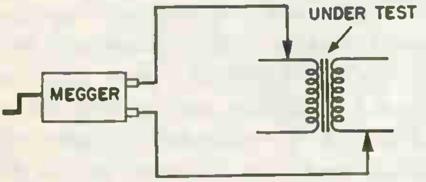

FIG. 27. How to test for leakage between transformer windings with a megger.

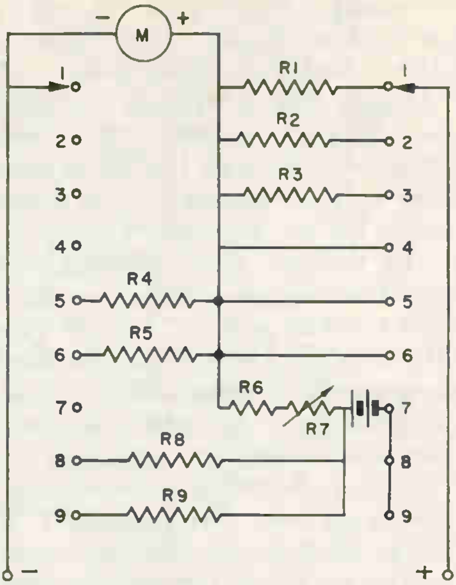

FIG. 28. Schematic diagram of a multimeter.

In the position shown, which we will call position 1, R1 is a voltage multiplier. It is in series with the meter. In position 2, R2 will be in series with the meter, and in position 3, R3 will be in series with the meter. If the meter is a 1-ma meter, by selecting R1 so its resistance plus the resistance of the meter is 1000 ohms, we could measure voltages up to 1 volt. By making the total resistance of the meter plus R2 equal to 10,000 ohms we could measure voltages up to ten volts in position 2, and by making R3 equal to 100,000 ohms we can measure voltages up to 100 volts in position 3.

In position 4 the meter is used as a 1-ma current meter. It is connected directly to the output terminals. In position 5, R4 is a shunt and will be connected directly across the meter terminals. In position 6, R5 will be a shunt across the meter terminals. If the resistance of the meter is 45 ohms, by making R4 equal to 5 ohms and R5 equal to .454 ohms we can measure currents up to 1 ma in position 4, up to 10 ma in position 5, and up to 100 ma in position 6.

In the last three positions, the meter is used as an ohmmeter. With a 3-volt battery and R6 + R7 plus the meter equal to 3000 ohms, we have a meter with a center scale resistance of 3000 ohms. In position 8, R8 is connected across the meter and R6 and R7. In position 9, R9 is connected across the meter and R6 and R7. If R8 is a 333-ohm resistor, the center scale resistance on this range becomes 300 ohms. By making R9 equal 30.3 ohms, the center scale resistance becomes 30 ohms.

Thus, with this arrangement we have three voltage, three current, and three resistance ranges. Additional ranges could be added by using a switch with more positions. Some of these positions could be for ac voltage measurements if we added a copper-oxide rectifier.

SUMMARY

The two main types of ohmmeters are the series type and the shunt type. Both use d'Arsonval meters. The series type has the zero at the right end of the scale; the shunt type has the zero at the left end of the scale. The shunt type is used to measure low resistance. Ohmmeters contain their own source of voltage, so the circuit in which measurements are being taken should be turned off.

An instrument called a "megger" is used to measure very high resistances. Instead of a battery, it has a 500-volt generator, and will measure resistances up to hundreds of megohms.

Current, voltage, and resistance meters are often combined in one instrument called a "multimeter."

Power Measurements

Power is the amount of electrical energy consumed in a circuit. It is measured in watts, kilowatts (thousands of watts), microwatts (millionths of a watt), or milliwatts (thousandths of a watt). In a circuit having only pure resistance, the power in watts is equal to the current in amperes multiplied by the voltage in volts, or $P = E \times I$. This is true in a dc circuit or in an ac circuit in which there is only resistance. In a circuit having inductance or capacity the phase angle between the voltage and the current must also be taken into account when figuring the power consumption. The phase angle is taken into account by multiplying the voltage and current by a figure known as the power factor, so the formula for power in an ac circuit is $P = E \times I \times PF$. The value of the power factor will be somewhere between zero and one. It is zero if the voltage and current are 90° out of phase, and one when the voltage and current are in phase. The power factor in an ac circuit is equal to the ratio of the resistance in the circuit to the impedance in the circuit. It is also equal to the cosine of the phase angle between the voltage and current.

Actually, you use this same formula for dc power, but since the power factor is always 1 in a dc circuit, it is ignored. Let's see how power is measured in dc circuits, in 60-cycle power-line circuits, in af circuits, and in rf circuits.

DC POWER MEASUREMENTS

It is easy to find the power in a dc circuit by connecting an ammeter in series with the circuit, and a voltmeter across it, then multiplying the indicated current by the indicated voltage. For example, if the voltage is 100 volts and the current is 10 amperes, the power consumed would be 1000 watts, or 1 kilowatt. (If this continued for 1 hour, we would say 1 kilowatt-hour of power had been consumed).

In making power measurements in this way, the position of the two meters in the circuit can make a difference. If they are connected as in Fig. 29A, the current drawn by the voltmeter flows through the ammeter. In a circuit where the current is low, this could add appreciably to the current indication, particularly if the voltmeter sensitivity is low. If the meters are connected as shown in Fig. 29B, the voltage indicated on the voltmeter will be slightly higher than the voltage across the load. If the current is very high, the drop across the ammeter may be enough to upset the calculation. At high currents the circuit at A should be used, at low currents, the one at B.

DC power can also be measured with a wattmeter, but it is usually simpler to measure it with a voltmeter and an ammeter.

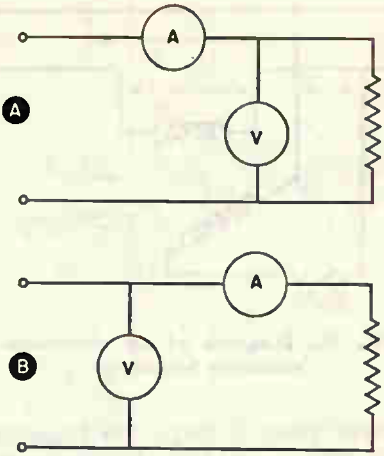

FIG. 29. Power can be measured by connecting an ammeter in series with the circuit, and a voltmeter across the circuit, then multiplying the readings. The arrangement at A is best for high currents, and the arrangement at B is best for low currents.

60-CYCLE POWER MEASUREMENTS

A wattmeter is generally used for measuring power in 60-cycle power line circuits. We cannot get the true power consumed by connecting a voltmeter and an ammeter into the circuit then multiplying the effective current by the effective voltage because we have not taken phase difference into consideration. The figure we would get by multiplying the effective current by the effective voltage is known as the apparent power and is expressed in volt-amperes.

A wattmeter takes the power factor into account. A dynamometer is the type of meter generally used as a wattmeter. Fig. 30 shows a schematic diagram of a wattmeter. The line

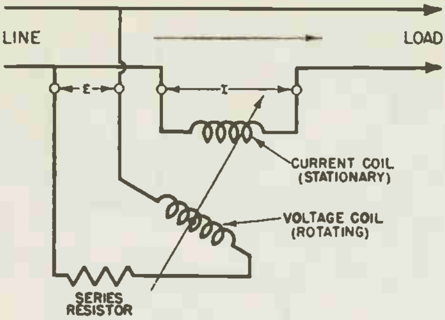

FIG. 30. Diagram of an electrodynamometer wattmeter.

current flows through the stationary coil. The movable coil is connected in series with a suitable resistance and connected across the line. The magnetic field of the stationary coil is proportional to the instantaneous current, and the magnetic field of the movable coil is proportional to the instantaneous voltage. The deflection of the pointer is proportional to the product of the magnetic fields. Since it is the instantaneous values of current and voltage that determine the deflection, it is an indication of true power.

Wattmeters are delicate instruments, and should be handled with care. They have maximum voltage and current ratings in addition to a maximum power rating. For example, a 500-watt meter should not be used to measure power of more than 500 watts. Also, if the meter is rated at a maximum voltage of 600 volts and a maximum current of 1.25 amps, you could overload the current coils by using it on a circuit when the voltage is 50 volts and the current 3 amps, even though the power in this circuit is only 150 watts. Similarly, you could overload the voltage coil by using the meter in a 1000-volt circuit when the current is .1 amp, even though the power is only 100 watts.

AF POWER MEASUREMENTS

Meters that are designed to measure the power output of audio-frequency devices such as audio amplifiers, radio receivers, etc. are designed to measure the voltage across a resistor. Since the voltage across a resistor and the current through it are in phase, the power factor will be 1, so the power will be directly proportional to the square of the voltage.

There are three general types of af power meters: the power output meter, the power level meter, and the VU meter.

Power Output Meter. The power output meter is a rectifier voltmeter with a resistor connected across it. The output from the device to be tested is applied across this resistor instead of to the usual load. The power dissipated in the resistor will be equal to $E^2 \div R$. Thus, if we know the resistance, we can determine the power by measuring the voltage across the resistance, squaring it, and dividing it by the resistance. Since the resistor is always the same, the meter can be calibrated directly in watts.

Power Level Meter. The power level meter is also a rectifier voltmeter, but it does not have a resistor built in across the meter. It must be connected across the load of the device under test. A high resistance voltmeter is used to place as little additional load on the circuit as possible.

This type of meter must always be connected across the same value of resistance for which it was designed, usually in communications work, 500 ohms. The power level meter is designed to indicate the ratio of output power to a certain reference level, and is therefore calibrated in decibels (db) rather than in watts.

A common reference level in communications work is 6 milliwatts of power into a 500-ohm load. This is called 0 db. Using the power equation $P = E^2 \div R$, we find that with 500 ohms and 6 milliwatts of power, the voltage is 1.73 volts. Therefore, by measuring the output voltage the meter can tell whether the power has gone above or below this reference level. If it is above, the meter indicates + db; if it is below, the meter indicates — db.

The advantage of this system is that it provides us with a convenient method of comparing different devices on a more or less common base.

For example, a manufacturer of a receiver may state in his specifications that the output of the receiver will be 0 db with a 100%-modulated input signal of 1 microvolt. This immediately provides us with a means of checking the receiver performance or comparing its rated sensitivity with that of another receiver.

It is important that you use this type of meter across the correct load impedance. Remember the meter is basically a voltmeter. It will indicate correctly in watts only when used across the load for which it was designed. For example, 1.73 volts across a 500-ohm load is 6 milliwatts, which we have set as zero db. Suppose we used this meter across a 10-ohm load. Now if the voltage is 1.73 volts, the meter, since it is a voltmeter, would indicate 0 db or 6 milliwatts. However, the actual power is $1.73^2 \div 10 = .3$ watt! Thus, to get an accurate reading with this instrument we must use it across the rated load of 500 ohms.

VU Meter. The VU meter is also used to indicate power ratios rather than watts of power. The unit used is called a volume unit or VU instead of a decibel, and the reference level is 1 milliwatt into 600 ohms. This is called 0 VU. With 1 milliwatt of power and 600 ohms of resistance, the voltage is .775 volts. If the voltage goes above this, the meter will indicate +VU, and if it goes below this, the meter will indicate —VU. Like the power level meter, it must be used across the correct load. These instruments are built using a special copper-oxide rectifier and an extremely sensitive meter. They are usually built right into the transmitter.

Fig. 31 shows a VU meter scale. It is only accurate in transmitters designed so that 100% modulation is obtained when the meter indicates 0 VU. The figures below the VU scale indicate the percent of modulation.

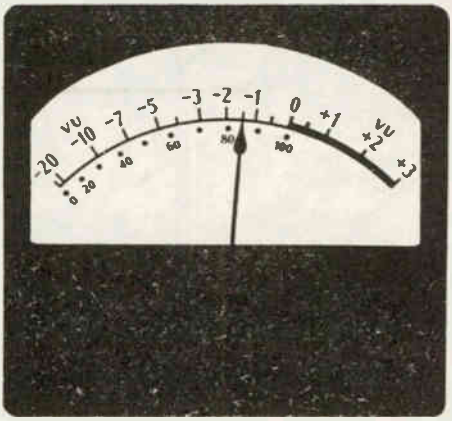

FIG. 31. A typical VU meter.

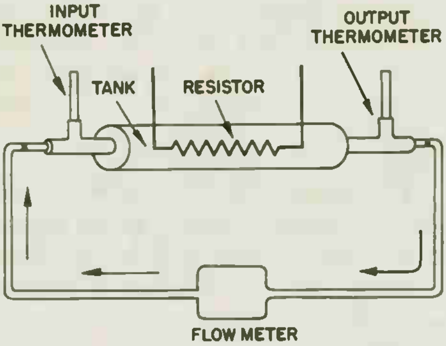

FIG. 32. How rf power can be measured without producing radiation.

RF POWER MEASUREMENTS

The radio frequency power output of a transmitter can be measured without actually producing radiation as shown in Fig. 32. Here a dummy load resistor is connected to the output circuit of the transmitter. This resistor is in a tank through which water is circulated to absorb the heat developed in the resistor. The water also goes through a flow meter that shows how much water flows through the unit in a given length of time. There are also thermometers that indicate the temperature of the water at the input and at the output of the tank.

Charts are provided with this type of measuring equipment so that you can calculate the power from the two temperatures and the water flow. This is called the calorimeter method of measuring power.

LOOKING AHEAD

In this lesson you have studied the three basic types of meters and learned how they can be used to measure current, voltage, resistance, and power. In later lessons you will learn about other types of instruments that use vacuum tubes in their circuits.

It is very important for you to understand how to use test equipment, because it is of little value unless you do.

Lesson Questions

Be sure to number your Answer Sheet 22CC.

Place your Student Number on *every* Answer Sheet.

Most students want to know their grade as soon as possible, so they mail their set of answers immediately. Others, knowing they will finish the next lesson within a few days, send in two sets of answers at a time. Either practice is acceptable to us. However, don't hold your answers too long; you may lose them. Don't hold answers to send in more than two sets at a time or you may run out of lessons before new ones can reach you.

1. What type of meter is generally used for dc measurements?
2. Give two reasons why the moving vane meter is not as widely used as the d'Arsonval meter.
3. Determine the resistance of the shunt needed to convert a 1-ma meter with a resistance of 100 ohms to a 5-ma meter.
4. If two ammeters connected in series with the same load, each indicate a current of 8 amps, what is the current flowing in the circuit?
5. What size multiplier resistor would you need to convert a 1-ma meter to a voltmeter with a full-scale voltage of 50 volts?
6. Find the sensitivity in ohms per volt of a voltmeter which uses a 10-microampere meter.
7. Why is a voltmeter with a high ohms-per-volt sensitivity more useful than one with a low sensitivity?
8. If the reading on a 50-volt voltmeter connected across a circuit is half-scale, indicating a voltage of 25 volts, and the meter sensitivity is 1000 ohms per volt, what is the total resistance of the meter and its multiplier?
9. Draw a schematic diagram of a series-connected ohmmeter.
10. If in a dc circuit a voltmeter connected across the load indicates 45 volts and an ammeter in series with the load indicates 7 amps, what is the power in the load?

THE VALUE OF REVIEW

Man has acquired so much new knowledge in recent years that it has become impossible for one person to know everything available about even a limited subject. Educational authorities realize this fact, and the colleges of today consider a man well-educated if he knows the elementary ideas *and knows where to find other information when he wants it.*

The field of radio and television has outgrown the memorizing ability of the human mind. Also, it is such a comprehensive field that occasionally you cannot recall important facts previously studied. Review is obviously needed.

Time spent in review several weeks or months after a book is studied will be far more profitable than an equivalent amount of extra time spent on the book initially, for your mind has then had a chance to file and store away the information secured from the first study. Each review results in more information being transferred from the textbook to your mind, and soon, with no conscious attempt to memorize, you will find yourself able to recall an amazing number of valuable facts.

NATIONAL RADIO INSTITUTE • WASHINGTON, D. C.

ATTENUATORS, FILTERS, AND EQUALIZERS

29CC

STUDY SCHEDULE NO. 29

☐ 1. **Introduction** . . . . **Pages 1-2**

The differences between attenuators, filters, and equalizers are discussed.

☐ 2. **Impedance-Matching and Power Transfer** . . . . **Pages 2-6**

We take up methods of measuring power, and then go into impedance-matching.

☐ 3. **Resistive Pads and Attenuators** . . . . **Pages 6-21**

Here we take up simple attenuators, and symmetrical and non-symmetrical attenuators.

☐ 4. **Equalizers** . . . . **Pages 21-29**

You study line equalizers, pickup equalizers, and tape-system equalizers.

☐ 5. **Filters** . . . . **Pages 29-44**

We take up different types of filter circuits, and then go into filter design.

☐ 6. **Answer Lesson Questions.**

☐ 7. **Start Studying the Next Lesson.**

ATTENUATORS, FILTERS, AND EQUALIZERS

ATTENUATORS, filters, and equalizers are all basically classified as networks. A network is an arrangement of electronic components, usually resistances or reactances, designed to provide some special effect. Actually, every electronic circuit is a network of some sort. However, when an engineer or technician speaks of a network, he is usually referring to some special group of components within a circuit. Such a network might be anything from a simple arrangement of resistors used for impedance matching to a complex group of reactances providing frequency selection.

Networks of this sort will be found in every field of electronics. They provide an efficient method of controlling signal strength, noise reduction, and phase shift. They can select one particular control signal from a number of signals being transmitted simultaneously over the same control line. In fact, some type of special network will be found in all but the very simplest of circuits.

Networks can be classified into three general types: attenuators, equalizers, and filters.

Attenuators. An attenuator is a network consisting of pure resistance; its operation is independent of the frequency or the phase of the signal. Its effect on all signals is the same at all frequencies.

Filters. A filter is frequency-selective. A filter always contains reactances of some sort, and will respond to different frequencies in different ways. In addition, a filter will usually shift the phase of the signal in some way. By using the proper values of circuit components and arranging them in special ways, we can make networks that will have almost any desired effect on the signal as it passes through the circuit from the supply to the load. Filters are used in electronic equipment to pass certain frequencies and reject others. They are broadband devices in that they tend to respond to a certain band of frequencies rather than to a specific frequency.

Equalizers. Equalizers are used to correct for any undesired frequency discrimination or phase shift in other equipment or in connecting cables.

If these networks were perfect, each would do only the job it is intended to do. An attenuator would simply change the amplitude of the signal. A filter would pass a certain band of frequencies and reject all outside of this band. An equalizer would correct any undesired phase shift or frequency discrimination. Actually, leakage and stray capacitance cause each to do a little of all three. Although, in this lesson, we may speak of one of these networks as if it did its job and its job alone, you should remember that a certain proportion of undesired effects is unavoidable. The secret of successful design lies in holding these effects to a minimum. At video and rf frequencies, good shielding and the proper layout of the parts will help to prevent trouble caused by leakage. At audio frequencies, the coupling between the cores of the coils, and the coil resistance may become problems.

In earlier lessons, we learned about some of the simpler types of networks. These consisted of voltage dividers, power-supply filters, tuning circuits, and vacuum-tube coupling circuits. In this lesson, we will look at some of the more complex networks. We will learn to recognize some of the basic network configurations and their effect on a signal. We will discuss the advantages and disadvantages of the various filters and problems in designing practical filter circuits.

First, let's see what problems are involved in impedance-matching and power transfer.

Impedance-Matching and Power Transfer

In setting up and adjusting electronic equipment, impedance-matching between stages and efficient transfer of power from one stage to another or to an antenna are important problems. We can tell how effectively these problems have been solved by measuring either the signal power or the signal voltage at the input or output of the two stages and comparing the two values to see if there has been a gain or a loss.

UNITS OF MEASURE

In an earlier lesson, you learned about the unit of measurement called the decibel and how it is used to express the ratio between input and output power. You also learned that voltage ratios can be expressed in decibels, but only when the impedances across which the two voltage measurements are taken are equal.

There is another unit of measurement which you will run into from time to time called the "neper." This unit originated in Europe and differs from the decibel in that it is based upon a different system of logarithms. In computing decibels, we use the system of common logarithms, with the base 10. In computing nepers, the system used is known as the natural logarithm system in which the base is an odd number, 2.71828. One neper equals 8.686 db, and 1 db equals .1151 neper. This unit is not widely used in the United States, but you will find it in some textbooks and reference material.

POWER MEASUREMENTS

Decibel Meters. Decibel meters have been used to read the power in the line directly in db. These are ac voltmeters calibrated in db units, with the zero-power-level indication at about center scale. They are de-

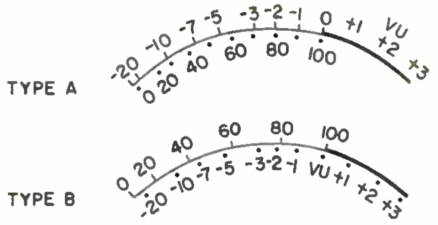

FIG. 1. Two types of VU meter scales.

signed to be connected across a specific value of impedance. Not all db meters have the same scale markings, damping, or zero levels. In the past, different services have used different values as the standard line-impedance across which the db meter is to be connected and have used different power levels as the zero reference level. Some have used .006-watt as the reference point, some .0125-watt, and others .001-watt. Some have used 500 ohms and some 600 ohms as standard line impedances.

When using a meter of this type, if the power in the line is more than the reference value, it produces a higher voltage across the line, and the meter reads to the right of the zero mark, showing a plus db reading. If the power is less than the reference value, the voltage is less, and the needle moves to less than center scale, indicating a minus db reading.

VU Meters. Since 1940, a standard type of power-level meter has been used in broadcast work and in many other audio applications. This is an ac volt-meter of the rectifier type called the volume unit or VU meter. Unlike db meters, all VU meters are built with identical characteristics. They are calibrated to read relative power levels when connected across a 600-ohm impedance line. The zero-reference level used is .001 watt (1 milliwatt). The VU meter is essentially a peak-reading meter, since with a relatively rapid pulse or steep wave, these meters rise to about 99% of the peak value very quickly, but fall off slowly.

VU meter scales are calibrated in plus or minus VU, and zero to 100% modulation. Two different types of VU meter scales are shown in Fig. 1.

The VU meter is designed to operate with a 3600-ohm external resistor as shown in Fig. 2. When the meter is connected across the line, it "sees" the 600-ohm source and load impedances in parallel. Thus, the impedance into which the meter is "looking" is 300 ohms. Since the meter has an impedance of 3900 ohms, an external 3600-ohm resistor is connected in series with the 300-ohm resistance of the parallel-connected source and load to match this impedance to that of the meter.

The resistor is not made an integral part of the meter because it may be

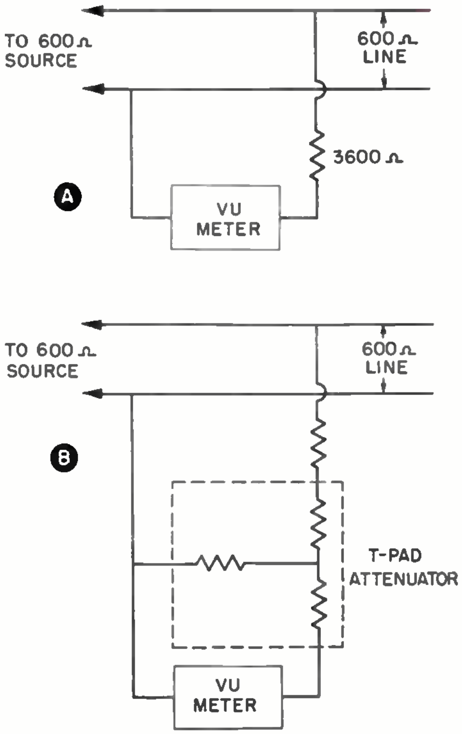

FIG. 2. A VU meter connected across a 600-ohm line is shown at A; a T-pad attenuator is added at B.

necessary to insert a T-pad attenuator in the meter circuit as shown in Fig. 2B. In broadcast work, a reading of zero VU or 100 on the percentage scale indicates 100% modulation. If the power required for 100% modulation is greater than the one milliwatt zero reference level, the meter would, of course, read farther upscale, and an attenuator called a T-pad is needed to make the meter indicate the correct percentage of modulation. Also, in some applications, the power in the line may be greater than the +3 VU at the high end of the meter scale. In these cases, a T-pad is needed to keep the meter from reading off-scale. Of course, in a case such as this, the loss introduced by the pad must be mentally added to the meter reading.

LOAD MATCHING

One of the most important considerations in the study of electronics is the transfer or transmission of power. In fact, the transmission and/or control of energy in the form of electrical power is the only purpose of any electronic system.

Let's look at some of the factors which affect this. In Fig. 3, we have shown a power source that develops an emf of 40 volts. Any source of power (generator, battery, or oscillator) has a certain amount of internal impedance, which consists of the distributed resistance, capacitance, and inductance in the source. We have assumed that our power source (let's call it a generator) has an internal impedance of 50Ω and have shown this as Z_I.

It is easy to see that the terminal voltage, E_T, is going to be equal to the emf minus the voltage across the internal impedance Z_I. The value of the voltage drop across Z_I will depend on the current flowing in the circuit as well as the value of Z_I, so the terminal voltage will vary with the current as long as the emf and Z_I remain constant. If the circuit is broken at the switch, no current will flow, there will be no voltage drop across Z_I, and E_T will be 40 volts. Now let's connect our generator to a load and see what happens.

If the selector switch is at A as shown, we will have a circuit consisting of Z_I which is equal to 50 ohms in series with Z_A, which is equal to 30 ohms. This gives us a total impedance of 80 ohms being supplied by our 40-volt emf. Through Ohm's Law ($I = E \div R$) we can determine that a current of .5 amp will flow in the circuit.

This means that we will have a voltage drop of 25 volts across Z_I, and a drop of 15 volts across Z_A. Therefore, although our power supply is actually generating 40 volts, 25 volts are dropped internally, and we have a terminal voltage, E_T, of only 15 volts.

If we look at the circuit from a power standpoint, we find that a total of

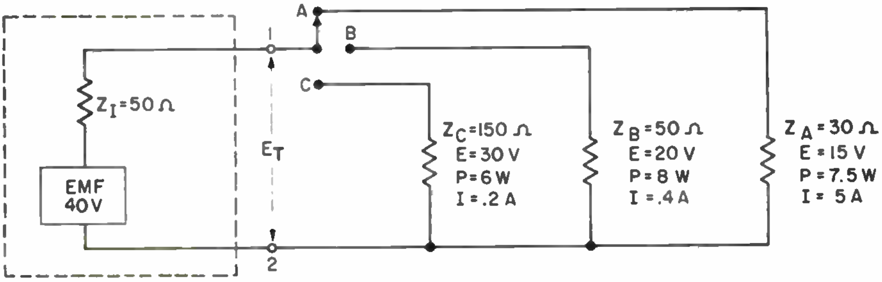

FIG. 3. Effect of load on power generation and transfer.

20 watts (40-volt emf x .5 amp) is developed by the power supply. However, 12.5 watts of this power (25 volts E_{Z1} x .5 amp) is wasted internally and only 7.5 watts is actually used by the load. This is obviously a very inefficient situation. If we have a load which consumes only 7.5 watts, it is a waste of equipment and energy to develop 20 watts to supply it.

Let's move the selector switch to Position B and see what effect a 50-ohm resistance has in our circuit. Now, our 40-volt emf will be feeding a total resistance of 100 ohms, and our circuit current will be .4 amp. We will have 20 volts dropped internally, leaving our terminal voltage at 20 volts. The total power developed will be 16 watts, and half of it, or 8 watts, will be consumed by the load. The other half will be wasted internally.

This is an improvement over the first circuit. First of all, we are developing a total power of only 16 watts, and we are getting 8 watts of this to our load. Thus, we have much better efficiency since we are wasting only 8 watts internally.

We actually have more power available in our external circuit with less total power generated. Notice that in this circuit the impedance of the load equals the impedance of the source; we say that they are "matched." Now, let's see if we can improve this still further by moving the selector switch to Position C.

In this position, the total impedance is 200 ohms, and the current will be .2 amp. The terminal voltage will be 30 volts, and the internal drop will be only 10 volts. The total power developed by the generator is only 8 watts. Of this, 6 watts is delivered to the load, while only 2 watts is wasted internally. Also, the voltage across the load has been increased. We have a much more efficient situation than we had before because we are wasting only 2 watts out of 8. However, we are delivering less power to the load than we were with circuit B when the load and source impedances were matched.

Thus, it is easy to see that a situation where the load impedance is much less than the source is always very inefficient and doesn't give much useful power. We can also see that we have the most power delivered to the load when the impedances are matched, but we do waste half of the power in the process. Further, the greatest efficiency exists when the load impedance is much larger than the source impedance although the actual power delivered to the load is less than when we have matched impedances. It is obvious that we will usually avoid having the load impedance less than the source impedance.

However, when it comes to a choice of having either maximum power with matched impedances or high efficiency with proper mismatching, we have to consider the specific application. For example, consider the circuit shown in Fig 4A, where the impedances are mismatched. If a large amount of power is required to operate the 450-ohm load, efficiency will be the most important. Let's assume that we have a large power requirement and the emf of the power source equals 10 kv. At 10 kv, 20 amperes of current will flow to the load, and a total power of 200 kw will be developed. Of this 200 kw, 20 kw will be wasted internally and 180 kw will be consumed in the load.

In the circuit of Fig. 4B we have shown the same load, but have matched the impedances. Notice that we have not shown the impedance matching system, but have just represented it by changing the value of the load resistance. In this circuit we would get more power to the load but the energy wasted would be tremendous. Our 10 kv emf would give 100 amps of current and the total power

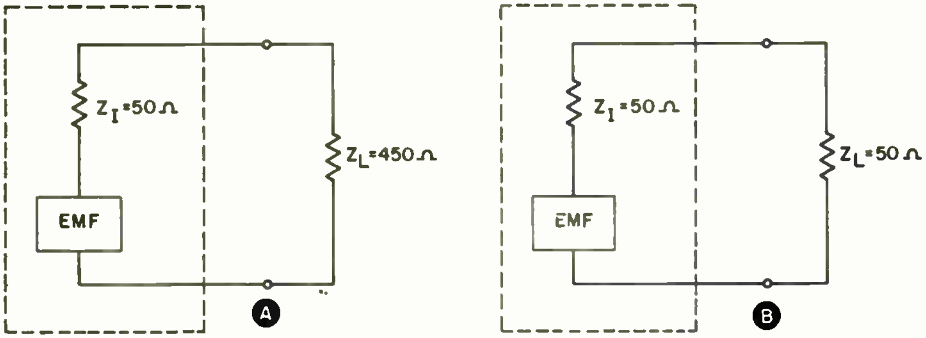

FIG. 4. Greatest efficiency with mismatched impedances, A; greatest power transfer with matched impedances, B.

developed would be 1000 kw. Of this, 500 kw would be wasted internally and 500 kw would be consumed by the load. Although we would have 320 kw more power available to do work than we had available with the mismatched impedances in Fig. 4A, we would waste 480 kw more in order to get it. The cost of producing this extra wasted energy would make it impractical to match impedances. In addition, the cost of equipment capable of handling 100 amperes of current would be much greater than that needed to handle 20 amperes. Thus, impedance matching becomes too expensive to be practical when large amounts of power must be handled.

In communications and control circuits, however, extremely small amounts of power are used, and power waste is not so expensive. Here, the important consideration is getting enough of the available power to the load for the equipment to operate properly. Often the available power is so low that unless the maximum amount is transferred to the load, the equipment will operate poorly or not at all.

For example, a speaker or speaker system must be matched to the output of the amplifier or it may not receive sufficient energy to operate properly. Similarly, a microphone must be matched to the input circuit of an amplifier or the losses will be severe.

Now that we have seen the problems involved in transferring power, let's look at the networks used to do so.

Resistive Pads and Attenuators

Resistive pads and attenuators are used to reduce or control signal levels, to match impedances, and to reduce the inductive effect of transformers coupled together through a line. Usually, they are used to reduce signal levels, to match impedances, or both.

SIMPLE ATTENUATORS

To see how an attenuator can introduce a loss without causing an impedance mismatch, it is best to examine some simple circuits. In Fig. 5A, we have a power source having a constant emf of 40 volts and an internal impedance of 50 ohms supplying power to a resistive load of 50 ohms. The load and source are matched and the power delivered to the load is 8 watts.

Suppose we want to reduce the power delivered to the load from 8 watts to 4 watts. We can do this by inserting a 43-ohm resistor in series with the load as shown in Fig. 5B. This makes a total impedance in the circuit of 143 ohms (50+50+43). The current is then .28 ampere (40÷143) and the voltage across the load is 14 volts (.28 x 50). This means the power delivered to the load is 4 watts (.28 x .28 x 50).

We can also reduce the power to 4 watts by adding a 58-ohm resistor in parallel with the load as shown in Fig. 5C. The impedance of the parallel combination will be 27 ohms, and the total impedance in the circuit will be 77 ohms (50+27). The circuit current will be .52 ampere, dividing through the parallel combination so that .28 ampere flows through the load. The voltage across the source impedance will be 26 volts (50 x .52), leaving 14 volts across the parallel combination (40—26). This means the power delivered to the load will again be 4 watts (.28 x .28 x 50).

In each case, we have delivered 4 watts to the load. However, the impedance match is destroyed in both cases. With the series resistor, in Fig. 5B, the impedance looking into the external circuit from terminals 1 and 2 is now 93 ohms (43 ohms and 50 ohms in series). With the parallel resistor, in Fig. 5C, the impedance seen looking into the circuit from terminals 1 and 2 is 27 ohms (50 ohms and 58 ohms in parallel).

Now, let us see if we can reduce the power delivered to the load from 8 watts to 4 watts and still keep the load matched to the source. Look at Fig. 5D. Here we have a 116-ohm resistor in parallel with the load, giving us a total impedance of 35 ohms for the parallel part of the circuit, and a 15-ohm resistor in series with the 35 ohms offered by the parallel combination. Now, the total impedance of the combination is 50 ohms, the total imped-

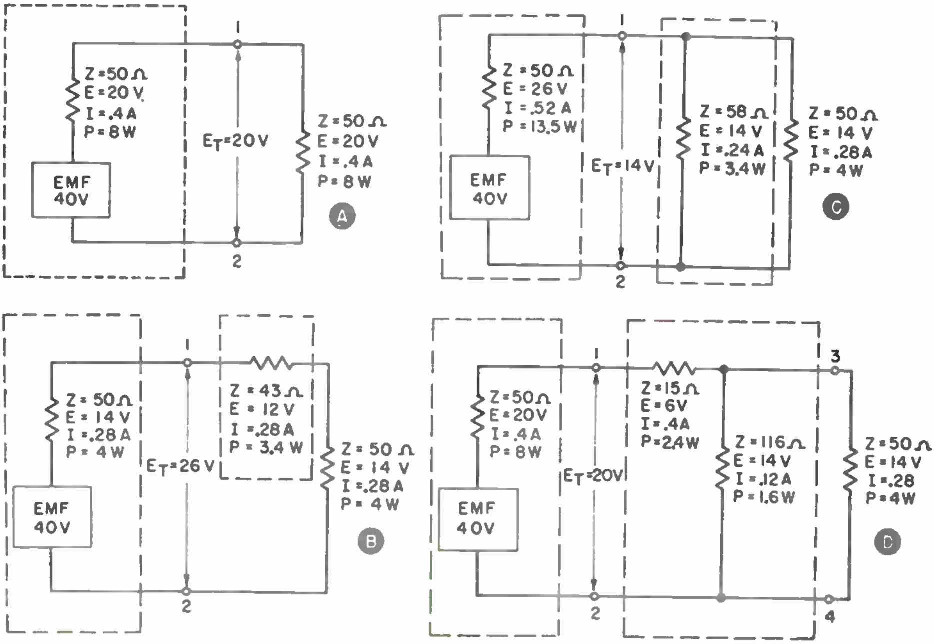

FIG. 5. Effect of dropping resistor on impedance match.

ance in the circuit is 100 ohms (50+50) as in Fig. 5A. The voltage across the load will be 14 volts, the current through it will be .28 ampere, and the power to it will be 4 watts. The total impedance as seen looking into terminals 1 and 2 is still 50 ohms. Thus, the load is still matched to the source even though the power in the load has been reduced to 4 watts.

A simple attenuator such as this that consists of one series resistance and one parallel resistance such as those we have been discussing is called an L pad.

The L Pad. Although the L pad is a definite improvement over a single resistance, it has one major disadvantage. This is the fact that it is unsymmetrical. In other words, it does not have the same impedance at both ends.

Up until now, this has not concerned us because we have been concerned only with matching a load to a source. However, in a perfect impedance match this is not enough. We do not have a perfect match unless the source sees exactly the same impedance looking towards the load as the load will see looking back toward the source.

Looking at the circuits shown in Fig. 6, you will see what we mean by this. In Fig. 6A, when the source looks into the circuit it sees an impedance of 50 ohms. In addition, if we look back into the circuit from the load we also see an impedance of 50 ohms. This is considered to be a perfect impedance match because the load sees exactly the same impedance looking toward the source as the source sees looking toward the load.

Now, let's put an L pad in the circuit as shown in Fig. 6B and see what we have. First, let's look into the circuit toward the load from terminals 1 and 2. Doing this, we see an impedance of 25 ohms in series with the parallel branch containing two 50-ohm resistors, whose combined resistance is 25 ohms. This gives us a total impedance of 50 ohms, which is equal to the source impedance, and we say that the load is matched to the source.

However, if we look back into the circuit towards the source from terminals 3 and 4, we do not see the same impedance. Now, we see an impedance of 50 ohms in parallel with an impedance of 75 ohms. This is a combined impedance of 30 ohms and does not equal the load impedance of 50 ohms. Thus, our L pad matches the load to the source, but does not match the source to the load.

Since an L pad is unsymmetrical, it cannot be used to provide a perfect impedance match between two equal impedances. However, it is often used to provide a match for two unequal impedances. Fig. 7 shows a circuit where a 50-ohm load and a 70-ohm

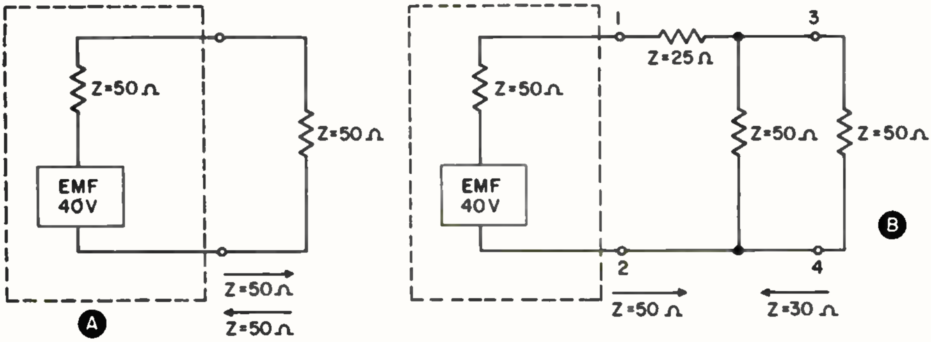

FIG. 6. Effect of unsymmetrical section on impedance match.

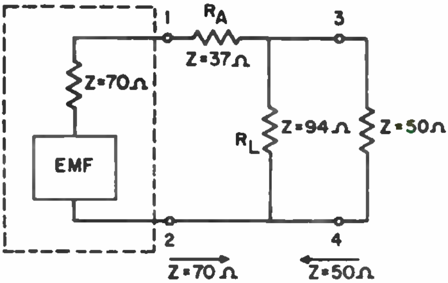

FIG. 7. Using L pad to match unequal impedances.

source have been matched by using an L pad.

Looking into the load from terminals 1 and 2, we see an impedance of approximately 70 ohms (37 ohms in series with the parallel combination of 94 ohms and 50 ohms). Looking back toward the load from the terminals 3 and 4, we see an impedance of almost exactly 50 ohms (94 ohms in parallel with the series combination of 70 and 37 ohms). Of course, the L pad always introduces a loss in the circuit and is not used to match impedance unless the loss can be tolerated or is actually desirable.

Minimum-Loss Matching Pads. By using two fairly simple formulas, we can compute the resistances for an impedance-matching L pad that will introduce the smallest possible loss. To find the value of the series or arm resistance of the pad, we use the following formula:

$$R_A = Z_I\sqrt{1 - \frac{Z_O}{Z_I}}$$

In this formula, R_A = arm resistance; Z_I = source or input impedance; and Z_O = load or output impedance.

To find the value of the parallel or leg resistor, we use the formula:

$$R_L = \frac{Z_O}{\sqrt{1 - \frac{Z_O}{Z_I}}}$$

Here, R_L = leg resistor, Z_I = source or input impedance, and Z_O = load or output impedance as before.

Let's use these two formulas to see if the L pad we used in Fig. 7 provides the smallest possible loss. In this circuit, our input impedance is 70 ohms and the output impedance is 50 ohms. Substituting these values in the formula for obtaining the arm resistance, we get:

$$R_A = Z_I\sqrt{1 - \frac{Z_O}{Z_I}}$$

$$= 70\sqrt{1 - \frac{50}{70}}$$

$$= 70\sqrt{1 - .72}$$

$$= 70\sqrt{.28}$$

$$= 70 \times .53$$

$$= 37\ \Omega$$

From this, we can see that the 37-ohm arm resistance which we used in the circuit is correct for the arm value of a minimum-loss pad.

To find the correct leg value, we substitute our 70-ohm input impedance, and our 50-ohm output impedance in the formula for finding R_L:

$$R_L = \frac{Z_O}{\sqrt{1 - \frac{Z_O}{Z_I}}}$$

$$= \frac{50}{\sqrt{1 - \frac{50}{70}}}$$

$$= \frac{50}{\sqrt{1 - .71}}$$

$$= \frac{50}{\sqrt{.29}}$$

$$= \frac{50}{.54}$$

$$= 92.5\ \Omega$$

This is equal to the leg resistor that we used in the circuit, so we know that the L pad used in Fig. 7 not only matches impedances, but it also introduces the least possible loss for a matching pad. Remember, the two formulas given here are used only to determine the values of resistance for use in a minimum-loss matching pad.

If we are going to design an impedance-matching pad, we will also be interested in knowing just how much attenuation will be introduced by our minimum-loss pad. So far in our discussion of impedance matching and attenuation, we have compared the power delivered to the load with the total power developed by our source. To do this, we have completely analyzed each circuit component as to impedance, voltage, current, and power so that you could actually see what happened to the power and where and why it happened. The amount of the losses provided by our attenuator was rated in watts. Although this is a good approach for purposes of analysis, there is a much simpler way of evaluating attenuation.

Since attenuators are so much a part of communications systems where the decibel is commonly used to express performance, it is logical that the decibel has come to be used as a measure of attenuation. Actually, the decibel is a very convenient unit for use with attenuators because we are concerned with power ratios. As we learned in an earlier lesson, the amount of change in decibels in a circuit is equal to 10 times the logarithm of the ratio of the input power and the output power. Thus, the attenuation or loss in a circuit in decibels can be found with the formula:

$$\text{db} = 10 \log \frac{P_I}{P_O}$$

This formula can be applied to any attenuator quite easily when the power in the circuit is known. However, instead of computing the necessary circuit values to obtain the power ratios in Fig. 7, we can use a more direct formula. This formula uses the input and output impedances directly, and can be used to determine the attenuation in decibels that will be introduced by any minimum-loss pad. In this formula, the loss in decibels equals:

$$\text{db} = 10 \log \left(\sqrt{\frac{Z_I}{Z_O}} + \sqrt{\frac{Z_I}{Z_O} - 1} \right)^2,$$

where Z_I = input impedance and Z_O = output impedance.

Let's apply this to the circuit in Fig. 7 to see how much attenuation our minimum-loss pad will introduce. Substituting in the equation, we have:

$$\begin{aligned}
\text{db} &= 10 \log \left(\sqrt{\frac{70}{50}} + \sqrt{\frac{70}{50} - 1} \right)^2 \\
&= 10 \log (\sqrt{1.4} + \sqrt{1.4 - 1})^2 \\
&= 10 \log (\sqrt{1.4} + \sqrt{.4})^2 \\
&= 10 \log (1.18 + .63)^2 \\
&= 10 \log (1.81)^2 \\
&= 10 \log 3.27 \\
&= 10 \times .5145 \\
&= 5.1 \text{ db loss}
\end{aligned}$$

Thus, the minimum loss possible in an impedance-matching pad for the circuit shown in Fig. 7 is 5.1 db. We have already discovered the proper values of arm and leg resistance for this pad.

SYMMETRICAL PADS

Symmetrical attenuators are similar to L pads except that they have either an extra series arm or an extra leg resistor.

The T Pad. Fig. 8 shows one of the most common types of symmetrical attenuators. This type of attenuator is usually called a T pad because the component resistors are arranged in the schematic so that they form the letter T.

As you can see, the impedances are perfectly matched because the load sees the same impedance looking towards the source from terminals 3 and 4 as the source sees looking into the load from terminals 1 and 2.

T pads can be designed to introduce any desired amount of attenuation. Let's use the circuit shown in Fig. 8 as an example and see what values we need in the T pad. First of all, the power input is 40 watts, and we want a power output of only 1 watt. Using our formula we find that:

$$\text{db} = 10 \log \frac{P_I}{P_O}$$

$$= 10 \log \frac{40}{1}$$

$$= 10 \log 40$$

$$= 10 \times 1.6021$$

$$= 16 \text{ db}$$

Now we must find the reduction factor K from the following formula:

$$K = \log^{-1} \frac{\text{db}}{20}$$

The symbol "$\log^{-1}$" is called an antilog, which means that our answer will be the number whose logarithm is $\frac{\text{db}}{20}$. Substituting our desired attenuation of 16 decibels in the formula, we find:

$$K = \log^{-1} \frac{16}{20} = \log^{-1} .8$$

Now from our log tables, we find that the number which has .8 for a logarithm is 6.31. Thus, our reduction factor K equals 6.31.

Next, we use the reduction factor K in two formulas. The first one will give us a multiplying factor for the arms, and the second will give us a multiplying factor for the leg. Multiplying these by either the source or the load impedance will give us the values for the arm and leg resistors.

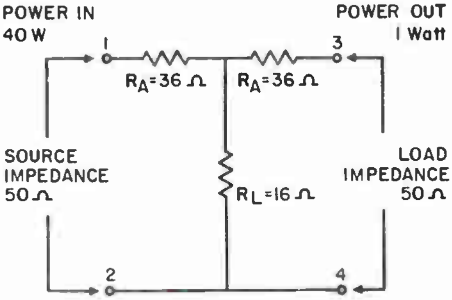

FIG. 8. T pad providing 16-db attenuation.

The formula for the arm factor is:

$$A = \frac{K - 1}{K + 1}$$

Substituting the value of K, which is 6.31 in this formula, we get:

$$A = \frac{6.31 - 1}{6.31 + 1}$$

$$= \frac{5.31}{7.31} = .72$$

Now, by multiplying our 50-ohm impedance by the arm factor A, we find the value of the arm resistors:

$$R_A = AZ = .72 \times 50 = 36\ \Omega$$

Thus, both arm resistors of the T pad must be equal to 36 ohms to give us an attenuation of 16 decibels while maintaining an impedance match between a 50-ohm source and a 50-ohm load.

The formula for the leg factor is:

$$L = \frac{2K}{K^2 - 1}$$

$$= \frac{2 \times 6.31}{6.31^2 - 1}$$

$$= \frac{12.62}{39.8 - 1}$$

$$= \frac{12.62}{38.8}$$

$$= .325$$

Our leg resistor equals:

$$R_L = LZ$$

$$= .325 \times 50$$

$$= 16\ \Omega$$

The resistance values for any T pad giving any desired value of attenuation between two equal impedances may be obtained using these formulas. Because of their importance in attenuator design, we will list them again.

Attenuation in db: $\text{db} = 10 \log \frac{P_I}{P_O}$

Reduction factor K: $K = \log^{-1} \frac{\text{db}}{20}$

Arm factor A: $A = \frac{K - 1}{K + 1}$

Leg factor L: $L = \frac{2K}{K^2 - 1}$

Arm resistors R_A: $R_A = AZ$

Leg resistor R_L: $R_L = LZ$

For convenience in designing attenuators, the multiplying factors for many different values of attenuation have been worked out in the form of tables. Although these tables do not give the values for arm and leg factors for all possible values of attenuation, they are very handy for designing most attenuators. These tables can be found in many reference books.

Attenuation db	Arm factor A	Leg factor L
0	0	∞
1	0.061	8.07
2	.115	4.27
3	.173	2.78
4	.227	2.07
5	.280	1.64
6	.333	1.33
7	.382	1.11
8	.432	0.942
9	.476	.812
10	.520	.700
20	.818	.202
30	.939	.0632
40	.980	.0200

FIG. 9. Table of multiplying factors for the design of any T pad.

A typical example giving the attenuation in decibels and the arm and leg factors is shown in Fig. 9. To use the table, we simply look down the attenuation column until we find the desired loss value. Then we follow across the table to find the arm factor and the leg factor to use with the impedance of our particular circuit in order to compute our arm and leg resistance values.

The π Pad. Another type of symmetrical attenuator is shown in Fig. 10. This is call a pi pad because the component resistances are arranged like the Greek letter π. The π pad in Fig. 10 is like the T pad shown in Fig. 8 in that it has an attenuation loss of 16 db and 50-ohm input and output impedance.

Since the pi pad and the T pad have identical behavior, we can expect a definite numerical relationship between them. We can, for example, set up a pi network like the one shown in Fig. 10 and determine the various resistance values by using the A and L factors that we derived while designing our T network. However, we must use them in a different way, as you will see.

The resistance of the arm of the pi pad is equal to the impedance Z divided by the T pad leg factor L. Similarly, each leg of the pi pad is equal to the impedance Z divided by the T pad arm factor A. In equation form these are:

$$\pi \text{ pad: } R_A = Z/L$$

$$\pi \text{ pad: } R_L = Z/A$$

It should be noted that the factors A and L are exactly the same as those used for the T pad design and are computed the same as before. However, in the pi pad the factors are used for division instead of multiplication, and L is used to find R_A, and A is used to find R_L.

Now let's compute the resistance values of the pi pad components shown in Fig. 10. Our desired attenuation is 16 db, and the source and load impedances are 50 ohms. This is the same requirement that we had in the circuit shown in Fig. 8, so we can use the same A and L factors that we previously computed. For our pi-pad arm, we use the formula:

$$R_A = Z/L$$

$$= \frac{50}{.325} = 154\ \Omega$$

Our leg resistors are found from the formula:

$$R_L = Z/A$$

$$= \frac{50}{.72}$$

$$= 70\ \Omega$$

Thus, our two legs must be 70 ohms, and our arm 154 ohms to provide the same effect with a pi pad as we had with the T pad shown in Fig. 8.

The table shown in Fig. 9 can also be used to construct pi pads. Just remember to divide the impedance by A to find R_L and by L to find R_A. In ordinary use, there is no preference between a T pad and a pi pad. These networks are interchangeable and the type of pad used is a matter of personal choice. Usually, the choice will depend upon the values of resistors that can be obtained easily.

Ganged Attenuator Pads. The input impedance of a symmetrical pad is equal to its output impedance. Thus the input of one pad can be used as the load resistance for a preceding pad. This can be kept up a great number of times and the total attenuation of the pads in tandem will be equal to the sum of the individual pad losses.

Thus, if we have three 50-ohm to 50-ohm pads (symmetrical), giving re-

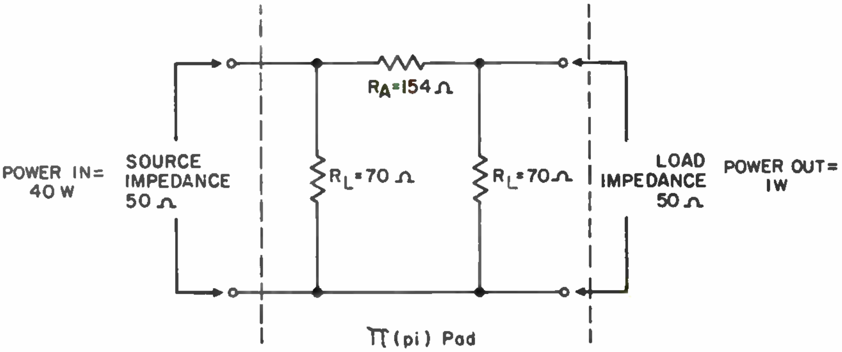

FIG. 10. Pi-pad attenuator (db = 16).

spectively 5, 8, and 4 db attenuation, we can connect these in any order and the whole combination will have an input impedance of 50 ohms. The attenuation will be 5 + 8 + 4 = 17 db when used with a 50-ohm load.

This is a very convenient feature of symmetrical pads, for it means that a great number of attenuation values can be realized with combinations of relatively few separate attenuators. Usually, if an attenuation of over 20 decibels is desired, it is better to obtain it by using two or more attenuators than by using one large-loss attenuator.

Balanced Attenuator Pads. All of the attenuator pads discussed so far have been designed for use with unbalanced lines which have one wire grounded. With balanced lines, where the wires are maintained at opposite potentials with respect to ground, these attenuators would not be suitable. The stray attenuator capacitance would upset the line balance and tend to increase noise pickup and cross talk.

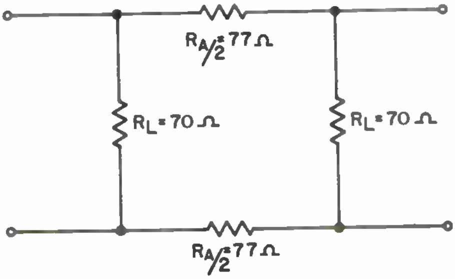

FIG. 11. Balanced pi pad—sometimes called an O pad.

The T and pi pads, however, can be balanced very easily. This is accomplished merely by splitting the series resistance arms in half, and inserting half of the resistance in the upper side of the line and the other half in the lower side of the line. Thus, the pi pad in Fig. 10 becomes the balanced pi pad shown in Fig. 11. In the same manner, the T pad of Fig. 8 is changed to the balanced version in Fig. 12. The balanced pi pad is sometimes called an O pad and the balanced T pad is sometimes called an H pad, because of their resemblance to these letters.

UNSYMMETRICAL PADS

In addition to being used to provide attenuation between equal impedances, T, H, pi, and O pads can also be used as attenuators between unequal impedances. When used in this way, they are designed to match the unequal impedances as well as provide attenuation. We have already studied one type of impedance-matching pad, which we called a minimum-loss L pad. However, the purpose of the L pad was to provide a minimum-loss matching network, and the attenuation it offered had to be considered because it was unavoidable, although undesirable.

The purpose of the networks which we will study now is not only to match unequal impedances but also to provide more attenuation than that which would be provided by a minimum-loss pad. When we studied the L pad, we said it was unsymmetrical because it did not look the same from both ends. The T and pi pads, which are used to match unequal impedances, also look different from each end and are called unsymmetrical T or pi pads.

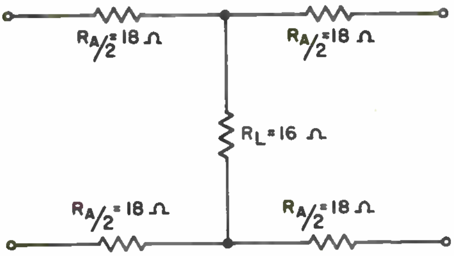

FIG. 12. Balanced T pad—sometimes called an H pad.

In studying the minimum-loss L-type matching pad, we learned that there will always be a certain amount of loss in a resistive matching pad. We also learned how to compute the amount of this minimum-loss in decibels and how to determine the proper resistance values. The minimum-loss L pad could also be considered as a modified T or π pad, as shown in Fig. 13A and B. Here we have shown the minimum-loss L pad as a T pad in which one of the arms has been reduced to zero. It can also be considered to be a pi pad in which one of the leg resistors has become so large it amounts to an open circuit, as shown in Fig. 13B.

From this, we can see that by introducing an extra arm or leg resistor of appropriate size, and changing the other resistance values, we can gain more attenuation and still maintain an impedance match. As soon as we do this, we will have changed our L-pad into an unsymmetrical T or pi pad. It should be noted that, although we can increase the attenuation above the minimum-loss and maintain an impedance match by using an unsymmetrical T or pi pad, we can never decrease the loss below the amount introduced by the minimum-loss L pad.

Therefore, one of the first things to do in designing an unsymmetrical attenuator is to determine the minimum possible loss. If this amount of attenuation is satisfactory, we will use an L pad as an attenuator. If we want more attenuation than the L pad will provide, we will design an unsymmetrical T or pi pad. However, if the minimum loss is more than we want, we will have to decide whether it is advisable to use an attenuator and an amplifier to match impedances or whether it is better to use some other method of matching impedances.

L-Pad Design. Before we go into the design of an unsymmetrical T or pi pad, there is one thing we should discuss regarding the minimum-loss L pad. When we considered the L pad earlier, we studied only left-handed pads like the one shown in Fig. 14A. In this circuit, the input impedance is larger than the output impedance and the arm resistor is in series with the input impedance. However, in a circuit like the one shown in Fig. 14B, the input impedance is smaller than the output impedance, and a right-handed L pad would have to be used.

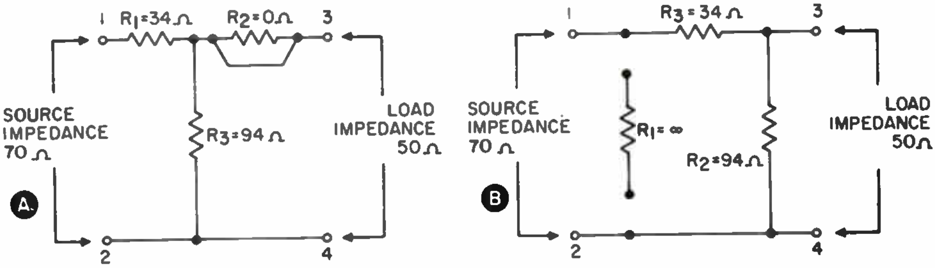

FIG. 13. The L pad can be considered as a modified T pad, as at A, or as a modified π pad, as at B.

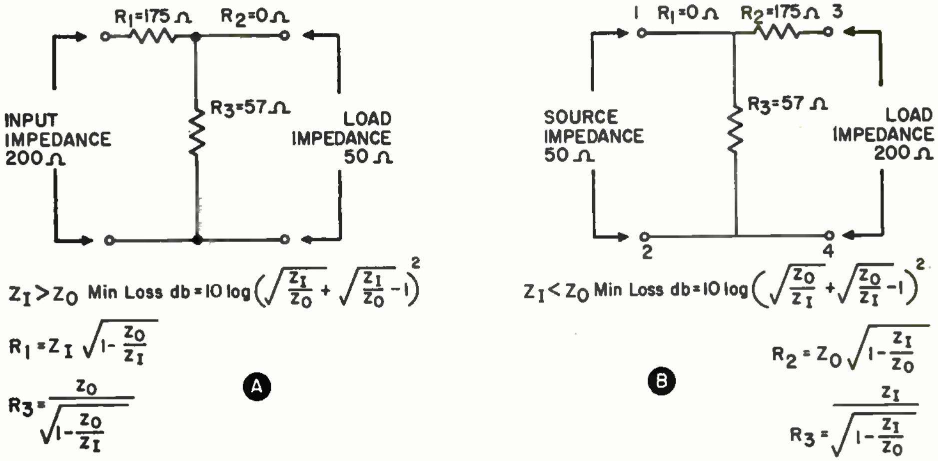

FIG. 14. Computing left-handed L pads, A; computing right-handed L pads, B.

The impedance values in the circuit shown in Fig. 14B are numerically the same, but reversed in position. The value of the arm resistor is the same as it was in a left-handed pad, but its position has changed. Because of this, our formulas for computing right-handed L pads are slightly different from those used in computing left-handed L pads. Also, the minimum loss in decibels will be figured a little differently. The formulas which we have already learned for computing left-handed L pads and their minimum loss are shown in Fig. 14A.

In a right-handed pad we compute for R2 and R3 instead of R1 and R3, and the formulas are slightly different. Now the positions of the output impedance and the input impedances in our formulas are just opposite what they were for the left-handed pads. You will also notice that the impedance relationships have been reversed in the minimum-loss formula.

Since computing the minimum loss is one of the first steps in designing any unsymmetrical attenuator network, this change in the minimum-loss formula is very important. As shown, when the input impedance, Z_I is greater than (>) the output impedance Z_O, the loss in decibels will be found from the following formula:

$$\text{Min. loss db} = 10 \log\left(\sqrt{\frac{Z_I}{Z_O}} + \sqrt{\frac{Z_I}{Z_O} - 1}\right)^2$$

However, when the input impedance Z_I is less than (<) the output impedance Z_O, the loss in decibels will be found from:

$$\text{Min. loss db} = 10 \log\left(\sqrt{\frac{Z_O}{Z_I}} + \sqrt{\frac{Z_O}{Z_I} - 1}\right)^2$$

Designing an unsymmetrical T or pi pad is simply using the proper formulas correctly. We will not attempt to show you how the formulas are derived, nor will you be expected to memorize them. The important thing is that you know how to use the formulas and where to find them when they are needed.

Unsymmetrical T or π Pads. The formulas for computing the resistance values of an unsymmetrical T pad are:

$$R_3 = \frac{2\sqrt{NZ_I\,Z_O}}{N - 1}$$

$$R_1 = Z_I\left(\frac{N + 1}{N - 1}\right) - R_3$$

$$R_2 = Z_O\left(\frac{N + 1}{N - 1}\right) - R_3$$

In the formulas, N is used to denote the power ratio: $P_I \div P_O$. We can find the value of N once we know our desired attenuation in decibels using the formula:

$$\text{db} = 10 \log \frac{P_I}{P_O}$$

Now let's use these formulas to compute an unsymmetrical T pad that will give us an attenuation of 15 db as shown in Fig. 15. The first thing we must do is determine whether or not an attenuation of 15 db with matched impedances is possible in this circuit. To do this, we compute the minimum possible loss for matched impedances. Since our input impedance is less than our output impedance, we use the formula:

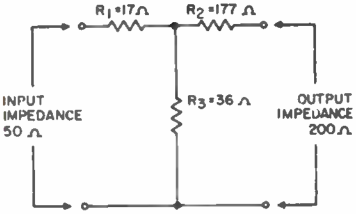

FIG. 15. Unsymmetrical T pad.

$$\text{Min. loss db} = 10 \log \left(\sqrt{\frac{Z_O}{Z_I}} + \sqrt{\frac{Z_O}{Z_I} - 1}\right)^2$$

$$= 10 \log \left(\sqrt{\frac{200}{50}} + \sqrt{\frac{200}{50} - 1}\right)^2$$

$$= 10 \log (\sqrt{4} + \sqrt{4 - 1})^2$$

$$= 10 \log (2 + \sqrt{3})^2$$

$$= 10 \log (2 + 1.73)^2$$

$$= 10 \log 3.73^2$$

$$= 10 \log 13.9$$

$$= 11.43 \text{ db}$$

Since our desired attenuation of 15 db is more than this minimum of 11.43 db, we know that it is possible to construct the desired attenuator.

Now, we must find the correct value of N to use. By substituting N in place of the power ratio in our formula:

$\text{db} = 10 \log \frac{P_I}{P_O}$ we get:

$$\text{db} = 10 \log N$$

$$15 = 10 \log N$$

$$\frac{15}{10} = \log N$$

$$1.5 = \log N$$

Checking our log tables, we find that 1.5 is the logarithm of 31.7, which we can round off to 32.

Now, using our formula for the leg resistor R_3, we find:

$$R_3 = \frac{2\sqrt{NZ_I Z_O}}{N - 1}$$

$$= \frac{2\sqrt{32 \times 50 \times 200}}{32 - 1}$$

$$= \frac{2\sqrt{32 \times 10{,}000}}{31}$$

$$= \frac{2 \times 100 \sqrt{32}}{31}$$

$$= \frac{200 \times 5.65}{31}$$

$$= \frac{1130}{31}$$

$$= 36\ \Omega$$

Next, our arm resistor R_1 is:

$$R_1 = Z_I \left(\frac{N + 1}{N - 1}\right) - R_3$$

$$= 50 \left(\frac{32 + 1}{32 - 1}\right) - 36$$

$$= \frac{1650}{31} - 36$$

$$= 53 - 36$$

$$= 17\ \Omega$$

And our other arm R_2 is:

$$R_2 = Z_O\left(\frac{N+1}{N-1}\right) - R_3$$

$$= 200\left(\frac{32+1}{32-1}\right) - 36$$

$$= 200 \times \frac{33}{31} - 36$$

$$= \frac{6600}{31} - 36$$

$$= 213 - 36 = 177\ \Omega$$

If we prefer, we can use a pi pad as shown in Fig. 16. The following formulas are for computing unsymmetrical pi pads.

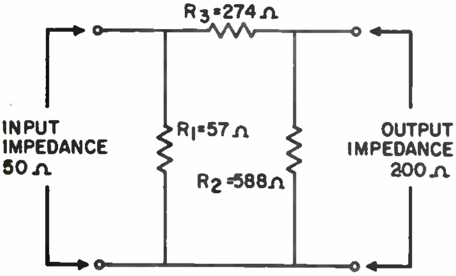

FIG. 16. Unsymmetrical pi pad.

The arm R_3 is:

$$R_3 = \frac{N-1}{2}\sqrt{\frac{Z_I\, Z_O}{N}}$$

$$= \frac{32-1}{2}\sqrt{\frac{50 \times 200}{32}}$$

$$= \frac{31}{2}\sqrt{\frac{10{,}000}{32}}$$

$$= \frac{31}{2} \times 100\sqrt{\frac{1}{32}}$$

$$= \frac{3100}{2} \times \frac{1}{5.65}$$

$$= \frac{3100}{11.3} = 274\ \Omega$$

The leg R_1 is:

$$\frac{1}{R_1} = \frac{1}{Z_I}\left(\frac{N+1}{N-1}\right) - \frac{1}{R_3}$$

$$= \frac{1}{50}\left(\frac{32+1}{32-1}\right) - \frac{1}{274}$$

$$= \frac{1}{50} \times \frac{33}{31} - \frac{1}{274}$$

$$= \frac{33}{1550} - \frac{1}{274}$$

$$= .0213 - .0036 = 0177$$

If $\frac{1}{R_1} = .0177$, then $R_1 = \frac{1}{.0177}$

$$= 57\ \Omega$$

The leg R_2 is:

$$\frac{1}{R_2} = \frac{1}{Z_O}\left(\frac{N+1}{N-1}\right) - \frac{1}{R_3}$$

$$= \frac{1}{200} \times \frac{33}{31} - \frac{1}{274}$$

$$= \frac{33}{6200} - \frac{1}{274}$$

$$= .0053 - .0036$$

$$= .0017$$

If $\frac{1}{R_2} = .0017$, then $R_2 = \frac{1}{.0017}$

$$= 588\ \Omega$$

Thus, we can construct either a T or a pi pad that will match unequal impedances and give us 15 db attenuation. A balanced T (H) pad or a balanced pi (O) pad could be constructed by splitting the arm resistors and dividing them between the upper and lower lines.

VARIABLE ATTENUATORS

The attenuation introduced by an L pad, a T pad, or a pi pad can be made

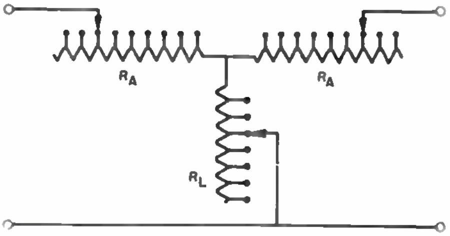

FIG. 17. The usual style of tapped T-pad variable attenuator.

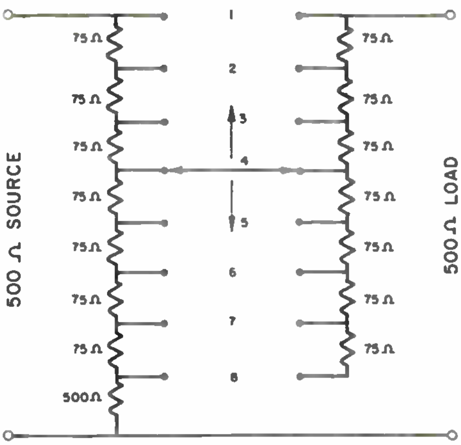

FIG. 18. An approximate T pad using only two variable resistors.

adjustable by using variable resistors for the arms and legs. The T pad of Fig. 8, for example, could be made with variable R_A and R_L values.

If this is done, however, the relations outlined in the table of Fig. 9 must be maintained or the variable pad will not have constant input and output impedances. We could do this by using taper-wound variable resistances ganged together so that all resistances varied by the proper amount when one control was operated. However, this would be quite difficult to achieve in actual practice because each resistor would have to be calibrated and wound with such precision that it would become quite costly.

A reasonable, practical design of the variable attenuator is made possible by the fact that attenuation does not need to be continuously variable. If the variations are made in equal steps of less than 2 db each, the variation will appear to be continuous for most purposes. This allows us to use a set of fixed resistors and a three-gang switch as shown in Fig. 17.

One advantage of using step attenuation in the design of the variable T pad is that such an arrangement can be calibrated very accurately. In addition, the gang switch can be made with large wiping contacts which will keep contact noise at a minimum. This is in contrast to a rheostat or a potentiometer which seldom can be reset to a given point, and usually has a high degree of contact noise.

To increase the amount of attenuation in this pad, the values of R_A must be increased and the value of R_L must be decreased. For this reason, then, it is possible to combine one of the R_A's with R_L so that the simpler construction shown in Fig. 18 can be used.

In the figure, the right-hand resistance forms the right arm of the T pad, the upper part of the left-hand resistance forms the left arm, and the lower part forms the leg. This arrangement is not a true T pad, but only an approximation since it is not possible to make the attenuator have exactly constant values of input and output resistance at all settings.

As shown in the table of Fig. 19, it varies from 336 to 861 ohms.

It will be noted that the use of this particular attenuator involves a loss of 1.9 db at the minimum setting. This is called the insertion loss of this particular device.

Decade Attenuator Pads. Suppose we have need for an attenuator adjustable in one decibel steps from 0 to

Switch position	Input Resistance	db Loss
1	336	1.9
2	432	3.5
3	522	5.0
4	605	6.5
5	680	7.9
6	748	9.3
7	808	10.8
8	861	12.4

FIG. 19. Input resistance and db loss of the approximate T pad for each switch point.

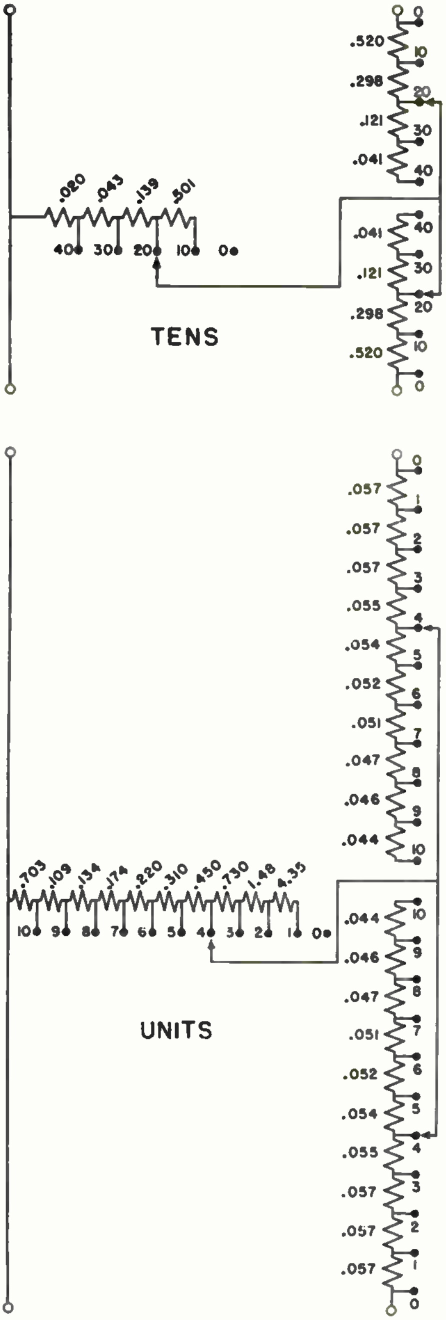

FIG. 20. A decade attenuator adjustable in 1 db steps from 0 to 50 db, designed for a source-load impedance of 1 ohm.

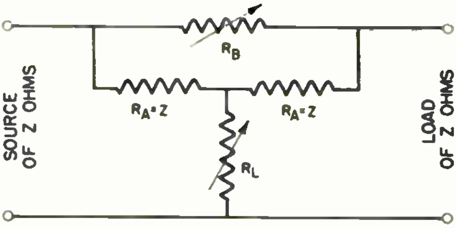

FIG. 21. The bridged-T is a true symmetrical pad with only two variable resistors.

50 that maintains perfect impedance matching at all settings. We could, of course, design a conventional T pad having 50 steps, but this would be expensive and awkward to use.

A better method would be to build two attenuators, one having four steps of 10 decibels each, and the other having ten steps of 1 decibel each. Then, if these are constant-impedance pads, they can be connected in tandem so that the separate attenuations will add. Thus, one knob controls the tens, and the other controls the units of attenuation. Such an arrangement is called a decade attenuator.

The design for such a decade attenuator is shown in Fig. 20. This decade pad is designed to work between a source of 1 ohm and a load of 1 ohm. To find the values for any other source and load impedance, simply multiply the value shown alongside each resistor by the impedance Z.

The Bridged T. A modification of the T pad, of considerable importance because it requires only two variable resistors, is shown in Fig. 21. This is known as the bridged T. It is a symmetrical attenuator having two fixed arms, bridged from input to output by a variable arm, and a variable leg.

The resistances of the fixed arms R_A are always equal to the input-output impedance Z. The bridge and leg resistors R_B and R_L are related to the impedance Z in this way:

$$R_B = B \times Z \text{ and}$$

$$R_L = L \times Z.$$

The multiplying factors, B and L, can be determined from the table in Fig. 22. Pay particular attention to the arm and leg factors for 6-db attenuation. Both are almost exactly equal to 1. This means that 6 db of attenuation can be obtained at any impedance by connecting four resistors, all equal to the impedance, in a bridged T. Any other degree of attenuation can be obtained by changing R_B and R_L to the proper values.

Attenuation db	Bridge-arm factor B	Leg factor L
0	0	∞
1	0.122	8.20
2	.259	3.86
3	.413	2.42

30	30.62	.0326
40	99.00	.0101

FIG. 22. Multiplying factors for design of the bridged-T.

You have seen how networks can be designed to give impedance-matching with minimum attenuation, or to give a desired amount of attenuation. Now let's look at some networks designed to correct uneven attenuation or phase shift at different frequencies. These are called "equalizers."

Equalizers

Transmission lines and certain types of equipment ordinarily introduce a certain amount of distortion in a signal because of unequal attenuation and phase shift at the various frequencies. It would be extremely difficult to design lines and equipment that would always provide a distortion-free signal. The more practical solution is to use compensating networks to introduce additional attenuation or phase shift so that all frequencies will be affected in substantially the same manner.

LINE EQUALIZERS

Long lines (such as telephone lines or cables) ordinarily attenuate high frequencies more than the low frequencies. Capacitance between the wires acts like a capacitor connected across the line ahead of the load, shorting out the high frequencies. A crude form of compensation could be obtained by connecting a capacitor in series with the line to partially block the low frequencies while passing the highs. A more practical arrangement uses an inductance-resistance combination shunted across the line to cause an equivalent loss of the low frequencies and balance the response.

Such an arrangement is the Western Electric 23A Equalizer shown in Fig. 23. As you can see, it consists of a coil and a capacitor in parallel, and a tapped series resistance. The components are mounted in an aluminum-finished metal box, and the resistor taps are brought out to terminals at one end of the box, so any needed value of resistance can be selected.

It can be easily adjusted to an unloaded line with ordinary station equipment. Suppose it is to be adjusted to a circuit consisting of the sending-station line amplifier, repeating coil, (which is an impedance-transforming device similar to a transformer), transmission line, receiving-station repeating coil, and receiving-

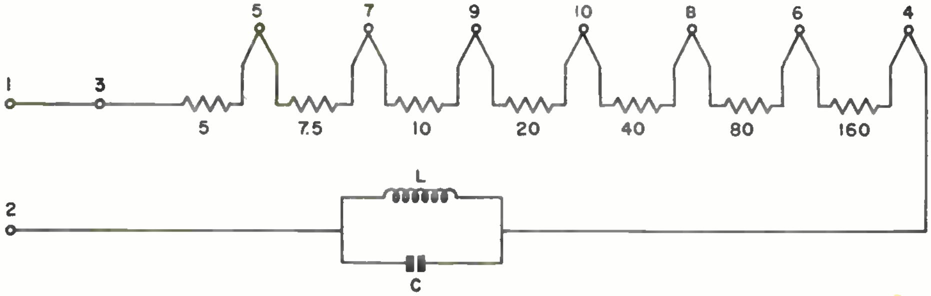

FIG. 23. The Western Electric 23A equalizer.

station line amplifier as shown in Fig. 24.

VU meters are connected across the line following the sending and receiving line amplifiers, and the receiving amplifier is terminated in a 600-ohm load. An attenuator pad is used ahead of the repeating coil at the sending end to prevent cross-talk or interference with other lines in the same cable. Another attenuator is used at the receiving end to avoid overloading the amplifier. To see what values of resistance to use in the equalizer, the output of a variable-frequency oscillator is fed into the sending amplifier, and the loss at 1000 cycles and 8000 cycles noted.

Then the equalizer is connected across the line side of the receiving repeating coil, but an adjustable resistance box is connected in place of the tapped resistor in the equalizer. That is, terminal 2 of the equalizer is connected to one side of the line. The resistance box is connected between terminal 4 of the equalizer and the other side of the line. Terminal 1 of the equalizer is left open. Various resistance values are tried (using the resistance box) until the loss is approximately the same at 1000 and 8000 cycles. Then the resistance box is removed and the portion of the fixed resistance in the equalizer with a value closest to that determined by experiment is connected in its place. This is done by connecting terminal 1 to the line from which the resistance box was removed, and moving the lead from the L-C combination from terminal 4 to the proper terminal. For example, if 12 or 13 ohms is needed, the lead would be moved from terminal 4 to terminal 7, since the resistance from terminal 7 to terminal 1 is 12.5 ohms, which is as close as we can get.

For temporary lines or intermittent service where a permanent installation is not justified, an adjustable equalizer such as the Western Electric 279A equalizer panel shown in Fig. 25 can be used to connect it to any one of several lines as the occasion requires.

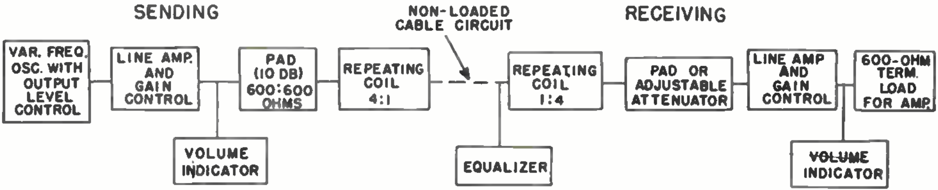

FIG. 24. Setup for equalizing a line.

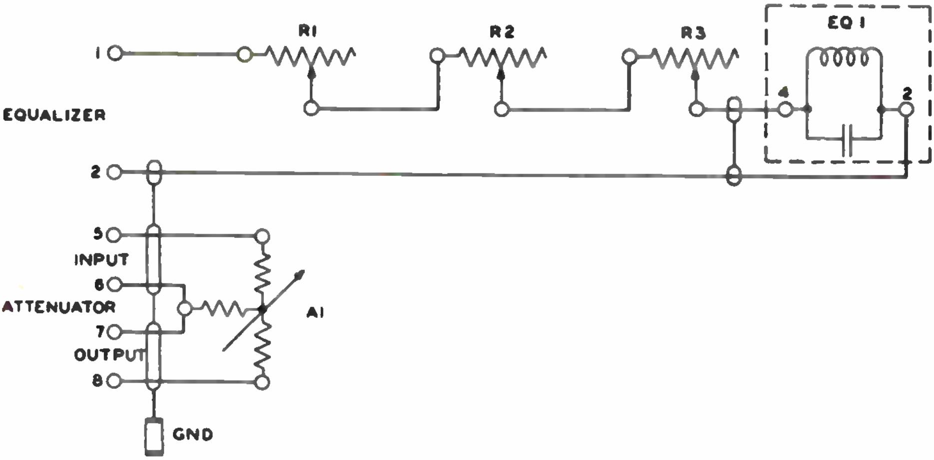

FIG. 25. The Western Electric 279A equalizer panel.

PICKUP EQUALIZERS

Another way in which equalizers are used is to compensate for the electrodynamic characteristics of phonograph and tape pickups. They are also used to compensate for the particular recording curve used in making records. These are called pickup equalizers.

Recording methods may be divided into two general classes: constant-velocity and constant-amplitude. When a record is cut, the stylus in the cutting head cuts a groove in the record. When no signal is applied, the groove forms a perfect spiral. When a signal is applied, the stylus moves in a transverse (side to side) direction, making a slight wiggle in the groove.

When a signal of constant amplitude is applied to a constant-velocity cutting head, the transverse velocity of the stylus is constant regardless of frequency, but the displacement from side to side decreases with frequency. With a constant-amplitude cutting head, the transverse displacement of the stylus is constant (for tones of constant amplitude), but the transverse velocity of the stylus varies directly with the frequency.

Just as cutting heads can be divided into two types, record pickup heads may also be divided into two classes, "velocity-operated" and "amplitude-operated." In a velocity-operated pickup, the output signal is generated by changing the flux of a permanent magnet as it passes through a coil. Different types of heads (magnetic, dynamic, variable reluctance) accomplish this in slightly different ways, but the operating principle is the same.

The voltage generated is proportional to the rate at which the flux changes, and the flux is changed by the movement of the stylus. Thus, the signal voltage generated is dependent on the speed of the stylus. This pickup is the natural opposite of a constant-velocity recorder. If a constant-level signal is recorded, a constant-level output is obtained.

The output of an amplitude-operated pickup is constant for constant groove undulation (side to side displacement) amplitude. Common amplitude-operated pickups are the crystal and ceramic types. These operate on the piezo-electric effect, generating a voltage by the physical distortion of a crystal. A constant-amplitude signal recorded with a crystal cutter will be

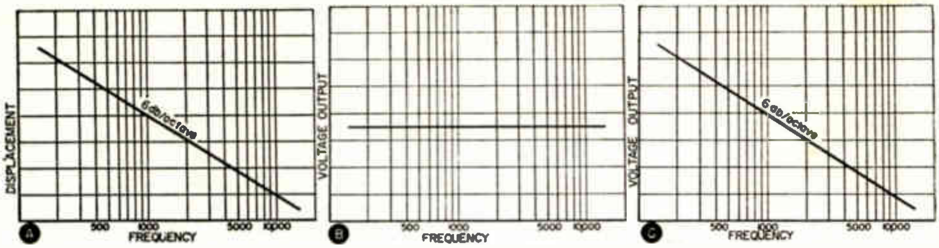

FIG. 26. A, variations of magnetic-cutter stylus displacement with frequency. B, output voltage of magnetic pickup on constant-velocity recording. C, output voltage of crystal pickup on constant velocity recording.

reproduced as a constant output voltage when played back through a crystal pickup. A constant-amplitude signal recorded with a constant-velocity cutter will be reproduced as a voltage which falls off at the rate of 6 db per octave as the frequency is increased.

Fig. 26A shows how the undulation amplitude varies with frequency in a constant-velocity record for tones of equal signal level. When a magnetic play-back head is used, the amplitude of the output signal is the same at all frequencies as shown in Fig. 26B, but with an amplitude-operated pickup, the voltage falls off as in Fig. 26C.

Fig. 27A shows the variation in stylus displacement with frequency for tones of equal amplitude when recorded with a constant-amplitude recording head. If the record is played back through a constant-amplitude pickup, the output voltage is the same at all frequencies as shown in Fig. 27B. If played back through a constant-velocity pickup, the output is as shown in Fig. 27C.

Recording Curves. In actual practice, both constant-velocity and constant-amplitude characteristics are used on parts of any record. When attempts were made to extend the high-frequency range of recordings, difficulty was experienced in keeping the high-frequency notes from dropping down to the noise level. Also, with constant-velocity recording, the stylus sometimes cut into the next groove when a loud, low note was recorded. These problems were solved by pre-emphasizing the highs and de-emphasizing the lows during recording, and using equalizers in the play-back amplifiers to make the necessary compensation.

The only trouble with this arrangement was that there was no agreement between companies as to exactly what system to use, that is, how much pre-emphasis was necessary or at what

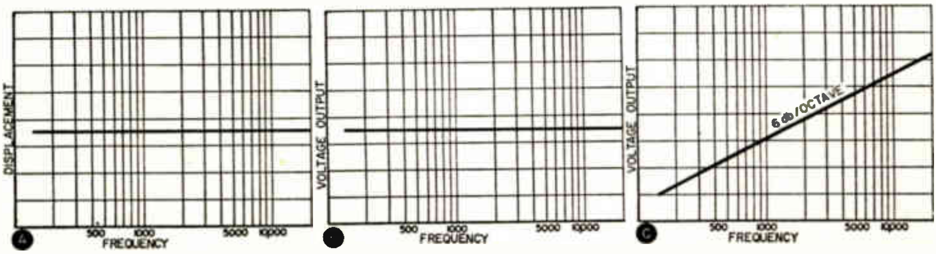

FIG. 27. A, crystal cutter stylus displacement variation with frequency for constant signal level. B, voltage output variation when record (in A) is played back through crystal pickup. C, output voltage variation when same record is played through magnetic pickup.

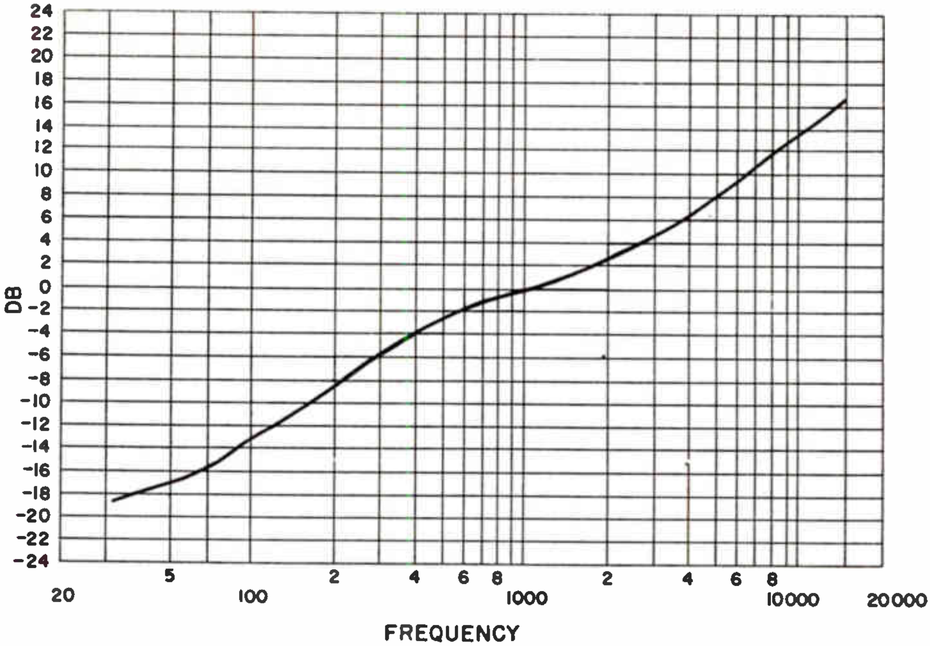

FIG. 28. The RIAA recording curve.

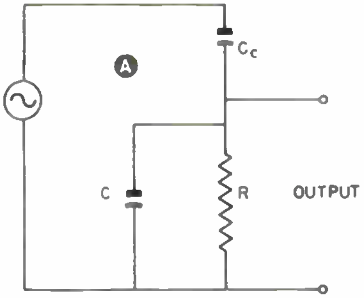
frequency it should start, etc. Various techniques were tried, and several recording curves were developed. As a result, it was very difficult to design playback amplifiers to reproduce all records satisfactorily with any type of pickup. Recently, the Recording Industries Association of America adopted a standard curve and recommended it to the entire recording industry. The RIAA curve, shown in Fig. 28, is identical to the NARTB (National Association of Radio and Television Broadcasters) curve and also to RCA's Orthophonic curve. The Audio Engineering Society has recommended it as a replacement for their AES curve. Nearly all the major record manufacturers now use this curve on their new records.

Equalizer Circuits. For best possible frequency response, a pickup must be terminated correctly at the input of the amplifier. The ideal pickup and termination would give a flat frequency response over the entire audio range.

Fig. 29 shows the equivalent circuit of a ceramic cartridge and its termination. The pickup can be thought of as a generator and a capacitor in series, and the load as a resistance and a capacitor in parallel. When the two are connected, an RC voltage divider results. At low frequencies, the reactance of C is so high it can be ignored, as in Fig. 29B, but its effects increase as the frequency goes up, as shown in Fig. 29C.

For any given pickup, C is fixed, as it depends on the cable length and the amplifier construction, so R is the only part that can be varied. Fig. 29D shows how varying R affects the output.

The equivalent circuit of a magnetic pickup and its termination is shown in Fig. 30A. This circuit contains inductance, capacitance, and reactance and acts as a damped resonant circuit. If R_L is too large, the output will have resonant peaks at frequencies deter-



EXACT EQUIVALENT LOW FREQUENCY HIGH FREQUENCY

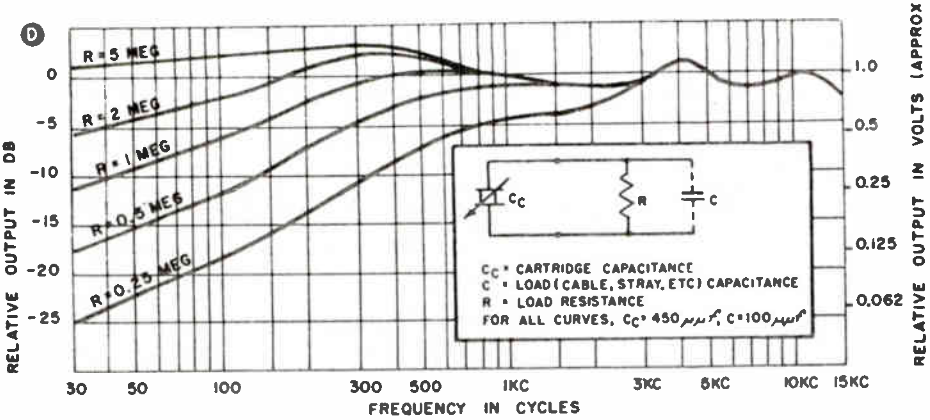


FIG. 29. A, B, C equivalent circuits of ceramic cartridge and termination; D, change in output with change in terminating resistance.

mined by the values of L and C_S. If R_L is small, C_S is effectively shorted and the inductance will cause the highs to fall off. Using a longer cable would cause C_S to increase, and there would be resonant peaks at a lower frequency. If R_L is reduced to compensate for this, the high-frequency output is reduced. The best frequency range is obtained by keeping the cable capacitance small and R_L high.

Fig. 30B shows a crystal pickup and its termination. The output of a crystal cartridge falls off rapidly at high frequencies. R_1 and C in series with R_2 correct for this. At low frequencies, capacitor C has little effect on the signal appearing at the output.

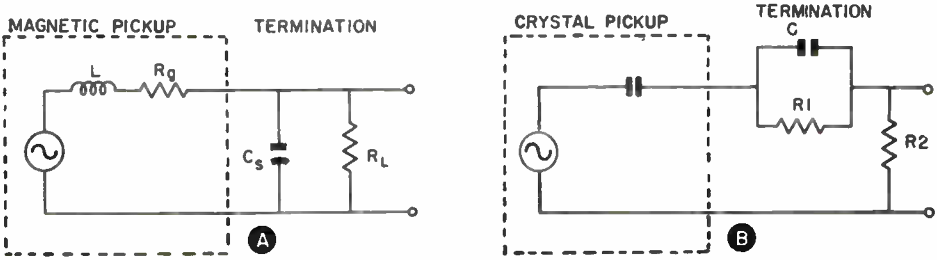

FIG. 30. Equivalent circuit and input termination for A, magnetic, and B, crystal pickup.

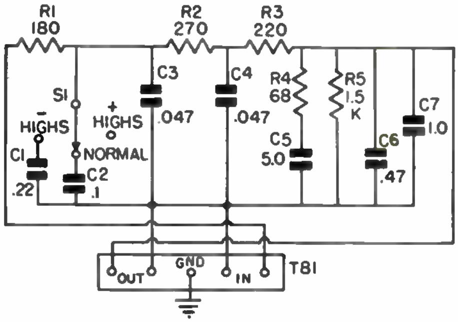

FIG. 31. The RCA MI-11888 pickup equalizer.

As the frequency goes up, the reactance of C goes down. This reduced reactance shunting resistor R_1 increases the signal at the output.

Turntable Equalizers. A typical equalizer for use with a broadcast turntable is shown in Fig. 31. This is the RCA MI-11888, designed to work with the RCA Type 70 Series turntable and the BQ-2A turntable, and is for use only with the MI-11874-4 pickup head.

The equalizer is mounted inside the turntable cabinet in the right-hand front corner, where it will be convenient for use by the operator.

Three settings of the equalizer are provided. In the diagram, the switch is shown in the "normal" position. When it is desired to accentuate the highs, the switch is moved to the "+Highs" position, which removes some of the shunt capacitance from the circuit. When the opposite effect is desired, the switch is thrown to the "—Highs" position, which adds shunt capacitance to the circuit.

The response curves for the different settings of the equalizer switch are shown in Fig. 32.

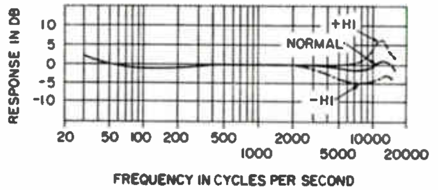

FIG. 32. Frequency response curves for the MI-11888.

TAPE SYSTEM EQUALIZERS

There are a number of factors that influence the frequency response of a record and play-back tape system. Fig. 33 shows the response curves for two standard tape speeds—15 inches per second and 7.5 inches per second. The slower-moving tape has the poorer high-frequency response. This is because, when a signal is recorded on a magnetic tape, the particles of the coating form many very small areas which act like tiny magnets having north and south poles. The slower the tape moves past the recording head or the higher the frequency of the applied signal, the shorter the magnetic bars become. This causes a canceling effect between the opposite poles, which reduces the magnetism induced in the tape.

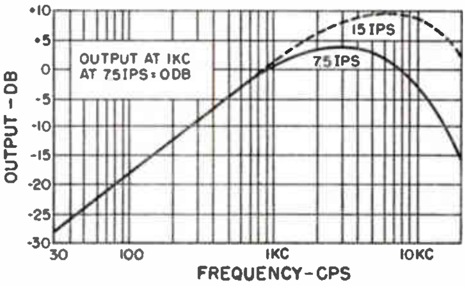

FIG. 33. Response of a record playback head.

Another cause of high-frequency loss is that the recording head is largely inductive. Thus, it has more impedance at high frequencies, decreasing the strength of the magnetic field between the pole pieces.

When the tape is played back, the voltage induced in the play-back coil varies with the rate of change of the flux lines. A high-frequency tone of the same amplitude occupies a shorter length of tape than a lower-frequency tone of the same amplitude. Thus, the

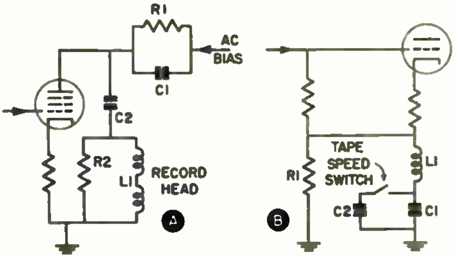

FIG. 34. Circuits for pre-emphasis.

change of flux lines is at a faster rate at higher frequencies (or a faster speed) than at a low frequency (or a slower speed).

To get a linear frequency response in a tape-recorder system, equalizing networks are necessary to boost the amplitude of the frequencies at both the high and low ends of the audio range. The usual practice is to boost the highs in the recorder and the lows (and sometimes also the highs) in the play-back amplifier. The former is called pre-emphasis and the latter, post-emphasis.

Pre-Emphasis. Two typical pre-emphasis circuits are shown in Fig. 34. In Fig. 34A, capacitor C_2 is in series with the recording head across the output of the amplifier tube. The reactance of C_2 decreases as the frequency increases, so a high-frequency signal will produce a higher current flow in the coil of the recording head than a low-frequency one will.

In Fig. 34B, a series-resonant circuit in the amplifier cathode circuit is used, At low frequencies, a degenerative voltage is developed across resistor R_1, feeding an out-of-phase signal to the grid, decreasing the gain. At higher frequencies, coil L_1 and capacitor C_1 (or C_1 and C_2 in parallel) have an increasing shunting effect on resistor R_1, decreasing the feedback, and the gain goes up. Capacitors C_1 and C_2 are connected in parallel for high tape speeds, but the switch is opened at low speed.

Post-Emphasis. Two typical post-emphasis circuits are shown in Fig. 35. In Fig. 35A, the bass response is boosted by the series network consisting of capacitor C_2 and resistors R_2 and R_3. The reactance of C_2 is so high at low frequencies that the series network of C_2 and R_2 has no shunting effect, and the lows pass unattenuated to the grid of the next stage. As the frequency goes up, the shunting effect of the two components increases, and a lower proportion of the high-frequency signal appears at the grid. Capacitor C_3 is an adjustable treble control used to correct for the very-high-frequency losses in a tape recorder system. At the higher frequencies, C_3 shunts some of the highs around R_3 and on to the grid.

In the circuit shown in Fig. 35B, the middle range of frequencies is fed back to the input circuit through re-

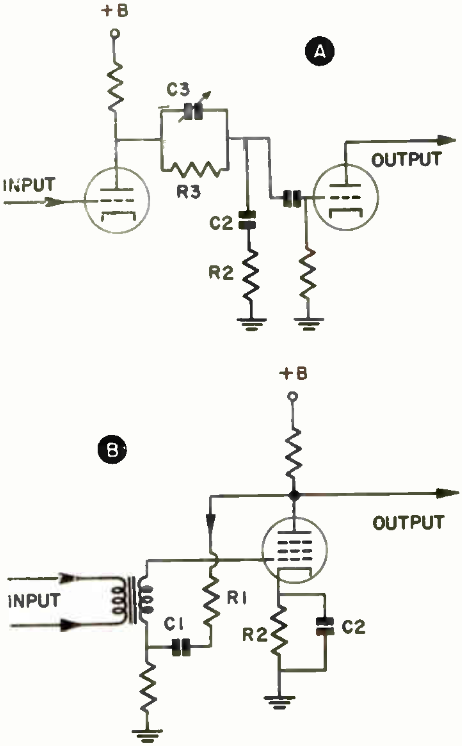

FIG. 35. Post-emphasis circuits.

sistor R_1 and capacitor C_1. There is no feedback of lows because of the rising capacitance of capacitor C_1. The feedback reduces the gain so the gain decreases with an increase in frequency.

The values of resistor R_2 and capacitor C_2 can be chosen to give a small amount of boost at very high frequencies. If C_2 is small, its low reactance at very high frequencies prevents cathode feedback and increases the high-frequency gain.

These are only some of the many uses for equalizers in broadcast service. Equalizers and filters, which we will take up in the next section of this text, are used to extend the frequency range of a sound system, to add sound effects without the use of mechanical apparatus, to remove undesirable sound effects, to improve tonal qualities resulting from poor acoustical location, and to compensate for variations in system response, acoustical conditions, and program material.

Filters

Basically, filters consist of an arrangement of reactive components that will respond in certain predetermined ways to different frequencies. Filters can be designed to pass low-frequency signals and block signals at high frequencies. Others can be designed to pass high frequencies and block low frequencies. Still others may either pass or block certain definite bands of frequencies. A fundamental rule is that a network cannot act like a filter unless it contains some reactive component, such as a coil or capacitor, that changes its reactance with frequency.

BASIC FILTER CIRCUITS

The operation of the filter depends not only upon the components used, but also on the values and circuit arrangements of the parts. Filter elements can be connected in series with the load or in parallel with the load. Let us see what effect these connections have.

High-Pass Filter. A capacitor in series with the load, or a coil in parallel with the load, as shown in Fig. 36A, forms a simple high-pass filter. At low frequencies, the current is blocked from the load by the capacitor or shorted around the load by the coil. As the frequency increases, more and more current is passed by the capacitor and reaches the load, or if a coil is used, the coil reactance goes up as

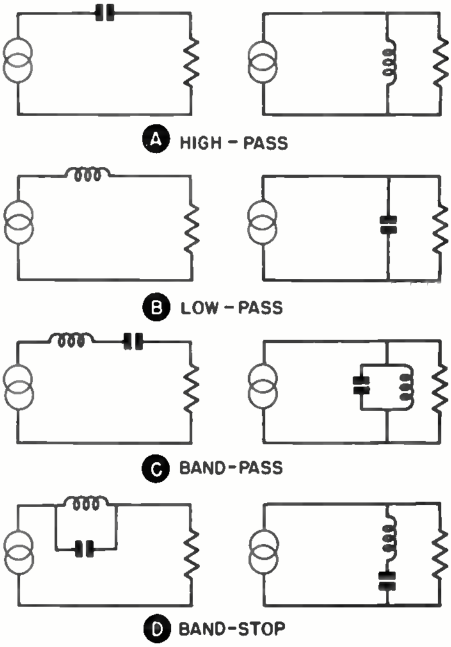

FIG. 36. Types of filters.

the frequency increases and more of the current is forced through the load.

Low-Pass Filter. If we put the capacitor in parallel with the load or the coil in series with the load as at B, the effect will be reversed, and we will have a low-pass filter.

Band-Pass Filter. Suppose we use both a coil and a capacitor as in Fig. 36C. If we put them in series with the load and each other we will have a band-pass circuit. Now, low frequencies will be blocked by the capacitor, and the higher frequencies will be blocked by the coil. However, at some intermediate frequency, the inductive and capacitive reactance will be exactly equal and opposite, the circuit will be series resonant and will pass current. This is a band-pass filter because a small band of frequencies about the resonant point will be passed. If we put the two in parallel with the load, low frequencies will be bypassed around the load by the coil, and high frequencies by the capacitor. At some frequency the two will be resonant, and act like a high impedance and the current will flow through the load.

Band-Stop Filter. Band-stop filters are shown in Fig. 36D. When the coil and capacitor are connected in parallel with each other and placed in series with the load, current reaches the load through the capacitor at high frequencies and through the coil at low frequencies. At resonance, the blocking action of the circulating current in the resonant circuit prevents current from reaching the load. If they are connected in series with each other across the load, at resonance the current will be shorted around the load. Above and below resonance, either the coil or the capacitor will block the current and force it through the load.

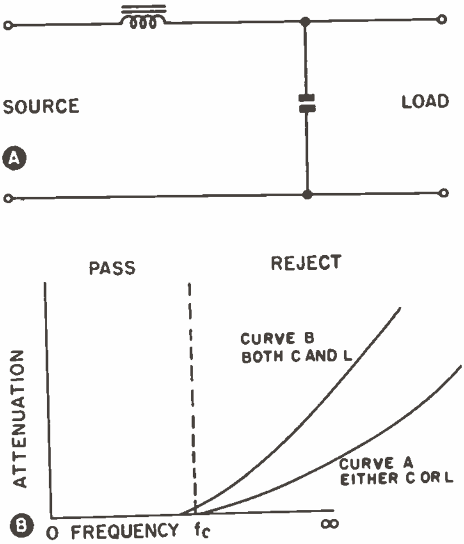

FIG. 37. Basic low-pass L filter, A; filter response curves, B.

These four basic circuits (low-pass, high-pass, band-pass, band-stop) illustrate the principles of filtering, but, in actual practice, we have to consider the sharpness of the cut-off action and the effect of the filter on the impedance relationship. For this rea-

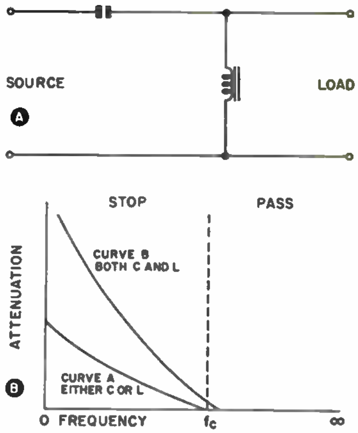

FIG. 38. Basic high-pass L filter, A; filter response curves, B.

son, most practical filter circuits are combinations of the principles we have discussed. One of the simplest of these is the L filter.

L Filter. Let's see why the circuit in Fig. 37 gives an improved response. Either the coil or capacitor alone forms a low-pass filter. With either one alone, the current in the load will decrease as the frequency goes up until, finally, at some high frequency practically no current reaches the load. By using both components, we get the benefit of two effects. If the values are chosen properly, at the cut-off frequency the coil will begin to block quite a lot of current and the capacitor will begin to pass a substantial amount of current. Thus, the coil blocks some of the current and the capacitor passes some that gets through the coil, and we have a sharper response curve as shown by curve B in Fig. 37B.

The high-pass filter shown in Fig. 38 also combines capacitance and inductance in an L-type filter arrangement. Notice that in the circuit in Fig. 38A, we use a series capacitor and a shunt coil to provide a sharper attenuation than we would get by using either component by itself. The response curves are shown in Fig. 38B.

Band-pass and band-stop filters can also be improved by arranging the components in an L network. In Fig. 39 we show the network and the curves for a band-pass filter. If the series-resonant and the parallel-resonant circuit shown in Fig. 39A are designed to resonate at the same frequency, the cut-off will be quite sharp as shown by the curves in Fig. 39B. This will result in a highly discriminating filter and a very narrow band of frequencies will be allowed to pass.

However, if we make the two circuits resonate at slightly different frequencies, we can broaden the pass-band as shown by the curves in Fig. 39C. Here, all the frequencies between the resonant frequency of the series circuit, denoted by f_1, and the resonant frequency of the parallel circuit, de-

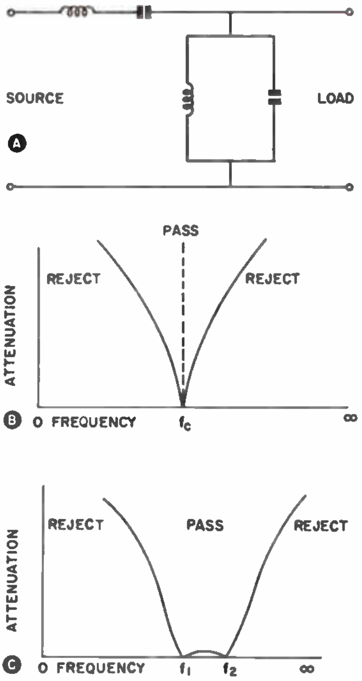

FIG. 39. L-type band-pass filter, A; sharp cut-off, narrow-band with arm and leg resonating at same frequency, B; sharp cut-off, wide-band with arm and leg resonating at different frequencies, C.

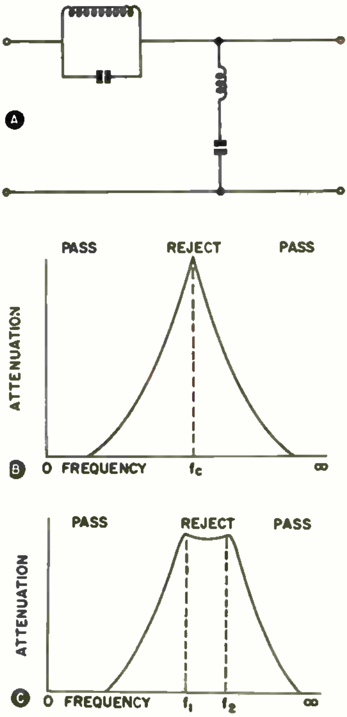

FIG. 40. L-type band-stop filter, A; sharp cut-off narrow band with arm and leg resonating at same frequency, B; sharp cut-off, wide band with arm and leg resonating at different frequencies, C.

noted by f_2, will be passed while all others will be rejected.

Similarly, a band-stop filter can be made by using the L networks shown in Fig. 40A. Notice that now the parallel resonant circuit is in series with the load and the series resonant circuit is in parallel with the load. When the parallel circuit resonates, it will tend to block current to the load. When the series circuit resonates, it will tend to short any signals away from the load. If the two circuits are designed to resonate at the same frequency, a narrow band of frequencies will be stopped as shown by Fig. 40B. If there is a difference in their resonant frequencies, the stop band will become wider as shown in Fig. 40C.

Although L pads can be designed to give sharp cut-off characteristics and provide almost any type of filtering action, they are unsymmetrical. In many filtering applications, it is very important to have the impedance matching in both directions. In such cases symmetrical filters must be used.

The low-pass L section shown in Fig. 37A can be made into a symmetrical *T section* by splitting the inductance L in two, and placing one half on each side of the shunt capacitor C. The same L section can be changed into a symmetrical *pi section* by using two capacitors of half the former capacity, and locating one at each end of the inductance.

In a similar manner, the band-pass and band-elimination L sections can also be made into symmetrical T or pi sections. A summary of the more common filter section forms, together with their attenuation characteristics, is given in Fig. 41.

MULTI-SECTION FILTERS

Now that we know that symmetrical filter sections "repeat" the load resistance for their input impedance, it is obvious that we can operate several filter sections in tandem. Thus, if we have three low-pass T sections, each designed for an impedance, let us say of 500 ohms, we can arrange them as shown in Fig. 42A. Here the second section acts as the load impedance for the first, and the input impedance of the last section is the load for the second filter section.

We may continue this arrangement for almost any number of sections. In all cases, however, the generator still works into a 500-ohm input impedance, and the impedance at the output continues to match the 500-ohm load.

Since the individual attenuations add, the tandem arrangement will attenuate the unwanted frequencies roughly three times as much as an individual section, while the wanted fre-

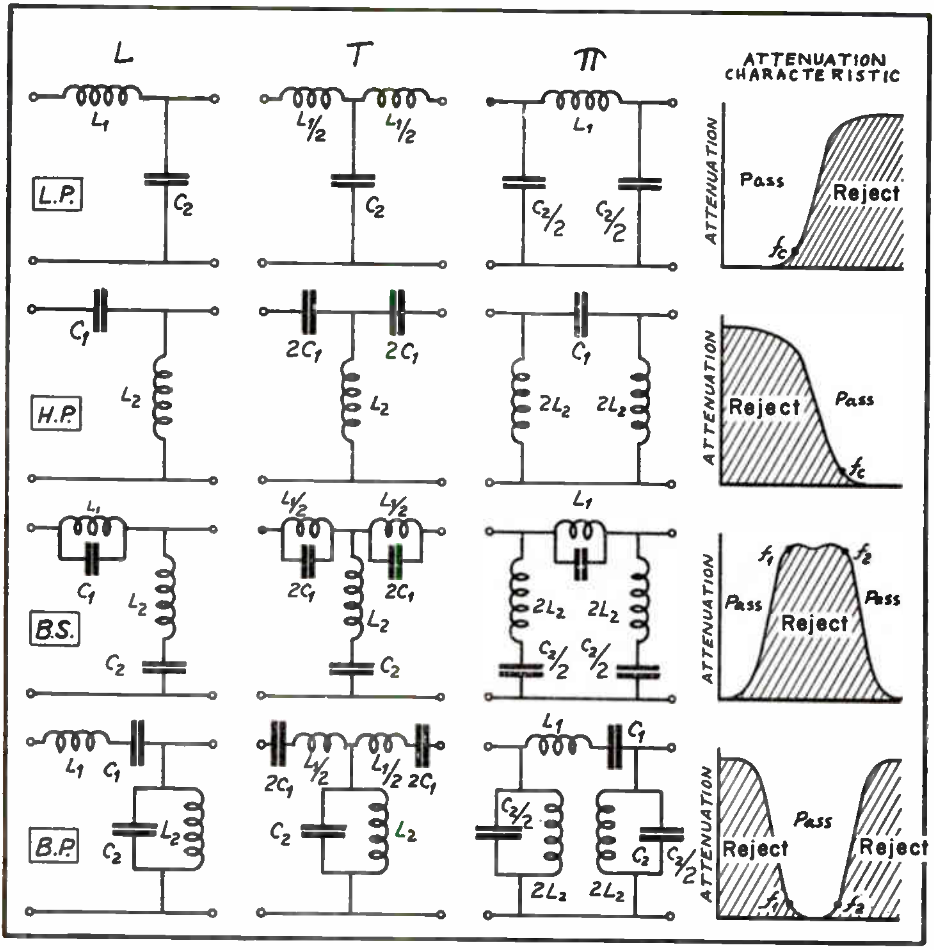

FIG. 41. The most common forms of L, T, and pi sections with their attenuation characteristics for low-pass, high-pass, band-stop, and band-pass filters.

quencies pass with little loss, and the overall response is improved. The two coils in series can be replaced by a coil of twice the inductance, as shown at B.

We may continue this arrangement for almost any number of sections. In all cases, however, the generator still works into a 500-ohm input impedance, and the impedance at the output continues to match the 500-ohm load.

In precisely the same manner, high-pass, band-pass, and band-stop multisection filters can be made. Wherever two arm capacities appear in series, however, the effective capacity is cut in half. These two capacitors, therefore can be replaced by a single capacitor. Where two coils appear in series, they can be replaced with a single coil of twice the inductance.

In cases where it is necessary to present a very high attenuation to one band of frequencies and, at the same

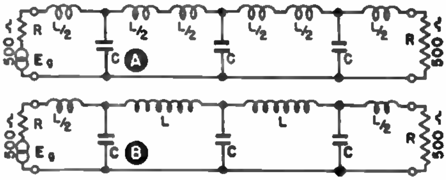

FIG. 42. Three low-pass T sections connected in tandem.

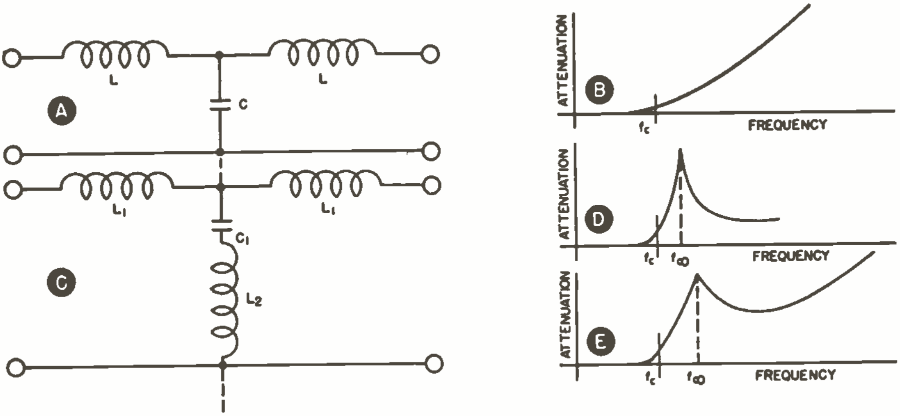

FIG. 43. A prototype section with high attenuation far from cut-off, and a derived section, with high attenuation close to cut-off, when put in tandem make a composite filter with a very sharp cut-off, and a high attenuation over the entire stop band.

time, pass an adjacent band of frequencies with little loss, we must use a filter with a sharper cut-off characteristic.

M-Derived Filters. Let us look at Fig. 43A. This is an ordinary low-pass T section, sometimes called a "constant K filter," with an attenuation characteristic like that shown in Fig. 43B. Since this is a basic filter section, it is often called a "prototype."

It is called a constant-K filter because of the fact that the product of X_L and X_C is constant at all frequencies. For example, at some frequency X_L may be 200 ohms, and X_C may be 50 ohms, and the product of the two is 10,000. At twice the frequency, X_L is 400 ohms, and X_C is 25 ohms and the product (the constant K) is still 10,000.

Let us modify the inductance and capacitance values of this prototype section so that an additional inductance L_2 can be placed in series with the capacitance C_1, as illustrated in Fig. 43C. If done properly, this does not change the section cut-off frequency, and it does not alter the response in the *pass band.*

In the *attenuation band,* however, we find that a startling change occurs. Since L_2 and C_1 form a series-resonant circuit, the section is "shorted out" at one frequency, and its response drops nearly to zero. This means that at one point in the stop band the attenuation is very high, reaching, theoretically, to infinity. In practical circuits, the attenuation does not reach infinity because of losses in the coil, but the response of such a section has a peak of great attenuation, as illustrated in Fig. 43D.

In choosing the value of L_1, C_1, and L_2 in the so-called derived filter, shown in Fig. 43C, a factor is used in special formulas to calculate their values. This factor, called the "M" factor, is determined by another formula based on how sharp the cut-off is to be. Since it is the sharpness of cut-off, or "M" factor, that determines the value of all L and C values in a derived filter, this arrangement is called an "M-derived" filter. Thus, an M-derived filter is one having infinite attenuation at some specific frequency, producing a sharper cut-off than a standard filter.

An M-derived section cannot be used alone, since after the infinite attenuation frequency, f_∞, is passed, the attenuation again drops to a low value. If, however, we connect a prototype and a derived section together in tandem, we realize a greatly improved filter performance. This means that we add the curve of Fig. 43B to that of Fig. 43D to get an over-all response like that shown in Fig. 43E.

Note that not only is the attenuation relatively high over the entire stop band, but also that the cut-off characteristic is much sharper. Notice also that the losses in the pass band near the cut-off frequency have been held to a minimum, which is impossible to realize by merely adding simple prototype sections together.

Fig. 43C does not represent the only practical type of derived filter section. The low-pass *pi-section* prototype in Fig. 44A, for instance, can be modified to appear as the derived section in Fig. 44B. The added capacitor C_2, in conjunction with coil L_1, now forms a parallel-tuned circuit, which at its resonant frequency serves to block the flow of current through the section. Here again, the result is an infinite-attenuation frequency in the stop band.

In constructing a multi-section filter, it is possible to use several derived sections. Furthermore, if different M values are used for each derived section, a separate infinite attenuation frequency for each section is obtained. In this way the over-all filter-response characteristic can have an extremely sharp cut-off, and very high attenuation at all points in the stop band. In general, filters that are made up of a prototype and one or more derived sections are called "composite" filters.

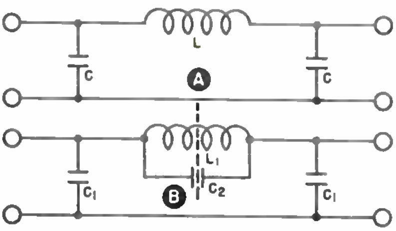

FIG. 44. A prototype low-pass pi section, and the corresponding M-derived section. Where the parallel-tuned circuit is resonant, the derived section has infinite attenuation.

INPUT-OUTPUT IMPEDANCE

Earlier we stated that symmetrical filter sections like the T and π sections in Fig. 41, possess input impedances that are *nearly* equal to the respective load resistances. Let us investigate this statement further.

Any symmetrical filter section has a characteristic or "iterative" impedance that is determined entirely by the values of inductance and capacitance. *It is only when the load resistance is made equal to this inherent characteristic impedance that the input impedance of a filter assumes an identical value.* In other words, for proper filter performance, it is desirable that we use source and load impedances that match the impedance of the filter itself.

Unfortunately, the characteristic impedance of a simple prototype filter section is not constant with frequency. Look at the low-pass T section in Fig. 41 to see why this is so. In the input terminals, the left-hand inductance arm $L_1/2$, and the shunt capacity C_2, together form a series-resonant circuit. Since these two are in resonance at the section cut-off frequency, the input impedance drops to a very low value at this point. In Fig 45, the solid curve shows how the characteristic impedance of a low-pass T section decreases rapidly from a nominal value for low frequencies to a theoretical zero value at the cut-off point.

On the other hand, the low-pass *pi section* in Fig. 41 resembles a split-capacitor parallel-tuned circuit, and it behaves like a parallel resonant circuit. For low frequencies, the section has a nominal characteristic impedance. As the frequency is raised, the input impedance increases, and at the cut-off point where the elements are

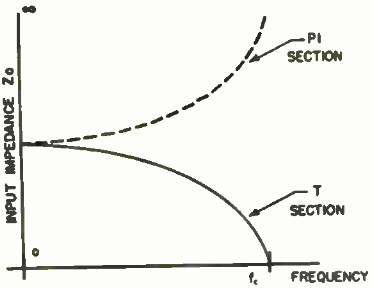

FIG. 45. The characteristic impedance of a prototype T section drops to zero at the cut-off frequency, and that of a pi section rises to a very high value.

resonant, the impedance approaches an infinite resistance. The dotted curve in Fig. 45 shows this typical impedance change for a pi section.

Although these two filter sections may have identical attenuation characteristics, their impedance variations are strikingly different. In general, it may be said that the impedance of any T section drops nearly to zero at a cut-off point, and that of any pi section rises to a very high value.

How can we match a source and load to a filter if the characteristic impedance of the filter varies so widely over the pass band?

In a great many filter applications where it is not necessary to work very close to the cut-off frequency, the change of filter impedance is not serious. In such cases, the impedance variation is ignored, and the source and load impedances are chosen to be equal to that of the filter at frequencies far removed from its cut-off frequency. This gives fair filter performance.

Under these conditions, however, the mismatch at cut-off substantially decreases the cut-off sharpness. For more accurate work, it is necessary to find a better method of matching the changing filter impedance. This *is done by a special type of T section to match a T section, or a special type of pi section to match a pi section,* called "half sections."

Terminating Half-Sections. Filters can be conveniently terminated by means of what are called half sections. Examples of half sections and how they perform are shown in Fig. 46. In A, we have shown the development of a half-section T. This filter is developed by dividing the T into two halves. Notice the value of the leg in the half sections is $2Z_2$, because the two impedances $2Z_2$ in parallel would have a value equal to Z_2, the impedance in the full T section.

Looking into terminals 1 and 2 of the left half of the T, we see the same basic arrangement as in the full T section. However, looking into the terminals 3 and 4 of the left side, the half section looks like the output of a π section filter.

Similarly, looking into terminals 1

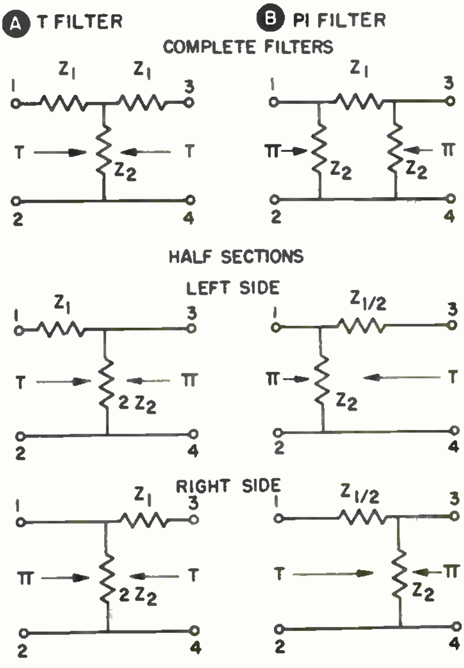

FIG. 46. How half-sections are developed from a T section (A) and a pi section (B).

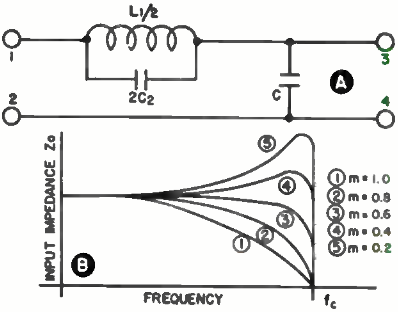

FIG. 47. A terminating half-section, and the variation of its characteristic impedance with frequency for different values of the multiplying factor M.

and 2 of the right half of the filter, we see the same basic configuration as we do at the input to a π section, and looking into terminals 3 and 4 we see it looks like a T filter.

The π filter can be broken down into two half sections as shown at B. Looking into terminals 1 and 2 of the left side, we see the circuit looks like the input to a π section, whereas looking into terminals 3 and 4 of this section we see a circuit similar to the output of a T filter. On the right side, looking into terminals 1 and 2, the circuit looks like the input to a T, and looking into 3 and 4, it looks like the output of a π filter.

Let us suppose that the M-derived pi section, shown in Fig. 44B, is split in half as indicated by the dotted line. If we consider only the right half, we have the half section shown in Fig. 47A.

Now looking into the terminals 3-4, this half section appears as a pi section. *Any full pi section, therefore, can be attached to these terminals without an impedance mismatch, since the two networks have the same impedance at all frequencies.*

Looking into the terminals 1-2, the half section resembles a T section, and the input impedance can be expected to drop to zero at the cut-off frequency. We find, nevertheless, that the manner in which this impedance drops to zero depends entirely upon the value of the multiplying factor M that we used to derive the total section in the first place.

If a value $M = 1$ is used, the half-section impedance varies like a prototype T section. This is shown by curve 1 in Fig. 47B. For lower values of M, the input impedance is more constant over the pass band. The input impedance variation for $M = 0.8$ and $M = 0.6$ is illustrated by curves 2 and 3, respectively. For still smaller values of M, let us say $M = 0.4$ and $M = 0.2$, the input impedance may rise to a high value before it drops abruptly to zero. See curves 4 and 5.

A value $M = 0.6$ gives the best performance, and results in a half-section input impedance that is very nearly constant over about 80% of the filter pass band.

We can use half sections like the one shown in Fig. 47A to match a constant-impedance generator to the variable impedance of a full pi section, or a number of pi sections in tandem. Furthermore, we can use an additional half section at the filter output to match the filter to a constant-impedance load.

A composite low-pass filter, made in this manner, is shown in Fig. 48A. The portion marked B is really the prototype pi section of Fig. 44A. The two terminating half sections, A and C, are made by splitting the derived pi section of Fig. 44B.

As two capacitors in parallel can be replaced by a single capacity, the composite filter can be simplified as shown in Fig. 48B.

Since two half sections have the same attenuation characteristics as a full-derived section, the over-all response of this filter looks like that shown in Fig. 43E. The half sections

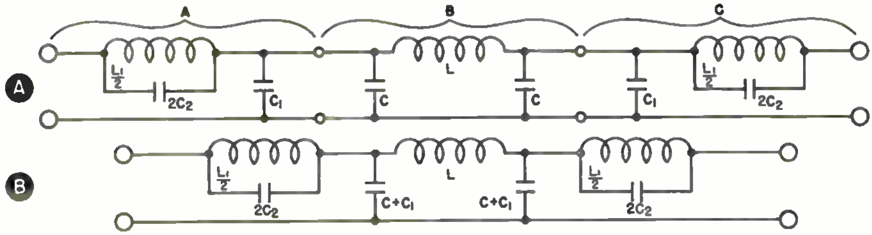

FIG. 48. A, a composite low-pass filter is made by using a prototype pi section and two constant-impedance terminating half-sections. B, the simplified filter, after combining parallel capacities.

have three uses: (a) they present a nearly constant impedance at each end of the filter; (b) they sharpen the cut-off response; (c) they supply an infinite attenuation at one point in the attenuation band.

In a similar manner, it is possible to construct half sections that accurately match a T-section filter. Thus, half sections, from the network shown in Fig. 43C, can be used to terminate a prototype T section like that shown in Fig. 43A. This gives the composite filter that is shown in Fig. 49A, which, in turn, can be simplified as shown in Fig. 49B. The half sections not only provide a good impedance match between source and filter, and between filter and load, but they also improve the general filtering action. The response curve for this composite filter is similar to Fig. 43E.

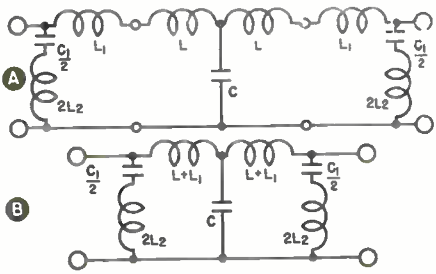

FIG. 49. The use of a T-section prototype with appropriate half sections to make a low-pass composite filter. The network is simplified by replacing two inductances in series, with a single inductance equal to their sum.

DESIGNING FILTERS

We have seen that it is the arrangement of components in a network that determines its general response characteristics. By properly arranging coils and capacitors we can make a network function as a low-pass, high-pass, band-pass, or band-stop filter. However, it is the values of the components that determine just where within the frequency range a filter will pass or reject signals. Therefore, to construct a filter we must be able to determine the values for components as well as their arrangement.

Before we can design a filter for some specific application, we must know which frequencies are to be passed, and which are to be rejected, and the amount of attenuation of unwanted frequencies necessary. In other words, we must know whether it is to be a low-pass, high-pass, band-pass, or band-stop filter. We must know the cut-off frequency of a low-pass or high-pass filter. For band-pass or band-stop filters, we need to know both the upper and lower frequency limits of the band to be passed or rejected. We should know how much attenuation of undesired frequencies is necessary, as it may be necessary to use a multi-section filter to obtain enough attenuation and a sufficiently sharp cut-off.

Let's assume, for example, that we want to construct a filter that will pass all frequencies between 0 and

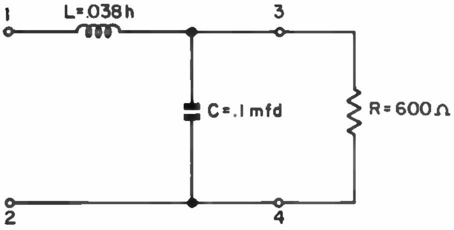

FIG. 50. Low-pass constant-K, L filter.

5000 cycles and attenuate all frequencies above 5000 cycles. Since we wish to pass low frequencies and attenuate high frequencies, we will want a low-pass filter. We know that we can obtain low-pass characteristics by using a series coil and a shunt capacitor in an L network as shown in Fig. 50. Next, we must determine the particular values of inductance and capacitance that will give us a cut-off frequency of 5000 cycles.

The L Filter. To do this, we apply our circuit values to special formulas that have been derived for filter network computation. For a low-pass filter the capacitance is found from the formula: $C = \frac{1}{\pi\ fc\ R}$; and, the inductance from the formula:

$$L = \frac{R}{\pi\ fc.}$$

In both of these formulas R is the impedance of a purely resistive load and fc is equal to the desired cut-off frequency in cycles per second. If we apply these two formulas to our circuit in Fig. 50, we find that the inductance equals:

$$L = \frac{R}{\pi\ fc} = \frac{600}{3.14 \times 5000}$$

$$= \frac{600}{15{,}700} = .038 \text{ henrys}$$

and, the capacitance equals:

$$C = \frac{1}{\pi\ fc\ R} = \frac{1}{3.14 \times 5000 \times 600}$$

$$= \frac{1}{15{,}700 \times 600} = \frac{1}{9{,}420{,}000}$$

$$= .0000001 \text{ farad or, .1 mfd.}$$

Thus, a coil of .038 henrys and a capacitor of .1 mfd arranged in an L network with a load resistance of 600 ohms gives us a low-pass filter with a cut-off frequency of 5 kc.

Converting an L Filter to a T or Pi Filter. We know from our previous discussion of filters that we can improve the cut-off curve for our filter and match impedances by converting the L network to a T or pi network. To do this, we simply use two coils of half the inductance value for the T filter as shown in Fig. 51A. Or, if we prefer the pi filter, we could use two capacitors of half the capacitance as shown in Fig. 51B. The choice of using either a T or a pi filter is simply a matter of convenience, as they give exactly the same performance. The

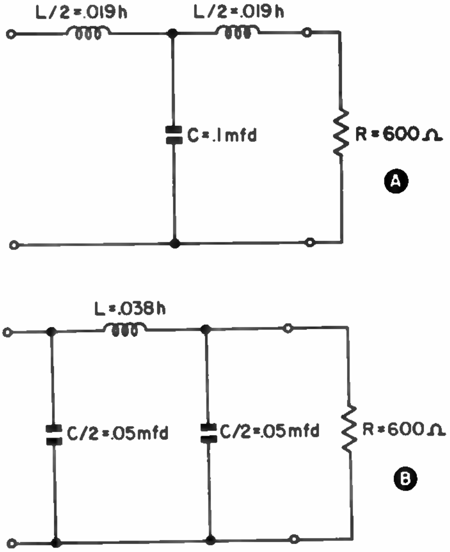

FIG. 51. Low-pass constant-K filter converted to T network, A; low-pass constant-K filter network converted to pi network, B.

choice is usually based on availability of components.

M-Derived Filter. The filter that we have just computed is a prototype, or constant-K filter. We know from the previous section on filter principles that we can get a sharper filter cut-off and obtain better impedance matching throughout the pass band by using an M-derived filter. An M-derived T section is formed by inserting an inductor in series with the leg capacitor of a prototype T section as shown in Fig. 52.

The addition of this new inductance causes the attenuation to rise sharply to a very high value as soon as the cut-off frequency is reached. This is due to the fact that the leg of the filter is designed to be series resonant at some frequency slightly above cut-off. When resonance occurs, nearly all the current is shorted around the load, giving us almost infinite attenuation.

In an ordinary constant-K filter, when the cut-off frequency is reached, the attenuation increases gradually to some maximum value as the frequency is increased above cut-off. In the M-derived filter, we actually make the attenuation curve above cut-off rise sharply by making the frequency of maximum attenuation occur nearer the cut-off frequency than it normally does. Therefore, the sharpness of the cut-off curve depends on the location of the frequency of maximum attenuation with respect to the cut-off frequency.

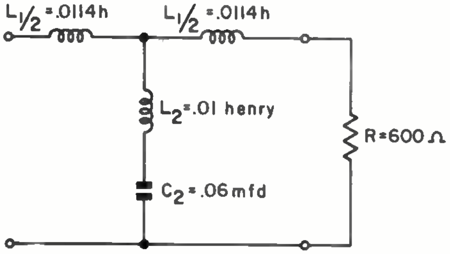

FIG. 52. Low-pass constant-K, L filter converted to M-derived T network.

The factor M from which the M-derived filter gets its name relates to the ratio of this frequency of maximum attenuation, f∞, and the cut-off frequency, fc. For a low-pass filter, M is found from the following formula:

$$M = \sqrt{1 - \left(\frac{fc}{f\infty}\right)^2}$$

For a high-pass filter, M is found from the formula:

$$M = \sqrt{1 - \left(\frac{f\infty}{fc}\right)^2}$$

Converting a Constant-K Filter to an M-Derived Filter. To change an ordinary constant-K filter to an M-derived filter, we add the proper reactance component to the filter and change all the values by an amount depending on the value of M. To see how this works, let's convert the low-pass constant-K, T section, shown in Fig. 51A to the M-derived filter shown in Fig. 52.

The first thing we must do is select a value for the frequency of maximum attenuation, f∞. If we make the frequency of f∞ equal to 6250 cycles, we can then find the appropriate value of M from the formula:

$$M = \sqrt{1 - \left(\frac{fc}{f\infty}\right)^2} = \sqrt{1 - \left(\frac{5000}{6250}\right)^2}$$

$$= \sqrt{1 - .8^2} = \sqrt{1 - .64}$$

$$= \sqrt{.36} = .6$$

To find our new value L to use for our arm coils L_1, we simply multiply our original value of L by our value of M. This gives us:

$$L_1 = LM$$

$$= .038 \times 6$$

$$= .0228 \text{ henrys.}$$

We divide this new value L_1 by 2 to obtain the correct value for each of our arm coils. Thus our new arm inductances are .0114 henrys each.

Our capacitor C_2 is also determined by multiplying the original value of C by M. Or

$$C_2 = CM = .1 \times .6 = .06 \text{ mfd.}$$

The value of the inductance L_2 that we inserted in the leg of our network is found by applying our original value of L in the following formula:

$$L_2 = \frac{1 - M^2}{4M} \times L$$

$$= \frac{1 - .36}{2.4} \times .038$$

$$= \frac{.64}{2.4} \times .038 = \frac{.02432}{2.4}$$

or, approximately .01 henry.

If we prefer, we can use the M-derived pi section shown in Fig. 53. In this filter, the value of our capacitor C_2 used in the T section is divided by 2 to form the two legs of our M-derived pi section. We have a new capacitor C_1 in parallel with our inductance L_1 to form our filter arm. The value of L_1 is the sum of the two arm inductances $L_1/2$ used in the T section. The value of C_1 is found by substituting the original value of C that we used in our L filter in place of the value of L in the formula:

$$L_2 = \frac{1 - M^2}{4M} L \text{ or,}$$

$$C_1 = \frac{1 - M^2}{4M} C = \frac{.64}{2.4} \times .1$$

$$= \frac{.064}{2.4} = .026 \text{ mfd.}$$

These formulas, along with those used for high-pass, band-pass, and band-stop filters, are shown with their appropriate circuit diagrams in Fig. 54. Notice that in these circuits and formulas, the subscript 1 indicates an arm reactance and the subscript 2 is used for the leg components where necessary to avoid confusion between reactances. Although we have shown the formulas for M-derived, high- and low-pass filters, we have not shown them for band-pass and band-stop filters. The m-derived band-pass and band-stop filters become much too complex for anyone except filter design specialists.

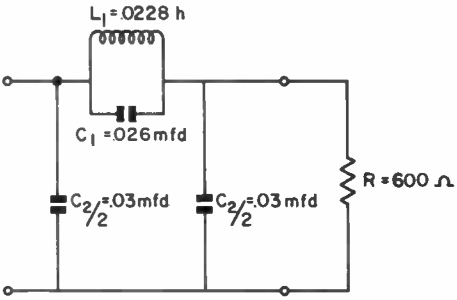

FIG. 53. Low-pass constant-K, L filter converted to M-derived pi network.

In these formulas, the units for F, L, C, and R are in cycles-per-second, henrys, farads, and ohms, respectively.

Factors Affecting Design. The standard equations for constructing filters are based on lossless elements which are pure reactances. Thus, in actual practice, the response of a filter may be somewhat different from what was expected. How great this difference will be depends on the care that was exercised in choosing the parts and in constructing the filter.

A high-Q coil has very little loss, since it is mostly inductance and very little resistance. When a lower-Q coil is used, the losses are increased. Also, when a low-Q coil is used in a tuned circuit, the response of the circuit is broadened. It will no longer be as sensitive to frequencies at or near the resonant frequency.

There is always some capacitance between the adjacent turns of the coil winding, and this lowers the Q and increases the losses. Coils wound with wire insulated with a material having

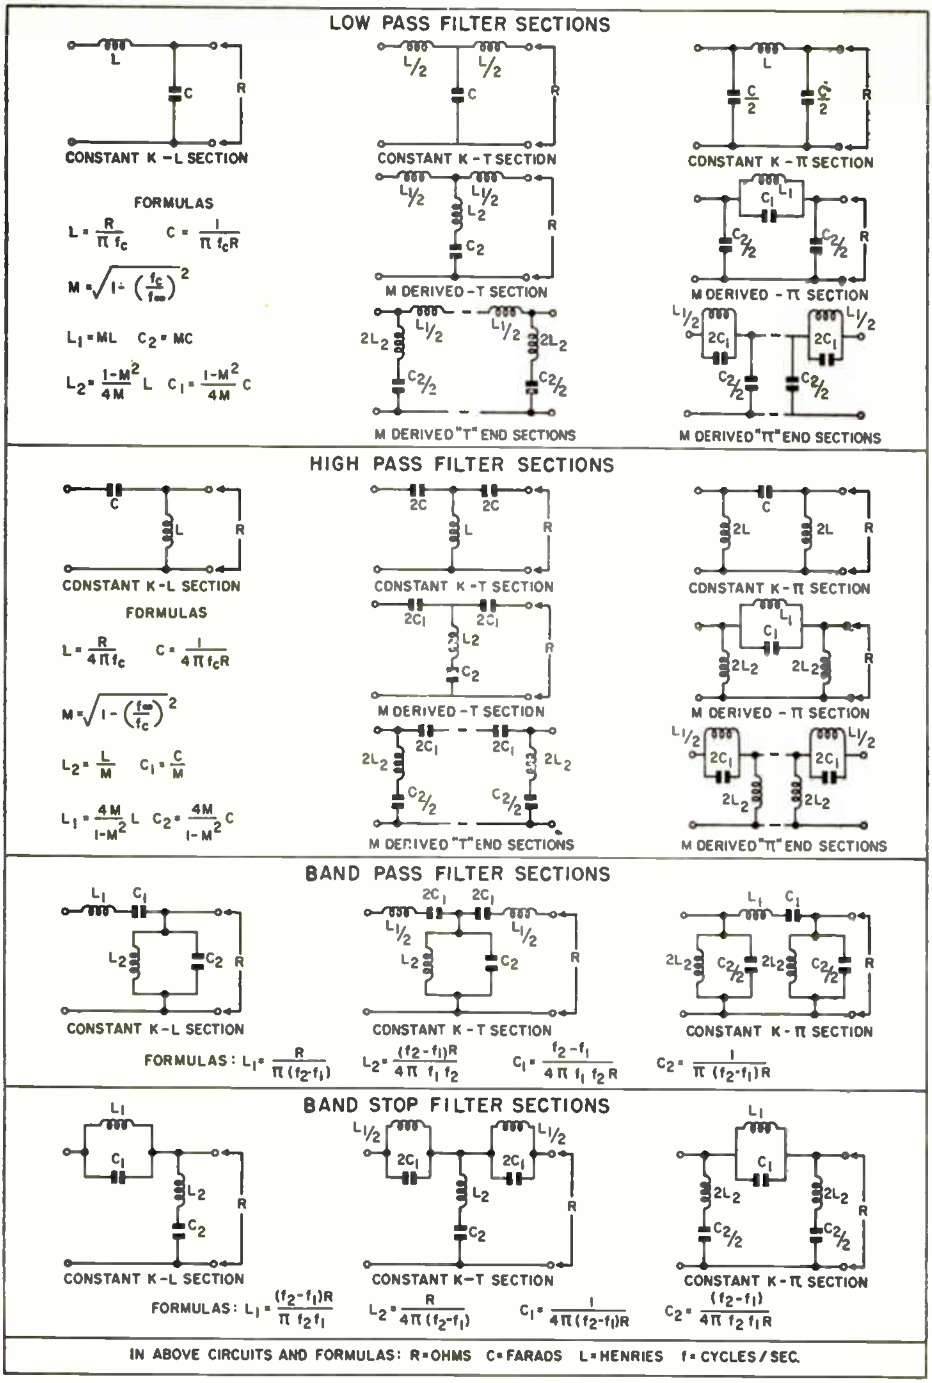

FIG. 54. Basic filter circuits and formulas.

low dielectric hysteresis loss are the best from this standpoint.

When two coils or two circuits are physically near each other, usually some coupling exists, although none may have been intended. The magnetic field about one coil or circuit induces a current in the other. Also the metallic parts of the two circuits form a small capacitance through which energy may be transferred. The Q of a coil is lowered by the loss of energy coupled out of it, and the response of the filter may be seriously altered.

This effect can be minimized by the proper placement of the parts (physical separation, mounting coils at right angles to each other, etc.) and by careful shielding. Shielding a coil lowers its inductance and also results in an energy loss because of the resistance of the shield, which increases the effective resistance of the coil. These effects lower the Q of the coil, but the reduction will be slight if the spacing between shield and coil is equal to at least the coil diameter at the coil ends and at least half this distance at the coil sides.

At power supply or audio frequencies, eddy current losses in iron-core coils may be reduced by constructing the cores of thin metal sheets called laminations. At higher frequencies, it is not practical to try to make laminations small enough or thin enough for use in coil cores. Coils used at these frequencies are air-core coils or have cores made from powdered iron mixed with a suitable binder The binder holds the particles together so that they can be shaped to the form desired and also insulates them from one another to prevent eddy currents. A type often used in communications equipment is the toroid coil. It is a single-layer or multi-layer coil wound on a doughnut-shaped powdered-iron core. An advantage of this type is that, so long as the core is unbroken, all of the lines of force are in the core and none outside. As a result, shielding is seldom necessary to prevent coupling between a toroid coil and another coil or circuit.

MEASURING FILTER RESPONSE

When checking filter response, great care must be exercised in setting up the equipment to avoid any stray coupling or leakage. All the units in the test setup must be bonded together and a good common ground provided.

Insertion Loss. The insertion loss of a filter is simply the loss in output, usually expressed in db, caused by inserting a filter in a circuit When the filter is to be tested before installa-

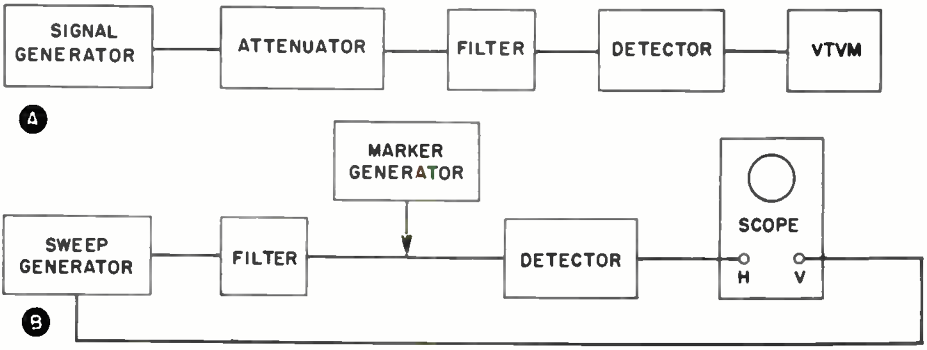

FIG. 55. Test setups for measuring (A) insertion loss, and (B) frequency response of a filter.

tion, a setup such as that in Fig. 55A can be used to measure this insertion loss. The signal source can be a signal generator, with or without modulation. For low frequencies, the output meter may be a db meter or a vtvm. For rf frequencies, a vtvm should be used. In some cases, the needed output is most conveniently obtained by feeding the filter output to a good receiver.

Using the lowest signal level that provides a usable indication with the filter in the circuit, the output is noted. Without changing the amplitude of the input signal, the filter is removed from the circuit, the circuit is reconnected, and the output is noted. The difference in the two readings is the insertion loss of the filter.

The attenuator at the input of the filter is provided to reduce the input signal to the lowest amplitude that will give a usable indication on the meter with the filter in the circuit. Unless the input signal is kept as low as possible, there may be so much leakage across the filter that the results obtained are inaccurate.

It is important for the shielding for the test setup to be as good as it can be made, particularly when dealing with rf frequencies. With rf frequencies, it is difficult to obtain accurate results at best, and without adequate shielding, it becomes impossible.

In most cases, the most satisfactory check of the insertion loss of a filter is simply to try the filter in the circuit and see if it does the job for which it was designed. Ordinarily, you'll know how much attenuation of unwanted frequencies is necessary and how much attenuation of wanted frequencies can be tolerated. If the circuit works satisfactorily after the filter is installed, you won't usually need to know or care exactly what the insertion loss measures.

Filter Response. The response curve of a filter can be checked either by a point-to-point method or by using a sweep signal generator and an oscilloscope to obtain a visual indication of the response curve. In the first method, the signal generator is connected to the input of the filter, and its frequency set to some point within the expected pass band. An output meter is connected to the output circuit and the signal generator set to give a convenient indication. Then the signal generator is set to the lowest frequency at which there is any response, and the frequency is advanced in equal steps, and the output at each frequency recorded. These readings are plotted on graph paper in db, the frequency being plotted horizontally and the output vertically.

A more convenient method of checking response is shown in Fig. 55B. Here the response curve can be observed and the effects of any adjustments noted. A marker generator set to the proper frequency and loosely coupled to the filter can be used to inject a pip at the cut-off frequency or any other point of interest within the band.

Lesson Questions No. 29

Be sure to number your Answer Sheet 29CC.

Place your Student Number on *every* Answer Sheet.

Most students want to know their grade as soon as possible, so they mail their set of answers immediately. Others, knowing they will finish the next lesson within a few days, send in two sets of answers at a time. Either practice is acceptable to us. However, don't hold your answers too long; you may lose them. Don't hold answers to send in more than two sets at a time or you may run out of lessons before new ones can reach you.

1. What are two reasons for using attenuators?
2. Use the table in Fig. 9 to compute the values of R_A (the arm resistors) and of R_L (the leg resistor) in a T-type resistive pad in which the output and input are both 60 ohms, and attenuation is 8 db.
3. Complete the following: A minimum loss L pad is used to (a) match unequal impedances; (b) provide attenuation and maintain an impedance match between equal impedances; (c) filter out undesirable harmonics.
4. What requirement must a network have before it can be considered a filter?
5. Name the four basic types of filter circuits.
6. Name the filter circuit you would use if you wanted to pass only the band of frequencies between 3,000 cycles and 10,000 cycles.
7. If we connect three low-pass T sections in tandem, what effect will this have on the attenuation of the unwanted frequencies as compared with a single low-pass, T-section filter?
8. What information must you have before you can design a filter circuit?
9. Compute the values of L and C in a simple, constant-K, L-section, high-pass filter having a characteristic impedance of 100 ohms and a cut-off frequency of 100 cycles.
10. Complete the following: A long line, such as a telephone line (a) attenuates the low frequencies more than the highs; (b) attenuates the high frequencies more than the lows; (c) attenuates the highs and lows about equally.

"WISHERS" AND "DOERS"

How often have you said, "I wish I had more money?" Thousands of times, possibly. But do you realize that if you are living in a town of, let us say, 5,000 inhabitants, there are exactly 4,999 others in your town who are saying exactly the same thing?

And yet, of these 5,000 "wishers," only about 100 are going to do something about it. The others are going to continue being "wishers."

Now, any man who shows enough "get-up-and-go" spirit to undertake this course proves that he is not a mere "wisher." When you enrolled, you showed that you wanted to be a "go-getter." Your job now is to keep going forward on the road you have mapped out for yourself.

Every lesson in this course, every job you work hard to get, is a step along this road. So don't let yourself wish that the lessons were easier, or that you could become successful without studying, or that jobs would come looking for you. Stay out of the class of the "wisher," and stay in the class of the "doer."

OPERATIONAL AMPLIFIERS

This lesson is your detailed study of one of the most important types of amplifiers used in electronics today – the operational amplifier. Its application is almost unlimited because of its great versatility. This type of amplifier is also the key element in all analog computers. The operational amplifier, in its numerous configurations, can help perform many mathematical operations.

Since you previously had a brief introduction to the operational amplifier, you should already have a basic idea of what it is and how it is used. However, this lesson will expand your basic knowledge of this important circuit.

Like any other amplifier, an operational amplifier has an input and an output. Amplifiers generally increase the level of the input signal and present it at a higher level at the output; therefore the operational amplifier circuit has gain and amplifies small signals that are applied to its input.

An operational amplifier is basically a linear amplifier which accurately reproduces the shape of the input signal. However, it possesses special characteristics which set it apart from more conventional amplifiers and permit it to be a much more versatile circuit.

The term "operational" came about because of the early use of an amplifier to perform mathematical operations. Today these amplifiers still perform their original operations, but they have also become adapted to be used for many other functions.

Operational amplifiers, commonly called op amps, come in many different forms. For example, the very earliest types of op amps were made with vacuum tubes. A typical vacuum tube op amp is shown in Fig. 1A, where you can see the vacuum tubes, resistors and capacitors mounted on a printed circuit board. The seven circular metallic devices are miniature vacuum tubes. The large rectangular object is a mechanical chopper. While you may still encounter tube type op amps in some older equipment, the majority of operational amplifiers in use today are transistorized units. A transistorized operational amplifier is shown in Fig. 1B. The large cylinder is a chopper. Again, all of the components are mounted on a printed circuit board.

Today integrated circuit operational

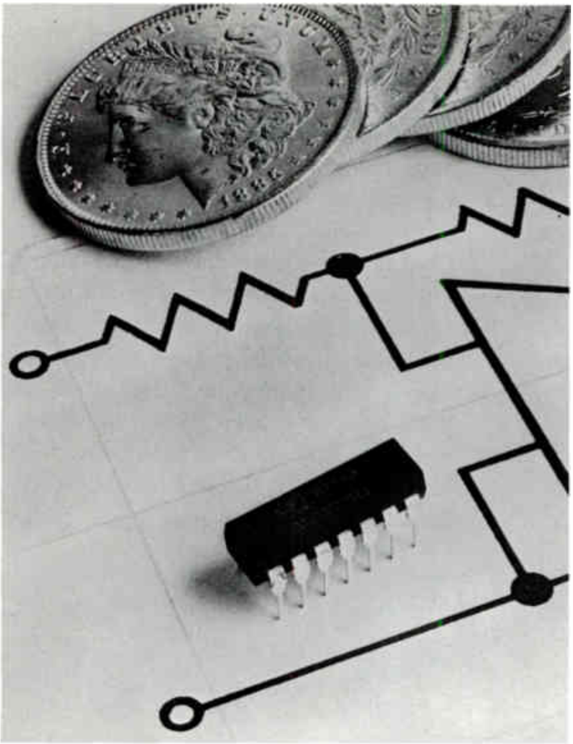
Fig. 1. A tube type operational amplifier (A) and a transistorized operational amplifier (B).

amplifiers are rapidly replacing the discrete component types in many applications. An integrated circuit operational amplifier is an entire miniature transistor amplifier constructed on a single chip of silicon, in much the same way a transistor is made, and housed in a small multi-lead package like that shown in Fig. 2. Notice the extremely small size of this amplifier. Such an amplifier is as sophisticated as and generally superior to the tube and transistor operational amplifiers of Fig. 1. Later in this lesson we will take a look at some of the circuit details of transistor operational amplifiers. The emphasis in this lesson will be on the transistor type circuit; these are the circuits you will most encounter in your work, in both discrete and miniature integrated circuit form.

An amplifier has to have certain distinct characteristics before it can be called an op amp. The extent to which it meets these requirements indicates how good an operational amplifier it is. Even though the perfect operational amplifier cannot be made, its value is based on how closely it can approach the characteristics of the ideal amplifier.

One characteristic of an ideal oper-



Courtesy Texas Instruments

Fig. 2. Integrated circuit operational amplifier in a dual in-line package.

ational amplifier is that it must be a dc amplifier, that is, it must amplify slowly varying signals or dc levels. In order to amplify or pass very low frequency ac signals or dc levels, direct coupled circuitry is usually used.

The ideal op amp should also have a zero output voltage if the input voltage is zero. Many amplifiers do not have this characteristic. With a zero voltage input signal applied, many amplifiers have a fixed dc output voltage. When the input signal is applied the output varies above and below this fixed dc output level. Although this is not detrimental to circuit performance, it is more convenient for an op amp to have the output voltage zero when the input is zero. If only ac signals are to be used, then a capacitor can remove this output level. However, remember that we want our op amp to have the capability of measuring, or amplifying, dc signals.

Thirdly, the ideal op amp must have very high input impedance. When connected to a source of signal voltage, its impedance is so high that it will not draw any current from the source; its input impedance is infinite.

Ideally the op amp must also have low drift. In other words, it must be a perfect dc amplifier whose output does not vary with changes in circuitry or surroundings.

The ideal op amp will have a zero output impedance. This means that if any load resistance is connected to it, the output will not be loaded down since there is no internal circuit resistance present. With a zero output impedance, the op amp is a perfect voltage source with an output voltage that remains constant regardless of the load connected to it.

Another ideal factor is minimum power consumption. A good op amp will not draw a lot of current from its power supplies during operation.

* Optimally, the amplifier should be a differential amplifier. Op amps can be constructed with a single-ended rather than a differential input. However, most operational amplifiers you encounter will be differential amplifiers.

In order to function at its best, the op amp must have very high voltage gain. A minimum figure is 1000 (most have gains higher than 10,000).

As noted before, the perfect op amp does not exist. Even so, actual operational drawbacks are hard to find. Just what degree of departure from the ideal that can be tolerated depends strictly upon the amp's specific application. Each requirement for an op amp will have to be investigated to determine those characteristics needed or desired. For example, a particular requirement may call for an op amp with input impedance greater than one megohm, voltage gain greater than 25,000 and output impedance less than 200 ohms. Even though these characteristics are less than ideal, they accurately satisfy the requirements of the particular application.

3-16-76

Fundamentals

An op amp is nothing more than a combination of some of the individual amplifier circuits you studied before. For example, a typical op amp may consist of a differential amplifier direct coupled to an emitter-follower which drives a complementary symmetry output circuit. All of these amplifiers and fundamentals you learned in previous lessons. Here we will collect this information and show you how an op amp is formed.

To begin, however, we will emphasize only the fundamentals of the op amp. Once you understand the overall concept, you can begin to study the detailed circuit operation.

In most of this lesson you will see the op amp designated by the symbol in Fig. 3. The letter A inside the triangle designates the gain of the amplifier.

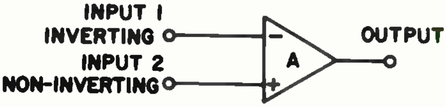


Fig. 3. Basic operational amplifier symbol.

This op amp has two inputs; therefore, it is a differential amplifier. The – and + signs on the inputs designate the inverting and non-inverting input lines. Input 1 is designated with a negative sign, indicating that it is the inverting input. If a signal is applied to input 1, the output will be 180° out-of-phase with the input. When input 1 is used, the op amp is an inverter. Input 2 is designated by a positive sign; it is the non-inverting input. Any input signal applied here will appear in the same phase in the output.

If we apply an input signal to the amplifier, an output signal will be generated. The input signal will be amplified by an amount equal to gain A of the amplifier. If the input signal is very small, it will appear greatly enlarged at the output because of the high gain.

If the input signal to the op amp is too high, the amplifier output will be clipped. For example, if we apply a 1 volt input signal to an op amp with a gain of 50,000, our output should theoretically be equal to the input multiplied by the gain, or 50,000 volts.

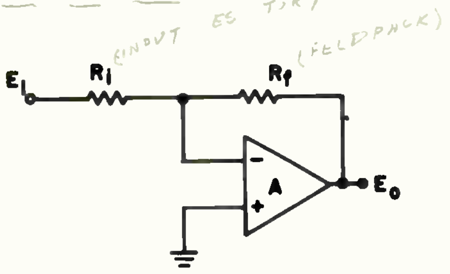
This, of course, cannot actually happen. The output of any amplifier is limited by the power supply voltages. Most op amps are powered with both positive and negative voltages. A typical transistor op amp, for example, uses power supplies of +15 and –15 volts. For this reason the output cannot swing any greater than ±15 volts (for a sine wave signal, no more than 30 volts peak-to-peak). Should the input voltage be too high and try to cause an output voltage beyond the power supply capability of the amp, the output signal will be clipped on both positive and negative peaks. This is due to the saturation of the output transistors.

Since its gain is so high, the op amp can be used satisfactorily with only very low level signals. The gain is also unstable, varying greatly from one amplifier unit to the other of the same type. One operational amplifier may have a gain of 25,000 while an identical amplifier may have a gain of 35,000. While the circuits of the two amplifiers may be identical, various characteristics of the components could cause large gain differences. For many applications this is a disadvantage.

✓

To overcome this problem we generally use negative feedback with op amps; some of the output voltage from the amplifier is fed back to the inverting input through a resistor. As you learned in the previous lesson, negative feedback reduces the overall gain of an amplifier and at the same time stabilizes it. It also improves frequency response

The most common op amp circuit is shown in Fig. 4. Here the non-inverting input to the amplifier is grounded. This eliminates the differential characteristics of the amplifier so we can use it as a single-ended circuit.



$$A = -\frac{R_f}{R_i} \qquad E_o = -\frac{R_f}{R_i}(E_i)$$

Fig. 4. Standard operational amplifier circuit.

Negative feedback is provided by the feedback resistor R_f connected between the output and the inverting input. An input resistor designated as R_i is also connected to the inverting input. The free end of this resistor is the input to the circuit. With this arrangement the gain of the circuit is determined strictly by the ratio of the feedback to input resistances: gain = R_f/R_i.

Negative feedback makes the gain of the circuit completely predictable. To control or set the gain of this amplifier, we simply select appropriate values of feedback and input resistors. For example, if the feedback resistor R_f is equal to 100K-ohms and resistor R_i is equal to 10K-ohms, the gain of the circuit is 100K/10K = 10. Keep this fact in mind.

Another important characteristic of this circuit is that it is an inverter. Since we are using the inverting input of the amplifier, the output signal will be 180° out-of-phase with the input signal. When expressing the gain, a negative sign is indicative of this inversion.

In Fig. 5 we show all the currents and voltages in a standard op amp circuit. The input resistor is designated R_i while the feedback resistor is designated R_f. Current flowing in the input resistor is designated as I_i; current flowing in the feedback is I_f. I_b is the current flowing into the input. It is generally the base current of a transistor. The amplifier input voltage, or that voltage appearing directly at the input of the amplifier, we label E_b. The input voltage to the entire operational amplifier circuit is designated as E_i. The output voltage is E_o.

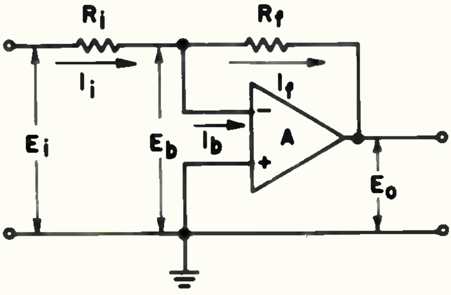


Fig. 5. Currents and voltages in an op amp.

Using these currents and voltages and some simple Ohm's Law relations, let's again see how the gain formula for this circuit is obtained. First of all, we know that the output is equal to the input voltage multiplied by the gain. The output voltage E_o, then, is equal to E_b times $-A$. To find the value of E_b, we algebraically rearrange the formula to produce $E_b = -E_o/A$. Remember that the negative sign indicates inversion.

From earlier lessons you found that the voltage across any component is equal to the difference in the two voltages at the ends, with respect to ground. For example, if we measure 10 volts at one end of a resistor and 7 volts at the other, the voltage across that resistor is 3.

With this in mind, we can write a formula for the voltage across the input and feedback resistors. The voltage across the input resistance R_i is equal to $E_i - E_b$. The voltage across the feedback resistor R_f is equal to $E_b - E_o$. Knowing the voltages across the resistance, we can write a simple Ohm's Law expression for the current through each resistance. For example, the current I_i through the input resistor is equal to the voltage across it $(E_i - E_b)$ divided by R_i. The current I_f through the feedback resistor is equal to the voltage across it, $(E_b - E_o)$ divided by the resistor R_f.

Refer to Fig. 5, where the current flowing into the amplifier is I_b. If we assume that our op amp is perfect and has an infinite input impedance, we can conclude that it will not draw current from the input source; therefore, $I_b = 0$. Because of this the input current I_i also flows in the feedback resistor R_f. This means that the input and feedback currents are equal. We can write a simple expression for their equivalence:

$$I_i = I_f$$

or

$$\frac{E_i - E_b}{R_i} = \frac{E_b - E_o}{R_f}$$

Now, let's make another assumption based on the characteristics of an ideal op amp. Earlier we said that the input voltage E_b is equal to the output voltage E_o divided by the gain $-A$. The gain is so high that the input voltage E_b is extremely small. It is so small, in fact, that for all practical purposes we can call it zero. If we assume a zero value for E_b, we can remove E_b figures from the formula. Thus simplified it reads:

$$E_i/R_i = -E_o/R_f$$

From this we can find that the output voltage is equal to the gain of the circuit, the ratio of the feedback to input resistances, multiplied by the input to the circuit:

$$E_o = -\frac{R_f}{R_i}(E_i)$$

The negative sign again indicates inversion. As you can see, we have used only algebra and Ohm's Law to determine the gain of the op amp circuit.

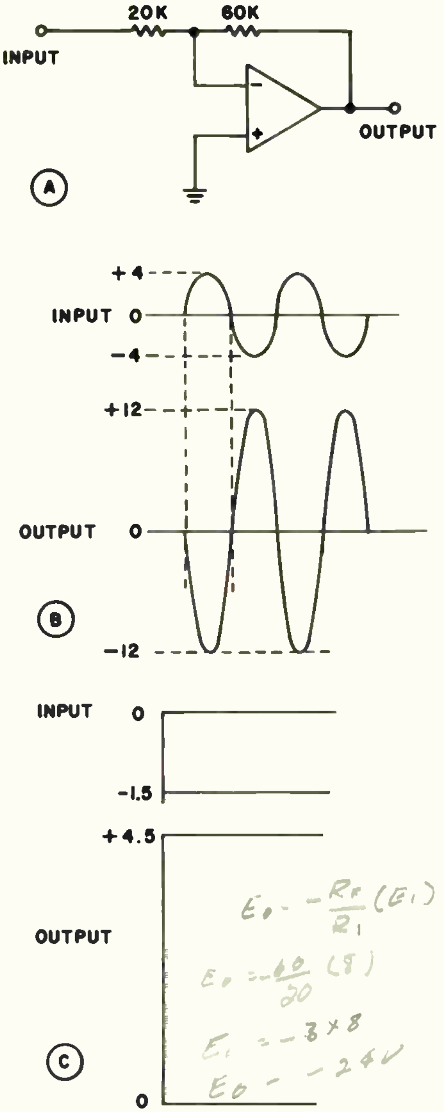
Keep in mind several things. We assumed that the input current to the amplifier was zero. As a result, we neglected it. We also assumed that the gain of the amplifier was infinitely high. Even though we had to use these assumptions to approach the ideal, the formula given will be quite satisfactory for an op amp with a gain of 1000 or more.

There is one very important characteristic of the op amp in its standard configuration. As mentioned earlier, the input impedance to a good op amp is very high. This, of course, is true in the circuit of Fig. 5. However, the input impedance of the circuit is not the same as the input impedance of the amplifier. The feedback and input resistor connections determine what the input impedance will be.

The input voltage to the amplifier (E_b) is near 0 volts, or ground. Since E_b gives the same effect as a true ground, we can more precisely call it a virtual ground. This is the case of the junction of the feedback and input resistors at the inverting input of the amplifier in Fig. 5. This point is called the summary junction because it is the input and output of all the currents in the circuit.

Since we can consider the right hand of resistor R_i as being connected to ground, the input impedance of the amplifier circuit is equal to the value of resistor R_i. If R_i is 100K-ohms, then the input impedance of the circuit is also 100K-ohms. This is a usually desirable characteristic of this circuit because the exact input impedance to the circuit is known. In the case of the input impedance of the amplifier, we do not always know its exact value. Of course, if it is high enough it will not affect the circuit. Therefore, we need not always be concerned with it. However, the input resistance produced by resistor R_i often is not high enough to suit the application. In that case we have to make a compromise in the gain of the circuit by adjusting the values of R_f and R_i to give an appropriate input resistance.

Now let's see how a typical op amp circuit works. Fig. 6A shows an op amp with a 60K feedback resistor and a 20K input resistor. From this circuit you know that the input impedance is equal to 20K, the value of the input resistor. We can figure the gain of the circuit by finding the ratio of the feedback to the input resistance (60K/20K = 3). The circuit will amplify an input signal by a factor of three.



$E_0 = -\frac{R_f}{R_1}(E_1)$

$E_0 = -\frac{60}{20}(8)$

$E_i = -3 \times 8$

$E_0 = -24V$

Fig. 6. A conventional op amp circuit (A), typical ac input-output waveforms (B) and dc input-output levels (C).

Fig. 6B is a sine wave input signal of 8 volts peak-to-peak. If we apply the peak signal voltage to the input of the amplifier circuit, the output shown in Fig. 6B will be produced. Notice that the amplitude of the output is 3 times that of the input. The peak output voltage is 12 volts or 24 volts peak-to-peak. Notice also that the input and output signals are 180° out-of-phase, designating the inverting characteristic of the op amp circuit.

The op amp can also amplify dc signals. Fig. 6C shows a negative 1.5 volt input applied to the amplifier circuit. This is amplified and inverted to produce an output of +4.5 volts. If the input signal is removed from the circuit and the input line grounded, then the output of the amplifier should be 0 volts. Because of unbalanced amplifier circuits, the output may be only near 0 volts. In most op amps it is necessary to reduce the output to exactly zero; some form of compensating voltage must be applied to the circuit to bring the output voltage to zero.

A popular variation of the circuit shown in Fig. 6 is one where both the input and feedback resistors are equal. Since these resistors are equal, the gain of the circuit is equal to 1. We say that the amplifier has unity gain. An op amp connected this way is called a unity gain inverting amplifier. Since it has no gain you might think that it has no application. However, it is widely used where we want to maintain the amplitude level of a signal and at the same time obtain 180° phase inversion. The circuit acts as a good isolation amplifier with a relatively high input impedance and low output impedance.

In many ways this circuit also acts like the emitter-follower circuit you studied in a previous lesson. The gain is 1, but in this case the amplifier produces inversion which the emitter-follower does not. The low output impedance gives the circuit the ability to provide power amplification.

It is important to note that we can obtain gains less than or greater than 1 because we set the amplifier gain strictly by the ratio of the feedback to input resistors. If we make the input resistance greater than the feedback resistance, the gain will be a fraction. If we put a 2 volt peak-to-peak signal into an amplifier with a gain of .5, the output will be half this, or 1 volt peak-to-peak. The amplifier, with its gain of less than 1, is actually producing a loss. Even though this circuit appears to be ineffective, it is often used in analog computers.

SELF-TEST QUESTIONS

(a) True or false: An op amp is usually a differential amplifier.

(b) True or false: The gain of an op amp circuit is equal to the ratio of the input to feedback resistors. RF : RIN

(c) True or false: An op amp can amplify both ac and dc signals.

(d) True or false: The output signal of an op amp is inverted, or 180° out-of-phase with the input.

(e) True or false: An op amp cannot be connected to provide a gain less than one.

(f) What is the gain of an op amp whose input resistor is 12K and feedback resistor is 84K? 7

(g) An op amp circuit, like that in Fig. 4, has a gain of 4. The input signal is a dc voltage of −3.5. What is the amplitude and polarity of the output?

(h) Name five important characteristics of an op amp.

-16-

1: HIGH OPEN LOOP GAIN
2: HIGH INPUT IMPEDANCE
3: LOW OUTPUT IMPEDANCE
4: WIDE FREQ. RESPONSE
5. DIRECT COUPLING
6: LOW DRIFT
7: LOW POWER CONSUMPTION
8: DIFFERENTIAL INPUTS.

E0 = -4(-3.5
E0 = 14✓

Applications

Early use of op amps was limited primarily to analog computers. Vacuum tube op amps were large, expensive and complex. In order to obtain the accuracies necessary in an analog computer, op amps had to be quite sophisticated. But because of their high cost and complexity, they were not practical for more common electronic applications. However, as transistor op amps were developed, many of the problems associated with the vacuum tube types were eliminated.

For that reason, the op amp has become a practical circuit element. Today it is a common building block, not only in analog computers, but also in many other electronic devices and systems. Design engineers now use op amps as a matter of course in equipment they design.

The op amp is quite versatile in electronic circuits. By varying the types of components in the input and feedback circuits and their particular connections, an extremely wide variety of different operations can be performed. In fact, the op amp is practically unlimited in its application.

In your work you will discover op amps in several major connections. You have already seen the most common op amp connection, where the amplifier provides gain and phase inversion. Now let's examine some other typical op amp connections.

NON-INVERTING OP AMP CIRCUIT

There are times when the phase inversion of the common op amp is not desirable. In such applications we might want a high input impedance, a low output impedance, a particular gain, and no inversion of the signal. This operation can be accomplished by providing the gain in an op amp circuit and compensating for the phase inversion with a unity gain inverter.

Fig. 7 shows how this is done. Suppose we want a gain of 3 with no phase inversion. Amplifier 1 provides the gain of 3. Since this circuit produces phase inversion, we follow it with a unity gain inverter stage to remove the inversion produced by the first amplifier. While this circuit is used in some situations, it wastes parts and power. There is a simpler way to eliminate phase inversion.

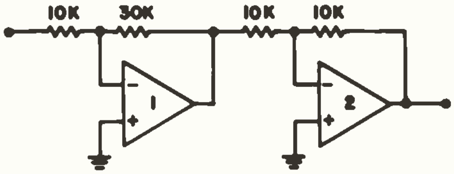

Fig. 7. Using a unity gain inverter to correct for inversion.

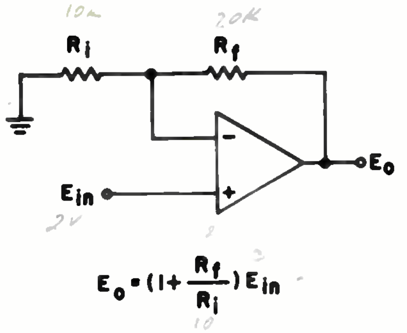
In Fig. 8 we show a non-inverting op amp circuit. In this circuit the non-inverting (+) input is not grounded. Instead, we apply the input voltage to this terminal. Input and feedback resistors are connected to the inverting input, but the end of input resistor R_i (normally connected to a signal) is connected to ground. This connection provides a gain that can be adjusted by setting the values of resistors R_f and R_i. The output voltage of this circuit is equal



$$E_0 = \left(1 + \frac{R_f}{R_i}\right) E_{in}$$

Fig. 8. A non-inverting op amp circuit.

to the input voltage multiplied by (1 + R_f/R_i). As you can see the gain is again a function of the ratio of the feedback to input resistances. But because of the particular connections, a value of 1 must be added.

Let's take a typical example and calculate the gain of this non-inverting circuit. Assume feedback resistor R_f is equal to 20K and input resistor R_i is 10K. If we have an input voltage of 2 volts, what will the output voltage be with the gain obtained?

First let's calculate the gain of the circuit: (1 + R_f/R_i) = (1 + 20K/10K) = (1 + 2) = 3. If the input voltage is 2 volts, then the output voltage will be 2 times 3, or 6 volts. Keep in mind that this is a non-inverting circuit. If the input is a sine wave, then the output will be in phase with the input. If the input is a dc voltage, the input and output polarities will be the same.

One of the biggest advantages of this circuit is the high input impedance. With the standard op amp configuration, the input impedance is equal to the value of the input resistor. For some applications this may be very low, causing undesired loading on the driving source. However, in this circuit the input signal is applied directly to the non-inverting input. This input is usually a very high impedance (an infinite impedance for an ideal op amp). Therefore, very little loading of the driving source will occur.

OPERATIONAL AMPLIFIER FOLLOWER

Take a close look at the gain formula for the non-inverting amplifier circuit in Fig. 8. The gain is equal to 1 plus the ratio of the feedback to the input resistances. What would happen if we were to increase the value of resistor R_i in this formula? The ratio of R_f to R_i would decrease. If we made R_i infinite, or disconnected it from the circuit altogether, the gain of this amplifier circuit would be 1. When this condition occurs, we have what is known as an op amp follower.

You already know about cathode and emitter-follower circuits. These are non-inverting buffer circuits whose output is very nearly equal to the input. The non-inverting op amp circuit is easily converted into a follower type circuit. The input resistor is removed and 100% feedback from output to input through resistor R_f is provided to the inverting input terminal. For this type of circuit the feedback resistance can be eliminated and the output connected directly to the inverting input.

The typical follower circuit is shown in Fig. 9. In this circuit the output voltage is equal to the input voltage. The input impedance is extremely high; the output impedance is very low. While the circuit

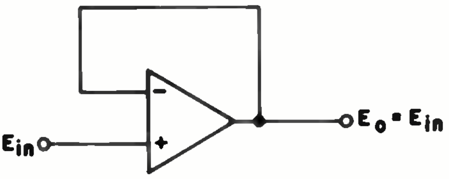


Fig. 9. An op amp follower.

25K

provides no gain or phase inversion, it is useful as an isolation amplifier and a power amplifier.

A particular voltage source may have a high output impedance and, therefore, will be loaded substantially when connected to a load. This may be an undesirable situation, but it can be eliminated with the follower. The high impedance source is connected to the very high input impedance of the op amp follower. Because of this high input impedance, it will not substantially load the voltage source. The output voltage of the op amp is equal to the input. However, its output impedance is very low and can supply substantial current to a load.

A DIFFERENTIAL AMPLIFIER CONNECTION

Since most op amps are differential amplifiers, they have both inverting and non-inverting inputs. In the circuits that we have discussed, however, we have not used this differential input capability. In the standard op amp connection, the non-inverting input is connected to ground. The differential op amp amplifies the voltage difference between the two inputs. If one of these inputs is connected to ground, the difference will simply be the amount of voltage applied to the other input. This forms what is known as a single-ended amplifier input. This means that both the input and output signals are measured with respect to some common ground reference.

There are occasions when it is desirable to use the differential capabilities of the op amp. At the same time, we want to take advantage of the fact that negative feedback around the amplifier can stabilize the circuit and make the gain predictable. The circuit shown in Fig. 10 produces this differential amplifying capability with controlled gain.

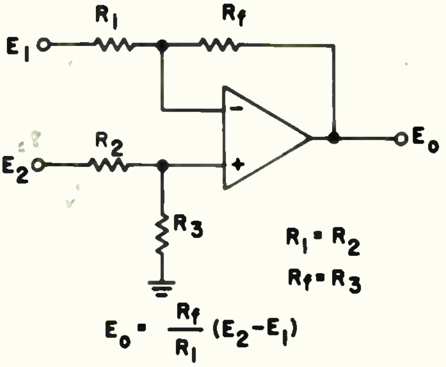

Fig. 10. Using an op amp as a differential amp.

In this circuit the two input resistors are R_1 and R_2. These two resistors are generally made equal. The feedback resistor R_f is connected as usual. Resistor R_3 is connected between the non-inverting input and ground. Resistors R_3 and R_f also are made equal to each other. The gain of the circuit is expressed as R_f/R_1 or R_3/R_2. The output voltage of this circuit is equal to the gain multiplied by the difference of input voltages E_1 and E_2. This gives us the output expression

$$E_o = \frac{R_f}{R_1}(E_2 - E_1)$$

We might also call this circuit a subtraction circuit, since we subtract input voltage E_1 from E_2 in the process of calculating the output.

Let's assume that resistors R_3 and R_f are equal to 100K and R_1 and R_2 are 25K. The gain of the circuit then is 100K/25K = 4. Now let's assume input voltages of $E_1 = 3$ volts, and $E_2 = 8$ volts. The output voltage of the amplifier is the difference between the two input voltages (5) multiplied by the gain of the circuit (4), or 20 volts.

Let's take another example of output voltage calculation of a differential amplifier circuit. Assume that the values of R_f and R_3 are 500K-ohms. Input resistors R_1 and R_2 are also equal to 500K-ohms. Input voltage $E_1 = +13$ volts, and input voltage $E_2 = -2$ volts. What is the output voltage? Using the output formula

$$E_o = \frac{R_f}{R_1}(E_2 - E_1)$$

we get

$$E_o = \frac{500K}{500K}(-2 - 13)$$

$$E_o = 1\,(-15) = -15 \text{ volts}$$

This circuit performs a very accurate algebriac subtraction operation.

AN OP AMP CONSTANT CURRENT SOURCE

In an earlier lesson, you learned how a transistor can be connected to form a constant current source. Now you will find out how an op amp can be connected to perform this same function.

The conventional op amp circuit is shown in Fig. 11. The input is applied to resistor R_i and the gain is determined by the ratio of R_f to R_i. The output voltage is generally applied to a load connected between the amplifier output and ground as shown. Earlier we mentioned that the input and feedback currents were equal. Because of the high input impedance of the op amp, almost no current flows into the inverting input. Therefore the input and feedback currents I_i and I_f in Fig. 11 are equal.

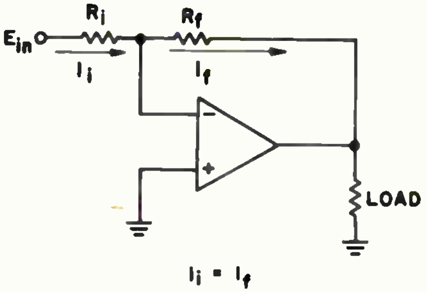

Fig. 11. A conventional op amp circuit with a load showing that the input and feedback currents are equal.

Using this fact, we can produce the constant current source op amp circuit. Fig. 12 shows the arrangement. First we cause a fixed current to flow through input resistor R_i. Since the value of R_i is constant, we can cause the current flow through it to be constant by applying a constant voltage to it. The Zener diode in Fig. 12 is used to provide the constant voltage to resistor R_i.

This fixed current also flows in the feedback resistor. Instead of connecting the load directly between the output of the amplifier and ground, we connect the load as the feedback element. In this way the constant current, determined by the

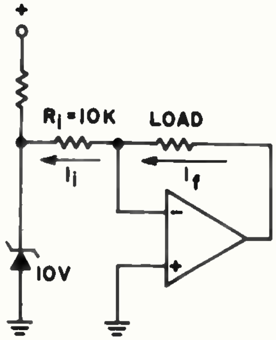

Fig. 12. A constant current source made with an op amp.

Zener diode and the input resistor, also flows through the load. The load resistance can be varied over a wide range of values but the current flowing through it will remain constant. For example, if R_i is a 10K resistor and the Zener diode provides a voltage of 10 volts, then the input current is equal to 10/10K = 1 milliampere. A constant current of 1 milliampere will flow through the load. This current will remain constant despite variations in load resistance.

VARYING THE GAIN OF AN OP AMP

In all the op amp circuits we have discussed, the gain is fixed by the values of the feedback and input resistors in the circuit. However, there are many occasions where we wish to control the gain or vary it continuously over a wide range of values. The most obvious way of varying the gain of any op amp circuit is to replace one of the fixed resistors with a potentiometer connected as a variable resistor.

A potentiometer is nothing more than a variable voltage divider, a resistive network whose output is less than its input by a factor determined by the resistance values used. The "pot" is a variable voltage divider with a continually adjustable resistance ratio.

Fig. 13A shows a typical op amp circuit with a variable resistor at both the input and the feedback positions. However, to control the gain of the amplifier, a variable resistance will usually be required in only one of these positions; a fixed resistor can be used in the other. By varying the input or the feedback resistance, the ratio of the two resistors will change and the gain will vary. Continuous adjustment of the gain is possible with this method.

With this arrangement it is more often desirable to control the gain with a potentiometer in the feedback path than in the input circuit. By varying the potentiometer in the feedback path, we obtain linear control of the gain. If we adjusted the input resistance, the gain would not be linear; it would not vary in a straight line with the value of the resistance. This is because the gain is a function of the ratio of the two resistances.

Also in this arrangement, the input resistance varies as the gain changes, altering the loading of the driving circuit.

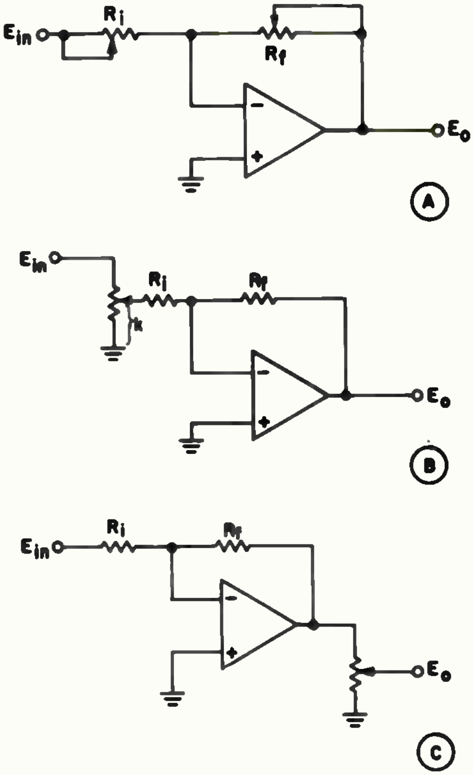

Fig. 13. Methods of varying the gain of an op amp.

The input impedance can even be set to zero, placing a dead short across the source driving the amplifier. In most instances, however, this is not a desirable situation.

An easy method of controlling the gain of an op amp circuit is to place a potentiometer before or after the circuit, as shown in Fig. 13B and C. In both circuits the op amp gain is fixed by the ratio of the feedback and input resistances; the amplitude of either the input or output is controlled with a potentiometer.

Fig. 14 shows a potentiometer connected as a variable voltage divider. The input voltage is applied between the upper end of the potentiometer and ground, causing current to flow through the resistance. The output voltage is taken between ground and the variable arm.

With the arm all the way to the top of the resistance, the output voltage will be equal to the input voltage. If we move the arm to the bottom of the resistance, the output voltage will be zero. Positioning anywhere between the two extremes causes the output voltage to be some fraction of the input voltage. For example, if the input voltage is 100 volts and we set the potentiometer arm to the center of the resistance value, the output voltage will be 50 volts.

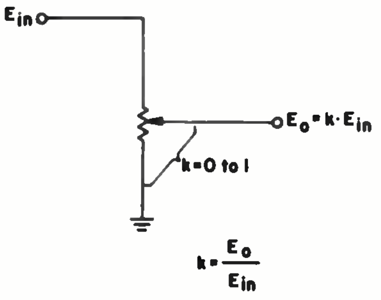

Fig. 14. The input-output relationship of a potentiometer.

In effect we are tapping off a portion of the voltage dropped across the resistance of the pot. Expressed as a fraction, the percentage of voltage tapped off between the arm of the pot and ground is known as the pot coefficient and designated k. In our example, where we assumed a 100 volt input, the coefficient is .5. Multiplying the pot coefficient by the input voltage gives us the output voltage value. With an input voltage of 100 volts and a pot coefficient of .25, the output voltage will be 25 volts. Since the pot is continuously variable, we can set any coefficient between 0 and 1, where the output and input voltages are equal.

Therefore, by connecting the pot at the input or the output of an op amp, we can vary the gain of the amp. The overall gain of the circuit shown in either Fig. 13B or C is equal to the amplifier gain multiplied by the pot coefficient. In other words, the overall circuit gain is equal to

$$\frac{R_f}{R_i}k$$

When the pot is used this way, the overall gain of the circuit can never be more than the total gain of the op amp.

One of the most useful circuits for varying the gain in an op amp is shown in Fig. 15. In this type of circuit, the input and feedback resistors are normally equal. Notice that the feedback resistor is indirectly connected to the output of the op amp through the arm of the pot. With this arrangement the gain of the amplifier circuit is equal to the reciprocal of the pot coefficient. If, for example, the pot

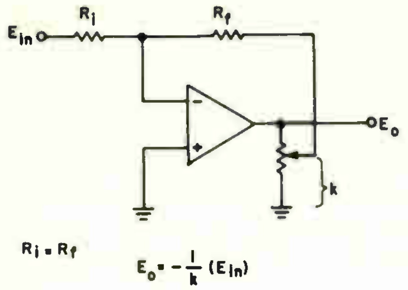

Fig. 15. A variable, high gain, op amp circuit.

coefficient k is .5, the gain of the amplifier is 1/.5 = 2. Since the coefficient of a potentiometer can be adjusted to any value between zero and 1, we can theoretically obtain any gain between 1 and infinity; the only limiting factor is the resolution of the pot setting.

For some potentiometers it is difficult to obtain very small variations in coefficients. We may want to obtain a gain of 1000 with our amplifier, in which case the coefficient would have to be .001. This coefficient is the ratio of 1 to the desired amplifier gain (k = 1/gain = 1/1000 = .001).

The output of voltage from the amplifier circuit, shown in Fig. 15, is equal to the gain of the circuit (1/k) multiplied by the input voltage. Keep in mind that the gain of the amplifier should not be adjusted so high that, with the given input voltage, it causes the output amplifier to swing to an output voltage beyond the power supply voltages used.

SELF-TEST QUESTIONS

(i) The non-inverting amplifier circuit of Fig. 8 has a feedback resistor of 120K and an input resistor of 30K. What is the gain?

(j) The differential amplifier circuit of Fig. 10 has values of $R_f = R_3 = 75K$ and $R_1 = R_2 = 15K$. The input voltages are $E_2 = -23$ and $E_1 = -16$ volts. What is the amplitude and polarity of the output?

(k) True or false: An op amp follower inverts the input signal.

(l) True or false: The load in an op amp constant current source is connected between the output and ground.

(m) A pot has an input voltage of 27 volts and an output of 9 volts. What is the pot coefficient k?

(n) The pot coefficient in the circuit of Fig. 15 is .004. What is the circuit gain?

3-18-76

Characteristics and Specifications

Most of the characteristics and specifications that we discuss in this section arise from the fact that an op amp is an imperfect device. Like any other electronic circuit, it is made from components that have specific tolerances on their values; undesirable characteristics cannot be completely eliminated in their manufacture.

Despite their imperfection, op amps are still quite useful; their usefulness depends entirely upon their application. By knowing and understanding the characteristics and specifications of op amps, you will be able to compare them and determine whether a particular amplifier is suitable for a given application.

INPUT OFFSET VOLTAGE

Almost all op amps have a differential input stage. As you have seen in previous applications, the two inputs providing inverting and non-inverting operation permit the op amp to be used in a wide variety of circuits. The desirable characteristics of a differential amplifier are taken advantage of in the op amp. As you recall, any differential amplifier amplifies the difference voltage between the two inputs. If we should connect both inputs to ground (0 volts), the difference between the two inputs should be zero; the output voltage would also be zero.

This, however, is only theoretically true. Because of small differences in the characteristics of the transistors used in the input differential amplifier, there will be a small difference of voltage that will be amplified by the high gain of the circuit and appear as a dc output voltage. Therefore, even when both inputs are at ground, there will be a measurable output voltage.

The small difference voltage, that appears in the input differential amplifier when both inputs are connected to ground, is caused by the differences in the emitter-base voltages of the two input transistors. If the emitter-base voltages, designated V_{be}, are exactly equal, there will be no difference between the two input voltages and the output voltage will be zero. When separate transistors are used to form the input differential amplifier, it is very difficult to find two transistors with identical V_{be}'s. For that reason there will be a small difference, appearing as an input signal that is amplified by the high gain of the circuit and appears as a measurable dc voltage at the output. The amount of voltage that must be applied between the input terminals to offset this output voltage is known as the input offset voltage.

★ VIP

In the design of a transistor op amp, the manufacturer normally tries to choose matched input transistors. Special test set-ups are used to compare the emitter-base voltages for the input transistors to match them as closely as possible. This reduces the input offset voltage. Some manufacturers produce special differential transistors with an extremely small difference voltage. Integrated circuit op amps, which you will study later, are very good in this respect. The transistors of the input amplifier are constructed on the same chip of silicon material and exhibit almost identical characteristics, reducing this input offset voltage to practically zero.

In a good op amp, this input offset voltage varies anywhere from several hundred microvolts to about 10-20 millivolts. When you consider the fact that the open-loop gain of an op amp is many thousands, this voltage can be amplified to a substantial signal at the output. For this reason we must generally take steps to correct this condition.

Fig. 16 shows a circuit that can be used to compensate for input offset voltage. This circuit is a standard inverting op amp circuit with feedback and input resistors. When we ground the input resistor as shown, the output voltage should be zero. In a practical circuit the output will not be zero, however, due to the input offset. If, for example, R_f = 100K and R_i = 100 ohms, the circuit gain would be 100K/100 = 1000. With an input offset voltage of 5 millivolts, the output would be .005 X 1000, or 5 volts. This is far from zero as you can see.

To compensate for this, we can apply a correction voltage from a potentiometer, as shown. The pot is connected to both plus and minus power supply voltages. This enables us to apply either a negative or a positive voltage to resistor R_1 which feeds the offset voltage into the op amp.

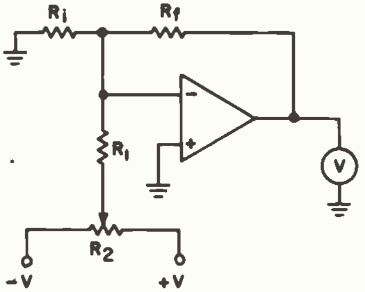

Fig. 16. Correction for input offset voltage.

Since we do not know in which direction the offset voltage will force the output, we can apply the desired correction voltage by making the input voltage polarity and the amplitude variable with the pot. With the input resistance R_i grounded and a voltmeter connected to the output, potentiometer R_2 is adjusted until the output voltage is equal to zero. The input offset voltage is then corrected.

The input offset voltage limits the magnitude of the input signal that the amplifier can amplify. For example, if the input offset voltage were 5 millivolts, we could not handle or amplify dc signals of 2 millivolts amplitude. Such small level signals, approximately the same magnitude of the offset voltage, will be confused with the offset voltage. An unpredictable output can result. However, by balancing out the offset voltage with a circuit like that in Fig. 16, we can then handle small amplitude signals. In noncritical applications where very low gain is used and where the signal voltages are many times larger than the offset, it is often possible to disregard the need for input offset voltage correction if a good op amp is used.

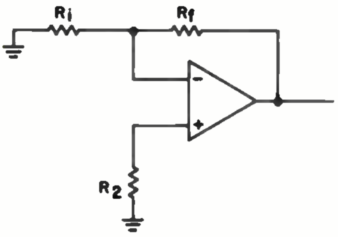
INPUT OFFSET CURRENT

The input offset current is the difference between the two input currents with both of the op amp inputs connected to ground. This difference in base currents is amplified and the result is an output voltage. The average of the two input base currents is called the input bias current. It is found by adding the input currents and dividing the sum by two.

This offset current is a function of the balance, or matching, of the input transistors in the differential input stage. Instead of being the result of differences in V_{be}, as with input offset voltage, the input offset current is a function of the degree of matching between the Betas and leakage currents of the input transistors. Because the two transistors used in the differential stage will not have equal Betas or collector-base leakage currents, different amounts of base current will flow when the inputs are connected to ground. This difference between the two currents (the input offset current) is amplified and produces an offset output voltage.

This current can be compensated for in the same way we correct for offset voltage (Fig. 16). Because of the directions of the current and possible opposite voltage offsets, it may be necessary to apply correction input to both the inverting and non-inverting inputs in order to compensate for both effects. Normally, however, the arrangement shown in Fig. 16 will enable you to null out the effect of input offset voltages and currents.

Fig. 17 shows an op amp circuit that can be used to help minimize the input offset current effects. Instead of connecting the non-inverting input directly to ground, as in previous circuits, we insert a resistor between this input and ground. By making this resistance equal to the parallel combination of the normal input and feedback resistances, the input currents can be made very nearly equal so that their results will cancel. The result will be a minimum of output voltage offset due to this input offset current. By making R_2 in Fig. 17 fully adjustable, it is possible to bring the offset to practically zero. If the input and feedback resistors are both 100K, the parallel combination will be equal to one-half this value. R_2 in the circuit would be made 50K for minimum offset current effects.



$$R_2 = \frac{R_f R_i}{R_f + R_i}$$

Fig. 17. Input offset current compensation.

INPUT IMPEDANCE

One of the most important characteristics of an op amp is the input impedance, the resistance at the input of the amplifier. In other words, each differential input represents a certain amount of resistance to ground to some driving source. It is desirable to have this input impedance as high as possible so that the circuit does not load or draw current from the source driving it.

Whenever this input resistance is connected to an oscillator, amplifier or other voltage source, current will flow through the input impedance and effectively load the driving source. If the input impedance is too low, excessive loading of the driving source may occur and result in reduced input voltage. Therefore the higher the input impedance, the lower the current drawn from the source.

Most typical op amps with no feedback connections have an input impedance of from 20K to 500K-ohms. This is the impedance of a typical bipolar transistor op amp. Higher input impedances can be obtained with Darlington input differential amplifiers. When field effect transistors are used for the input differential amplifier, extremely high values of input impedance (even thousands of megohms) are possible.

There is one special technique used with op amps to increase the input impedance. Known as bootstrapping, this technique involves taking some of the output voltage of the same polarity as the input voltage and feeding it back to the input. This compensates for the amount of current being drawn by that input from the source. In other words, we supply a current of proper polarity from the output of the amplifier to the input to furnish the current to the input normally drawn from the source. By effectively canceling out the current drawn from the source, the apparent input impedance becomes infinite.

The circuit shown in Fig. 18 uses this bootstrapping technique. Notice that resistors R_1, R_2, R_3 and R_4 have been added to form a voltage divider which taps off part of the output voltage which is fed back to offset the need for input current from the signal source.

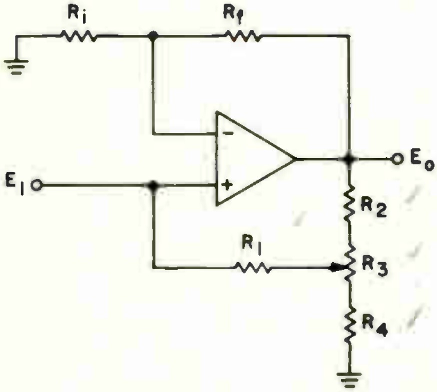


Fig. 18. A non-inverting op amp with bootstrapping to increase input impedance.

OUTPUT IMPEDANCE

The output impedance is the value of the effective internal resistance of the amplifier when it is acting as a voltage generator. The output of an op amp appears to be a source of voltage for whatever load it drives. The output impedance of the op amp appears in series with this load. Ideally we would like to have a very low output impedance so that little or none of the voltage produced is dropped across the internal impedance of the amplifier; almost all of it should appear across the load.

The output impedance of a typical transistor op amp without feedback is generally several hundred ohms. However, this value is reduced substantially when feedback is used. By using negative feedback, as we normally do with an op amp, output impedances of less than 1 ohm are easily obtainable. If the gain of the amplifier is very high, output impedances of .01 ohm are not too difficult to obtain.

POWER CONSUMPTION

Power consumption is the dc power required to operate the amplifier with the input and output voltages at zero and no load current flowing. This is the quiescent amount of current drawn by the amplifier when no input signal is applied or output is being developed.

Remembering that power is equal to the product of the voltage and the current, you can easily find the power consumed by an op amp. Most op amps use two power supplies, one to supply a negative voltage and the other a positive voltage. For example, a typical op amp may require + and − 15 volt power supplies. If the current drawn from each of these 15-volt power supplies is 2 milliamperes, power consumption would be 30 volts × .002 ampere = .06 watt, or 60 milliwatts.

INPUT VOLTAGE RANGE

The input voltage range is a measure of the maximum amount of voltage that can be applied between the two inputs of the op amp. If this value is exceeded, damage may occur to the input differential amplifier transistors. Normally this voltage range is restricted by the reverse emitter-base breakdown voltage of the input transistors.

OUTPUT VOLTAGE SWING

The output voltage swing is the peak or maximum output voltage, with reference to zero, that can occur without clipping or other distortion. This voltage swing is generally limited by the power supply voltages. For example, in an op amp with power supplies of ±15 volts, the maximum output voltage swing would be very nearly equal to 30 volts. For an ac sine wave at the output, this would be a 30-volt peak-to-peak value. Normally, the maximum output voltage swing is less than the supply voltage by an amount equal to the drop across the saturated output transistor and any series resistance.

When the input voltage is low enough so that, when it is amplified by gain of the amplifier it produces an output voltage within the output voltage swing, the amplifier is said to be operating in the linear region. That is to say, the output voltage is an enlarged copy of the input voltage. The amplifier does not distort the signal.

However, if the input voltage is made too large, the gain of the amplifier may be such that we exceed output voltage swing capabilities of the amplifier. In this case, the amplifier output will saturate. If the input signal is a sine wave, both the positive and negative peaks of the output will be clipped because the output transistors go into saturation. To avoid going beyond the output voltage swing capability, always check to be sure that the output voltage is less than the maximum value when you multiply the input voltage by the gain of the amplifier.

COMMON MODE REJECTION

The inputs to an op amp are the inputs to a differential stage. As you recall from your study of differential amplifiers, it is the voltage difference between the two inputs that is amplified by the stage and fed to the output. This means that if both input signals are equal, the output voltage should be zero.

The ability of the amplifier to produce a very small or zero output voltage for equal input voltages is known as the common mode rejection. The ratio of the common mode input voltage to the output voltage produced is known as the common mode rejection ratio. For example, if we apply 10 volts to both inputs of the amplifier and the resulting output voltage is 1 millivolt, the common mode rejection ratio is 10/.001 = 10,000.

Normally the common mode rejection ratio is specified in decibels. The common mode rejection ratio that we just calculated, expressed in decibels, would be equal to 20 log 10,000 = 20 × 4 = 80 db. The larger the common mode rejection ratio figure, the better the rejection ratio and the quality of the amplifier. Common mode rejection ratios of well over 100 db are not uncommon in op amps.

POWER SUPPLY REGULATION

The input offset voltage of an op amp is sensitive to changes in the power supply voltages. We call this op amp characteristic the power supply rejection ratio. This is basically the ratio of the change in input offset voltage to the change in the supply voltage producing it. Normally, the op amp has two power supplies, one held constant and the other varied in voltage. Therefore, any input offset voltage change is noticeable. The ratio of the input offset voltage change to the supply voltage that caused it is the power supply sensitivity.

The power supply sensitivity is a function of the balance or matching in the input differential amplifier. If the differential amplifier transistors are as closely matched as other components in the circuit, the change in input offset voltage for a power supply voltage change will be very small. The quality of the amplifier is inversely related to this variation.

OPEN-LOOP DC VOLTAGE GAIN

The voltage gain of the op amp without external feedback is called the open-loop dc voltage gain. As we mentioned before, the open-loop gain of an op amp is generally very large. Gains of 100,000 or more are not uncommon. However, most op amps will use some form of negative feedback to reduce the amplifier gain and make it more predictable.

As you saw earlier, negative feedback through a resistance between the output and the inverting input makes the gain strictly a function of the ratio of the feedback to an input resistance. It is very desirable to be able to control the gain in this way. In order for this relationship to hold true, however, the open-loop gain of the amplifier should be at least 100 times the desired closed-loop gain of the amplifier.

NOISE

All amplifiers are sensitive to and produce a certain amount of noise. Noise is a term that describes any stray signal voltage (produced within the amplifier or external to it) that is amplified and appears in the output. Noise is an unwanted signal, generally measured in terms of rms voltage, that may interfere with the amplification of a specific input. If the noise level of the amplifier is higher than the small signal to be amplified, the input signal will be completely masked; only an amplified noise output will occur. Therefore, it is important that the noise in the amplifier be minimized.

There are several types of noise which can occur in op amps. We generally break these down into noise components associated with specific frequency ranges. One of these, called the wide band noise spectrum, extends from about 1 kHz to 100 kHz. Noise produced in this frequency range is generally from thermal effects in resistors and from within semiconductor components, such as diodes and resistors. This type of noise is internally generated.

Another noise spectrum extends from the frequencies of 10 Hz to 1 kHz. Noise in this region is usually from the ac power line and frequencies harmonically related to it.

In the frequency range from 1 Hz to 10 Hz, noise is caused by structural imperfections in the components (particularly transistors) and is known as flicker noise.

In the frequencies above 100 kHz we move into the radio frequency spectrum, and amplifiers can pick up rf signals. Of course, this is undesirable. It is best to minimize the amount of noise produced both within the amplifier and external to it. This is particularly true if extremely low level signals are to be amplified properly.

DRIFT

Drift is a form of very low-frequency noise; it is the slowly varying change in the input offset voltages and currents in an op amp due to fluctuation in temperature, time and power supply voltages. We want to minimize drift in the design and application of the amplifier because variations in offset voltages and currents are amplified and interfere with the normal input signal.

No relationship exists between the input offset voltage drift and input offset current drift. As temperature, time or power supply voltages change, each of these factors will vary independently, often in opposite polarity to the other. Since drift is an undesirable characteristic of the op amp, every means must be taken to minimize or eliminate it. Let's now discuss the causes of drift and how it can be minimized.

A major cause for drift is temperature change. Electronic equipment using op amps can be subjected to a wide range of temperatures. Temperature effects can come from the environment or from heat in adjacent electronic components or equipment. Such temperature effects must be considered when designing and using an op amp.

Most operational amplifiers and components are available in two basic temperature ranges, the commercial range from 0°C to 70°C and the military temperature range of –55°C to +125°C. These are the typical temperature ranges over which the op amp must work for these specified applications. Since the temperature ranges are so wide, care must be taken to protect the amplifier.

Temperature variations cause changes in the input offset voltage and current which can produce undesirable amplifier action. As the temperature varies, the emitter-base voltage drops of the differential input transistors vary. Normally the emitter-base voltage drop decreases 2 millivolts for every °C increase in temperature. If the two differential input transistors are accurately matched, their emitter-base voltage drops will decrease together as temperature increases, maintaining a balance and keeping the input offset voltage reduced to a minimum.

Recall that the input offset voltage is due to the differences between the emitter-base voltage drops in the input differential amplifier. It is extremely difficult to control the manufacture of these transistors so that the emitter-base voltage drops track together with temperature. For that reason the input offset voltage will change when the temperature changes. Emitter-base junction voltages are so sensitive to temperature changes that a temperature difference of only .01°C between the junctions of two transistors in the input stage can produce an input offset voltage of 24 microvolts.

As you can see, it is important to hold the junction temperature of the two transistors to exactly the same value. Keeping the input offset voltage low, when individual transistors are used in the differential stage, is quite difficult. Generally the transistors can be mounted on a common heat sink. Also there are special differential transistor pairs manufactured, where both are made from the same silicon chip. Often special heating elements or ovens are used on the differential input stage to keep the temperature at a constant value to reduce the changes in the offset voltage that produce undesirable drift.

Drift due to changes in input offset voltage is generally specified in millivolts per °C of temperature change. For example, a typical drift may be .05 millivolt per °C. This can be evaluated by varying the temperature, noting the input offset voltage drift and then calculating the change for a given increment of temperature.

Fig. 19 shows a curve relating the change in input offset voltage to a change in temperature. At 25°C (room temperature), the input offset voltage is nulled to zero. Normally this is done by using the compensation circuit shown in Fig. 16. As the temperature is lowered, the offset voltage increases in the negative direction. Raising the temperature from 25°C causes an increased offset voltage in the positive direction. As you can see, the input offset compensation voltage applied by the circuit in Fig. 16 is effective only at one temperature; the output will drift due to the change in offset voltage at other temperatures.

Notice in this curve that the offset voltage does not change linearly with temperature. In other words, equal temperature change does not produce a proportional change in input offset voltage. In addition, the offset voltage in one amplifier varies independently from that in another.

The input offset voltage also tends to drift with time. That is, the input offset voltage will change over a long period of time. Normally this condition is expressed in microvolts of offset change per days or per thousand hours. This change is generally caused by the physical changes inside transistors because of their age. In most op amps, this characteristic is not particularly detrimental to the operation of the circuit. Only in the most

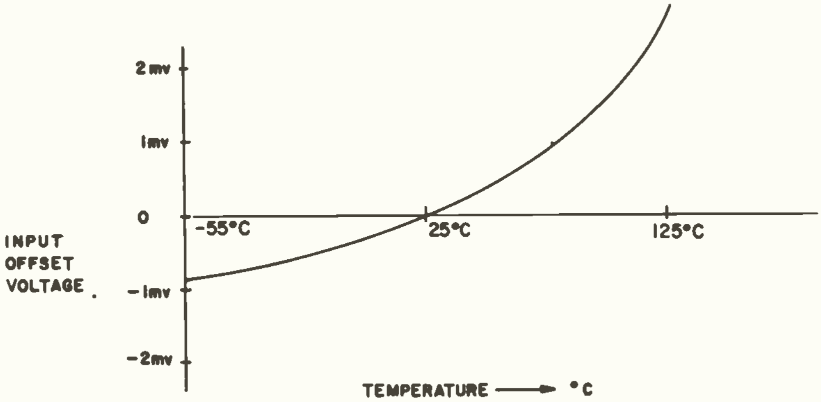

Fig. 19. Input offset voltage vs. temperature.

critical applications is the offset change with time a crucial factor.

The input offset current in an op amp also drifts with temperature and time changes. As you recall from our earlier discussion, the input offset current is a function of both the gain, or Betas, of the input transistors and the leakage currents. Both these factors increase when temperature rises. In silicon transistors leakage current generally doubles for every 10°C increase. If the input transistors are matched so that their Betas and leakage currents vary the same amount with changes in temperature or age, then the offset current will not change. However, it is extremely difficult to match the input transistors this closely; they will change differently with temperature, increasing the amount of input offset current with an increase or decrease in temperature.

Changes in Beta or leakage with temperature do not directly correspond to changes in input offset voltage. In one particular situation, they may vary together and their effects may add; in another case their effects may oppose one another. It depends upon the individual components and the circuit in which they are used.

Generally the same precautions used to minimize input offset voltage changes with temperature can be used in minimizing changes in input offset current. Mounting the transistors together on a common heat sink or using differential transistor pairs made on the same silicon chip will help eliminate the effects of temperature changes.

As with input offset voltage changes, the offset current will vary due to aging of the transistors. There is very little that can be done except to try to match the transistors for aging effects as closely as possible. These are usually long term, very slow drift effects which can be neglected for most applications.

FREQUENCY RESPONSE

As you learned in an earlier lesson on amplifiers, amplifier circuits generally respond to a specific band of frequencies. Amplifiers are classified according to the frequency range in which they amplify best. There are audio amplifiers, video amplifiers, rf amplifiers and dc amplifiers. The op amp is a special case in that it covers a wide range of frequencies. This wide frequency response capability adds to the versatility of the op amp.

We defined frequency response in terms of bandwidth. Bandwidth, as you recall, is the difference between the upper and lower three db cutoff points on the amplifier response curve. For op amps the lower frequency limit is dc. The upper 3 db point primarily depends upon the internal capacitances of the op amp circuit and components as well as external capacitance, inductance and other stray impedances. Op amps have been constructed to perform at frequencies up to 100 MHz.

Now let's take a look at a typical frequency response curve for an op amp. In Fig. 20 the upper curve shows the frequency response of the op amp operating with no feedback. The curve is designated as A_1. This is the open loop response that indicates how the gain of the amplifier varies with frequency. Notice that the gain remains constant for only a very narrow frequency range before it begins to decrease linearly as the frequency is increased. The 3 db down point for the open-loop gain occurs at an extremely low frequency, f_1, that is about 100 Hz or less. Beyond this point

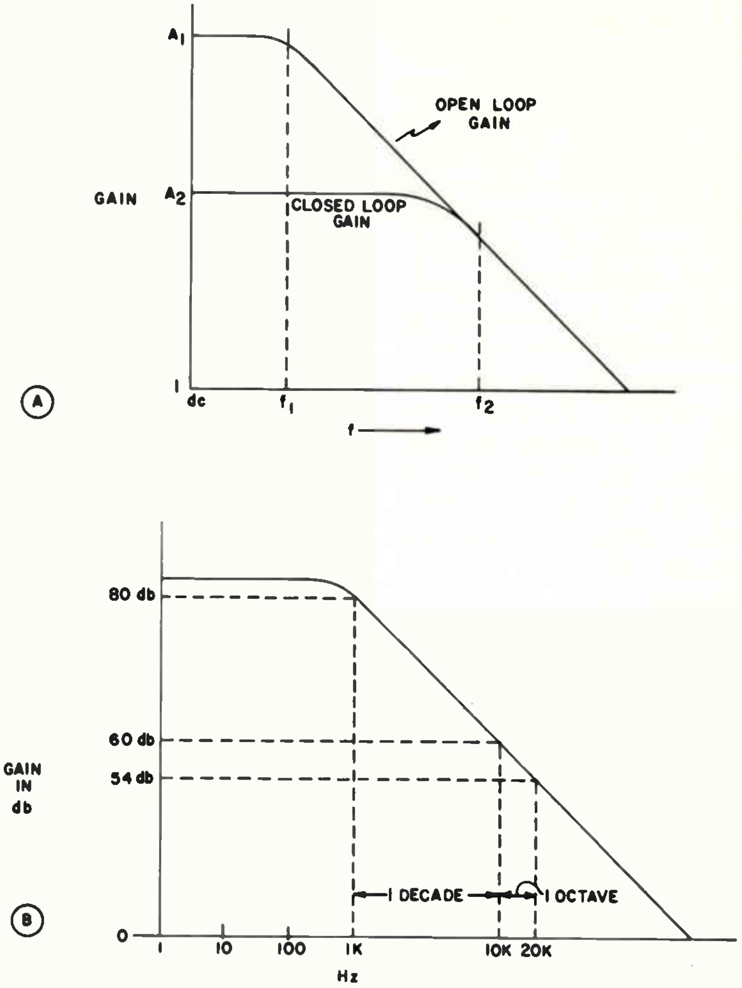

Fig. 20. Op amp frequency response (A) and an op amp frequency response curve that illustrates the roll-off characteristic (B).

the gain decreases in a straight line as the frequency increases until the gain is equal to one (unity).

The lower curve shown in Fig. 20A is the closed-loop frequency response of the op amp. If we apply negative feedback to the op amp, we immediately reduce its gain. At the same time we also increase its bandwidth. Notice that the 3 db down point (f_2) for the closed-loop gain response is far greater than that of the open loop gain response. Here we are trading off gain for frequency response by adding the negative feedback. Notice that the initial gain is lower, but that beyond the 3 db point, the closed-loop gain response merges with that of the open loop gain response and the gain drops linearly as the frequency increases.

The rate of decrease in gain with respect to frequency is generally called the roll-off. The gain roll-off characteristics of an op amp are generally set so that the gain decreases at a rate of 6 db per octave. This means that the voltage gain drops by a factor of 2 each time the frequency doubles. Expressing this another way we can say that the gain roll-off occurs at a rate of 20 db per decade; when the frequency is increased by a factor of ten, the gain is decreased by a factor of ten.

Fig. 20B illustrates this gain roll-off characteristic. The gain in this curve is expressed in db and the frequency in Hz. If the frequency should increase from 1 kHz to 10 kHz, we can say that the frequency increased by a decade or by a factor of ten. The gain of the amplifier at 1 kHz is 80 db, and it drops to 60 db at the 10 kHz point. 80 db represents a gain of 10,000 while 60 db represents a gain of 1,000. Therefore, as the frequency increased by a factor of ten, the gain dropped by a factor of ten.

Notice on this same curve that as we increase the frequency from 10 kHz to 20 kHz the gain drops a small amount. We have effectively doubled the frequency which represents one octave. The gain has dropped 6 db, representing a factor of 2. (60 db represents a gain of 1,000 while 54 db represents a gain of 500.)

There is one specification of an op amp that helps define the relationship between gain and frequency. Known as the gain-bandwidth product, this term will show you the general relationship between the gain of the amplifier and its bandwidth when negative feedback is applied.

The gain-bandwidth product of an amplifier is a constant which is determined by the amplifier design. This means that as we change the gain of the amplifier, the bandwidth must also change in order to keep the product of the two constant. For example, an amplifier with a gain-bandwidth product of 10^6 would have a bandwidth of 10^6 Hz at unity gain. Multiplying the gain of one by the bandwidth of 10^6 Hz we get 10^6 gain-bandwidth product. Now assume that we increase the gain of the amplifier to 100. As you would expect from looking at the curve of Fig. 20B, increasing the gain would have the effect of decreasing the bandwidth. With a gain-bandwidth product of 10^6 and a gain of 100, the bandwidth must be $10^6/100 = 10^4$ Hz or 10 kHz.

SLEWING RATE

The slew rate limit of an op amp is the maximum time rate of change of the output voltage for a step input voltage. This is sometimes known as the velocity limit. The slewing rate is usually specified in terms of the change in output voltage per unit of time; volts per microsecond is typical. It is closely related to the frequency response of an amplifier.

In a previous lesson you studied the square wave testing of amplifiers where a step voltage or square wave was applied to the input and the output of the amplifier then noted. The change in shape of the square wave by the amplifier gives much useful information about the response characteristics of the amplifier. A step response signal (square wave) contains a large number of high-frequency harmonic sine waves. If the amplifier passes these high-frequency harmonics faithfully, the output waveform should be the same as the input waveform. However, since some of the high-frequency components will be attenuated by the limited bandwidth of the amplifier, the output waveform will actually be different from the input waveform. The amount of difference determines the bandwidth of the amplifier. This can be calculated by measuring the output rise time of the square wave of the amplifier.

Fig. 21 shows a step voltage input applied to an op amp. Notice that the rise time for the pulse is zero. In a practical situation, the rise time of the input pulse would be finite. It is usually made so much smaller than the expected output rise time that its effects can be eliminated.

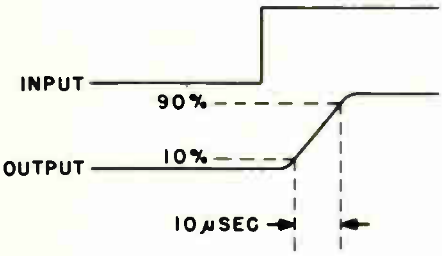

Fig. 21. The step response of an op amp.

The output of the op amp is also shown in Fig. 21. Notice that the output has a very definitely measurable output rise time. These waveforms might be displayed on an oscilloscope and the calibrated horizontal sweep and crt screen will be used to measure the rise time between the 10% and 90% points of the waveform.

Frequency Compensation. Because of the very high gain and frequency response characteristics of an op amp, the circuits are often susceptible to instability when feedback is used. Instability refers to the tendency of an amplifier to oscillate. Naturally any oscillation in an amplifier is undesirable. In op amps oscillation can be eliminated by using frequency compensation techniques.

As you know, the gain of an amplifier varies with the frequency. When feedback is used, the gain is relatively constant over a range of frequencies. Then as the frequency approaches an upper limit, the gain begins to roll off at a constant rate.

As you recall from your previous studies of amplifiers, as frequency increases the gain drops off and substantial phase shift is introduced. At the half power (3 db down) point the phase shift between the input and output signals will be 45°. This phase shift will increase further as the frequency is increased and the gain continues to roll off. It is possible that at some point during the roll-off the phase shift will equal 180°. Combining this with the 180° phase shift or inversion of the op amp and assuming a feedback connection, the output signal will effectively be in phase with the input. If the gain is equal to or greater than 1 at the point where the 180° phase shift occurs, then the amplifier will oscillate. The frequency of oscillation will be the frequency at which the phase shift is proper for in-phase feedback.

To avoid this unstable condition at high frequencies, it is often necessary to connect external resistor-capacitor networks to an op amp to shape the output response curve. This makes the gain roll off at a rate where the phase shift will not be 180° when the gain of the amplifier is equal to or greater than unity.

The phase shift characteristics of an amplifier depend upon the amplifier circuit and the various external resistor-capacitor networks used. Occasionally at high frequencies, these characteristics cause the phase shift to approach 180° when the amplifier gain is equal to or greater than one. Even without feedback an amplifier can oscillate in the open-loop condition. This is due to stray capacities and coupling between circuits of the amplifier caused by the common power supply impedance.

Such instabilities can be eliminated by using an external frequency compensation network that forces the amplifier to roll off at a 6 db per octave rate. Doing this makes the amplifier appear to have the frequency response of a simple R-C integrator network. Such a network has a maximum phase shift of 90°. Since the amplifier can never achieve the 180° phase shift, it will be stable over its useful frequency range.

SELF-TEST QUESTIONS

(o) What is the basic cause of input offset voltage?

(p) What causes input offset current?

(q) Why is a high input impedance desirable?

(r) What is meant by rise time?

(s) What determines the maximum output voltage swing of an op amp?

(t) What causes drift in an op amp?

(u) Does the circuit of Fig. 16 compensate for the effects of drift?

(v) A certain op amp has a gain of 120 db at 100 Hz. What is its gain at 1 kHz if the gain rolls off at 6 db per octave?

(w) Why are external frequency compensation networks often used with op amps?

Typical Circuit Techniques

Fig. 22 is a generalized block diagram of an op amp, showing its three stages. The first stage is called the input stage. It is always a differential amplifier. Usually a current source feeds the emitters of the differential transistors. This current source is either a single high value resistor or a transistor, forming an active current source. This stage is important because it determines the input characteristics of the op amp. The input offset voltage, input impedance and common mode rejection, for example, are primarily determined by how the input stage is designed.

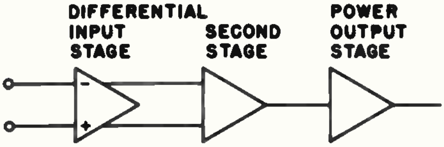

Fig. 22. An op amp block diagram.

Since op amps are dc amplifiers, the first stage is directly coupled to the second stage. The second stage provides more amplification and produces the proper level translation for the dc signals on which the ac input signals are riding. Without level translation there is a buildup in the dc voltage coupled from stage to stage. Also the output will not swing near ground so that the output is zero when the input is equal to zero volts. We could have shown the second stage in Fig. 22 as two blocks, one showing a gain stage and the other a level translator or shifter.

In many op amps there are more than two stages of gain. Usually the differential signal is eliminated after the second or third stage and only a single-ended output is fed to some form of power output stage.

The power output stage has two functions. First it tends to maximize the output voltage the amplifier can handle. (A large output voltage is a desirable op amp characteristic.) It also determines the output impedance (which must be as low as possible) and the current handling capabilities of the amplifier. In many cases the output stage must also provide some form of short circuit protection.

BASIC CIRCUITS

Let's now discuss in detail some amplifier circuits which illustrate how the blocks in Fig. 22 are filled. Fig. 23 is the circuit of a simple but complete op amp which illustrates most of the principles involved. In this circuit the first stage is made up of transistors Q_1 and Q_2, which form a differential amplifier. The input to transistor Q_1 is an inverting input, while the input to transistor Q_2 is the non-inverting input. The emitter of both stages of the transistors of the differential amplifier must be fed by some form of current source. In this case, a very simple current source is made by having a large value resistance (R_4) connected to minus supply $-V_{ee}$. Resistors R_1 and R_2 are the load resistors for the first stage transistor.

The collectors of transistors Q_1 and Q_2 are direct-coupled to the bases of transistors Q_3 and Q_4, which form the second stage. The second stage emitters are also fed by a current source, in this case

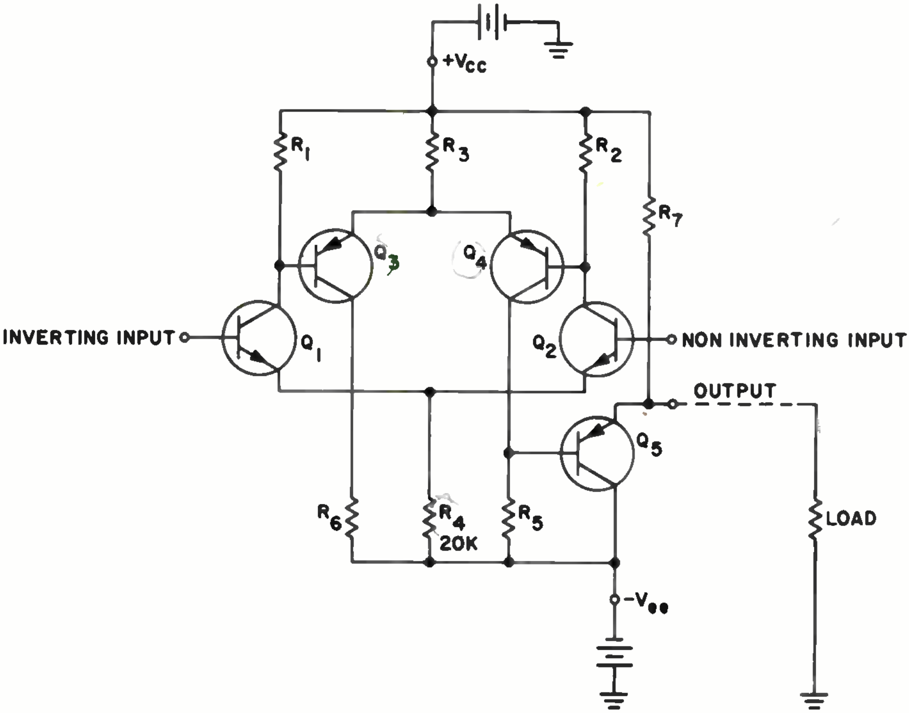

Fig. 23. A simple operational amplifier.

formed by a voltage $+V_{cc}$ and resistor R_3.

In this simple amplifier, NPN transistors are used for the first stage and PNP's are used for the second stage. The use of PNP transistors in the second stage automatically gives us the ability to level-shift the voltage. Remember that the voltage builds up only if we use transistors of the same polarity.

The collector voltages of the second stage are shifted to a level very near ground. The output of the second stage comes from the collectors of transistors Q_3 and Q_4. However, the output from the collector of transistor Q_3 is not used; it is simply returned through resistor R_6 to $-V_{ee}$. Meanwhile the output of transistor Q_4 goes to load resistor R_5 which is coupled to output transistor Q_5. As you can see from the diagram, the output stage in this op amp is made up of transistor Q_5 connected as an emitter-follower.

This amplifier, having most of the desired characteristics of an op amp, is suitable for general purposes. The transistors of the first stage must be matched very carefully in order to obtain a low input offset voltage and current.

To get an idea of the level of performance of this simple circuit, let's outline its characteristics: input impedance, 100K; input current, 600 nanoamps; equivalent input offset voltage, 1 millivolt; voltage gain, 73 decibels. This amplifier uses a simple differential amplifier for an input stage. However, in many cases a more sophisticated input stage design is required to increase the input impedance, increase the common mode rejection ratio or obtain lower values of input bias current.

The high input impedance and the low bias current are direct results of each other. To achieve a high value of common mode rejection ratio in both cases, an active current source is used to feed the emitters. The active current source is usually made up of a transistor and some resistors.

HIGH INPUT IMPEDANCE

In order to obtain a high input impedance, three methods are commonly used: ① Darlington connected transistors in the ② differential input stage, a field effect transistor differential amplifier input stage and ③ a standard transistor connection. We will now discuss these three approaches and the active current sources.

In Fig. 24 is an input stage using both a Darlington connected differential amplifier stage and an active current source. The current source is formed by transistor Q_5; resistors R_1, R_2 and R_3; and diode D_1. The purpose of the current source is to produce a constant current feeding the two emitters of the differential Darlington pair. This current should be stable enough not to change with temperature or bias conditions. Resistors R_1 and R_2 form a voltage divider taken from the power supply. The

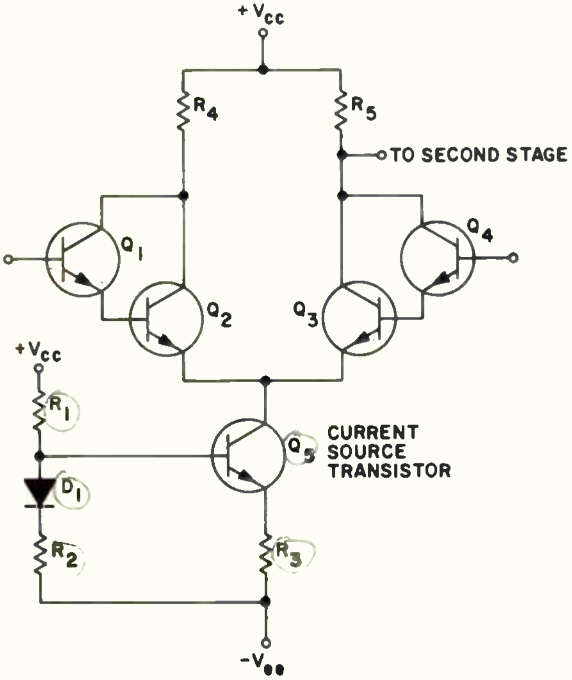

Fig. 24. A Darlington stage and an active current source.

voltage at the base of Q_5 is determined by this voltage divider. This means that the voltage drop across R_3 will also be determined by this divider, since the base potential and emitter potential will be the same. This now establishes a constant voltage across R_3 which implies a constant emitter current (emitter current = emitter voltage/R_3). The collector current is the emitter current multiplied by the alpha of the transistor. The output at the collector is a very high impedance, which simulates an ideal current source.

The use of a transistor as a current source gives us much better current stability than a high value resistor connected to the power supply. Diode D_1 is used in order to achieve a certain degree of temperature compensation. As you know, the emitter-base junction of a transistor has a negative temperature coefficient. That is, V_{be} decreases with an increase in temperature. Diode D_1 tends to cancel out the variation in temperature of the emitter-base junction by introducing an equal voltage with a polarity that cancels the effect. In this way, we obtain a more stable current with regard to temperature changes. For example, if the temperature increases, V_{be} will decrease, causing more voltage to appear across R_3 and increasing the current in Q_5. However, the drop across D_1 decreases, reducing the voltage applied to the base of Q_5 and the voltage appearing across R_3. Therefore, the current remains constant. We must be careful to match the two temperature coefficients of the emitter-base junction of the current source transistor with the one of diode D_1.

The differential amplifier stage in Fig. 24 is made up of Darlington pairs Q_1 and Q_2 on one side and Q_3 and Q_4 on the other. The effect is to achieve a much higher value of Beta. Therefore, for a certain emitter current, the amount of base current that flows into the input transistors will be much less than with a single transistor. This, of course, achieves a small value of input current and a much higher input impedance.

The use of the Darlington connection for the input stage of an op amp is limited because of the input offset voltage and the input offset temperature coefficient. The reason is that the input offset voltage is the net difference in V_{be} drops from one input to the other. Since we now have four transistors, it is more difficult to obtain a low value of input offset voltage. Also the V_{be} of the four transistors must be very closely matched for temperature coefficients, more so than if we had a standard differential pair.

In the input stage shown in Fig. 24, resistors R_4 and R_5 are the load resistors. The output from R_5 is used to drive a second single-ended stage. We could go to a differential second stage with PNP transistors as we did before, then convert to a single-ended output after the second stage.

Another method of obtaining a high input impedance is to use a standard differential amplifier stage, operate the transistors at a very low value of collector current and manufacture the transistors so that their Betas are extremely high at these low values of collector current. This is sometimes referred to as the super-Beta technique. It is very difficult to make transistors that have a very high Beta at low values of collector current. In order to get a high Beta, we must make the base of the transistors so thin that the reverse breakdown characteristics are severely restricted. Therefore, we must sacrifice the magnitude of our input voltage to low values in order to get the higher gain.

The use of field effect transistors to obtain high input impedance is shown in the complete op amp diagram of Fig. 25. This op amp offers a much higher performance than the first one we discussed. Transistor Q_5 forms the active current source that we discussed in the previous section. Diode D_1, the 3.3K resistor and the 224K resistor form the voltage divider used to establish the emitter voltage reference. As before, D_1 is used for emitter current stabilization with temperature. The collector of Q_5 is connected to the emitters of Q_2 and Q_4 and through 3K stabilizing resistors to the sources of field effect transistors Q_1 and Q_3. The two input signals are applied to the gates of transistors Q_1 and Q_3 which are N-channel field effect transistors. The sources of Q_1 and Q_3 are connected to the bases of Q_2 and Q_4, directly coupled.

As you know from previous lessons,

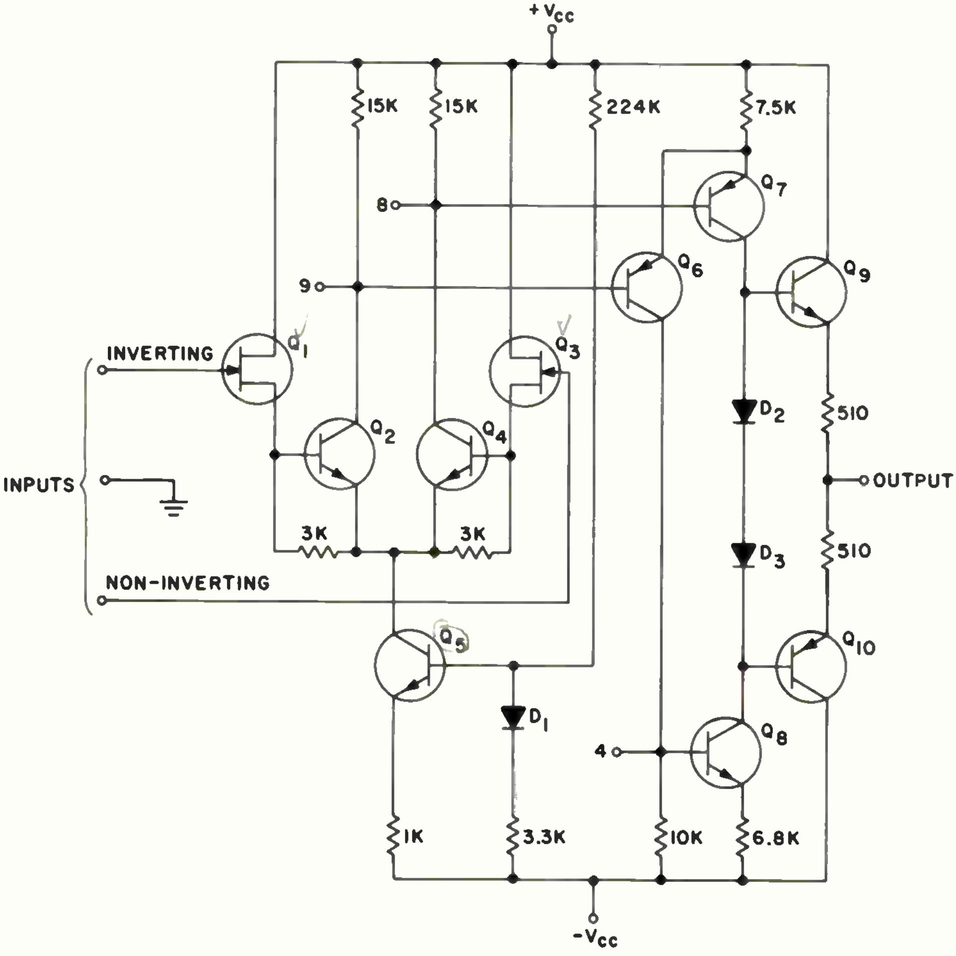

Fig. 25. Operational amplifier with FET's in input.

the field effect transistor is similar to a vacuum tube in its input impedance characteristics. You can typically obtain hundreds of megohms input impedance from a field effect transistor. Using this compound stage with field effect as well as bipolar transistors, the problems of input offset voltage drift and input offset voltage are quite difficult. The field effect transistors, in particular, do not have good tracking ability with temperature (for temperatures above about 70°C, the tracking is very poor). However, for commercial applications they give extremely low values of input bias currents and extremely high values of input impedance.

The 15K resistors in the collector circuits of Q_2 and Q_4 are the load resistors of the first differential stage. The two collectors of Q_2 and Q_4 are connected respectively to the bases of transistors Q_7 and Q_6 which form a modified differential amplifier. Transistors Q_6 and Q_7 are PNP devices. Here we use the complementary symmetry connection to obtain a dc level shift. This achieves direct coupling and level shifting at the same time. The output stage or power stage is formed by transistors Q_8, Q_9 and Q_{10}. The collector of Q_6 is connected to the base of Q_8, while the collector of Q_7 is connected directly to the base of Q_9. Q_9 and Q_{10} form a class B output stage. Q_8 is used to produce an out-of-phase signal into the base of Q_{10} so that we form a push-pull stage with Q_9 and Q_{10}. The output stage is essentially a complementary emitter-follower. Diodes D_2 and D_3 are placed between the two bases to reduce crossover distortion.

In a class B amplifier the transistors are biased to cutoff, conducting only on one-half cycle of the input driving signal. In a complementary symmetry class B amplifier, the positive half-cycle is amplified by the NPN transistor while the negative half-cycle is amplified by the PNP transistor. This is true for Q_9 and Q_{10} in Fig. 25; when one is conducting, the other is cut off.

With this arrangement, crossover distortion occurs. It is caused by the emitter-base characteristics of the transistors used. A silicon transistor requires a voltage of .6 to .7 volt across this junction before it conducts. With only .2 volt of forward bias, it is still cut off. The depletion layer in the junction effectively causes the transistor to be reverse-biased by about .6 to .7 volt. For that reason, a transistor is not operated exactly at cutoff as required for class B conditions. The result is that the input waveform must go more positive or more negative than .6 to .7 volt before the NPN or PNP transistor will conduct. During the zero crossing period of the input sine wave, neither transistor conducts, so the output signal appears as in Fig. 26.

This distortion can be eliminated by applying just enough forward bias to the transistors so that they operate right on the threshold of conduction, a condition required for proper class B operation. In Fig. 25 diodes D_2 and D_3 provide this forward bias. Each of these silicon diodes has a drop of .6 volt, for a total of 1.2 volts between the bases of Q_9 and Q_{10}.

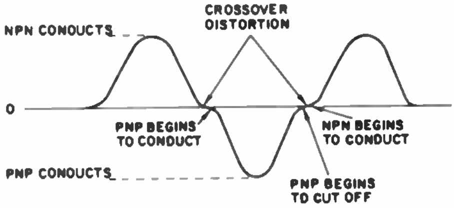

Fig. 26. Crossover distortion in a class B transistor amplifier.

This is just enough to overcome the depletion layer effects of Q_9 and Q_{10} in series. Now when Q_7 and Q_8 drive Q_9 and Q_{10} in the proper direction, they will conduct without producing the crossover distortion. The output is taken from the common emitters Q_9 and Q_{10}, through 510-ohm resistors which are there for short circuit protection.

In this amplifier we have seen several techniques. One of them is the use of field effect transistors in the input for high input impedance and low input bias current. Another is the use of an active current source. The second stage is formed of PNP transistors to obtain level shifting and some degree of gain. The last stage is a class B push-pull stage formed with a complementary pair of transistors.

To obtain an idea of the level of performance of the op amp just described, let's look at some of its characteristics: open-loop voltage gain, 100 db; input impedance, 100,000 megohms; input bias current, 20 picoamps; input offset current, 2 picoamps; input offset voltage, 10 millivolts; output voltage swing, 50 volts peak-to-peak. In this amplifier the voltage gain, input resistance and input bias current are considerably better than in the other one. However, the input offset voltage of 10 millivolts is not as low as it was in the previous amplifier.

IMPROVED OUTPUT STAGES

One of the most important op amp requirements is that it be able to produce a fairly high amount of output voltage into a low value of resistance. What this means is that a power amplifier must be used. The output stage in most op amps can supply a reasonable amount of power to a load, but for some applications, an external power booster amplifier must be used.

A typical booster output stage of an op amp is shown in Fig. 27A. This circuit is basically a current amplifier which provides wideband unity gain and peak currents up to ±200 milliamps into a 50-ohm load. Many common op amps can produce only a maximum of ±10 volts across a resistor of 3K or 4K. As you can see, this represents a very small amount of current. While using the technique that we will describe, currents of much higher values can be driven into a much lower load resistance. This configuration does not provide any voltage gain; the output voltage will be equal to the input voltage from an op amp.

The circuit in Fig. 27A is basically a set of cascaded complementary emitter-followers. It is made complementary so that the emitter-base voltage drops of Q_1, Q_3 and Q_2, Q_4 cancel each other. This makes the output voltage equal to the input voltage. The amplifier then has exactly unity gain. But because of its high input impedance and low output impedance, the circuit provides power amplification. When the output voltage from an op amp is applied to the input, the output voltage and polarity from the booster will be exactly the same. However, it is now capable of driving a larger current through the load than the op amp is.

Assume that the input to the booster circuit is at ground. This means that both transistors Q_1 and Q_2 become forward-biased. The voltage between the input and the emitter of Q_1 and Q_2 will be approximately .6 volt. This voltage is applied to the bases of Q_3 and Q_4. However, this voltage is insufficient to cause conduction of Q_3 and Q_4 so no current flows through the output load.

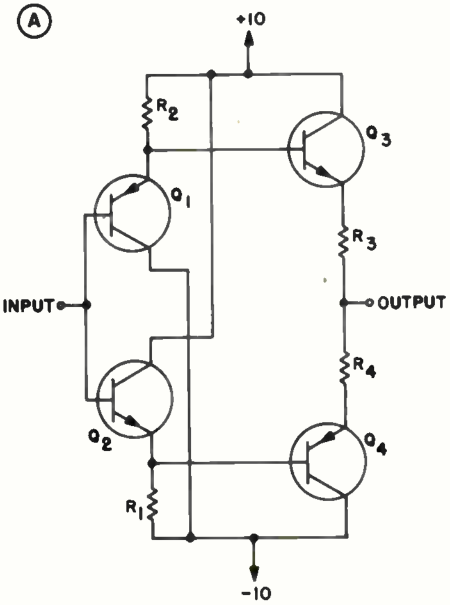

Fig. 27A. A current booster amplifier.

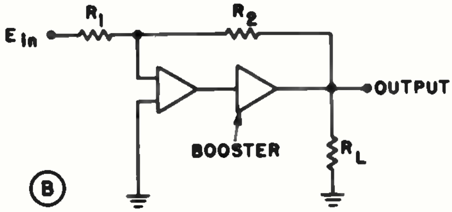

Fig. 27B. How the booster is normally connected to an op amp.

The output voltage at this time is essentially zero.

Now assume that we apply an input voltage of −5 volts. This causes transistor Q_1 to conduct more, producing a voltage of approximately −4.4 volts at the emitter of Q_1 and the base of Q_3. This voltage reverse-biases Q_3 so that it is cut off. The −5 volts at the input causes Q_2 to conduct less. The emitter voltage of Q_2 is approximately .6 volt more negative than the input, or −5.6 volts. This causes the emitter-base junction of Q_4 to conduct. Therefore, the output voltage is approximately .6 volt different, making the output −5 volts. The emitter-base voltage drop of Q_4 effectively cancels the emitter-base drop of Q_2, making the output voltage equal to the input voltage.

When +5 volts is applied to the input, Q_1 conducts less and the voltage at the base of Q_3 becomes approximately +5.6 volts. Q_3 conducts and its emitter is .6 volt less than its base, so the output voltage is +5 volts. As you can see, this is a unity gain dc power amplifier. Resistors R_3 and R_4 in the circuit are generally low in value so they do not contribute substantially to a change in the output voltage. They are used primarily for short-circuit protection. If the output accidentally short-circuits, the current flow through transistors Q_3 and Q_4 will be limited by R_3 and R_4.

For proper operation of this circuit, the emitter-base voltage characteristics of all the transistors must be closely matched so that their effects will cancel. The greatest error is introduced because the emitter-base voltage drops for NPN and PNP silicon devices are slightly different. For example, the V_{BE} of the NPN will be .6 volt; the V_{BE} of the PNP transistor will be .64 volt under the same conditions of bias. The difference would be .04 volt. This small error is generally of little consequence. Its effect can be minimized by using the booster amplifier within the feedback loop of the op amp to which it is connected. Fig. 27B shows how the booster is normally connected. The output of an op amp is fed into the booster and the load connected to the booster output. Instead of the normal feedback resistance being connected from the inverting input to the op amp output, the normal connection to the op amp output is connected to the booster. The small offset voltage produced by the imperfectly matched transistors is somewhat overcome by the use of this negative feedback.

CHOPPER STABILIZED AMPLIFIERS

A chopper stabilized amplifier is a dc amplifier in which modulation techniques are used to minimize the effects of drift. Variations in the temperature, power supply voltages and component characteristics will cause the output voltage of a dc amplifier to drift. This is an undesirable condition as it introduces an error in the output. Careful circuit design and accurate matching of components aid in minimizing drift. However, for critical applications it must be reduced further. To do this, the dc input to be amplified is passed through a chopper where it is converted into a square wave in the audio frequency range. This square wave is amplified by a standard ac amplifier. The ac output then is rectified, or converted back into dc, by the chopper; the resulting dc voltage is amplified in the standard dc amplifier.

It is the drift in the input stage of a dc amplifier that gives us the most trouble. The small drift voltage that occurs will be amplified many times by the remaining stages of amplification. Therefore, even a small input drift voltage can appear as a large offset at the output. If we can minimize the effect of drift in the input stage, then any drift in the remaining amplifier stages will have a minimum effect on the output voltage. We do this by converting the dc input voltage to ac early in the amplifier, where drift has no effect. We then convert this back to a dc signal of substantial amplitude and feed it the rest of the way through the dc amplifier.

Most op amp applications can make use of the standard unstabilized circuitry. However, for very critical applications, chopper stabilization is used to reduce drift to practically zero.

Fig. 28 shows a chopper stabilized op amp. The dc portion of the amplifier consists of the differential stage made up of Q_1 and Q_2. Transistor Q_3 and its associated components make up a temperature-compensated current source for the differential input stage. The output of the differential stage is taken from the collector of Q_2 and fed to a complementary amplifier stage, Q_4. Additional gain is produced in this stage and its output is coupled to transistor Q_5 and the emitter-follower output circuit.

The input signal applied to this circuit is actually fed to two places. First the high-frequency components of the input are passed through capacitor C_5 to the differential input stage. Any dc at the input is eliminated by capacitor C_5. The values of capacitor C_5 and resistor R_3 are chosen to act as a high-pass filter that passes only frequencies above a certain cutoff point. All dc and very low-frequency ac signals are passed through R_1 and C_1, a low-pass filter, to a chopper.

As you recall from a previous lesson, a chopper is nothing more than a switch that alternately connects and shorts out the dc signal at the input of an ac amplifier. In this circuit transistor Q_6 is used as a shunt switch. When Q_6 is open,

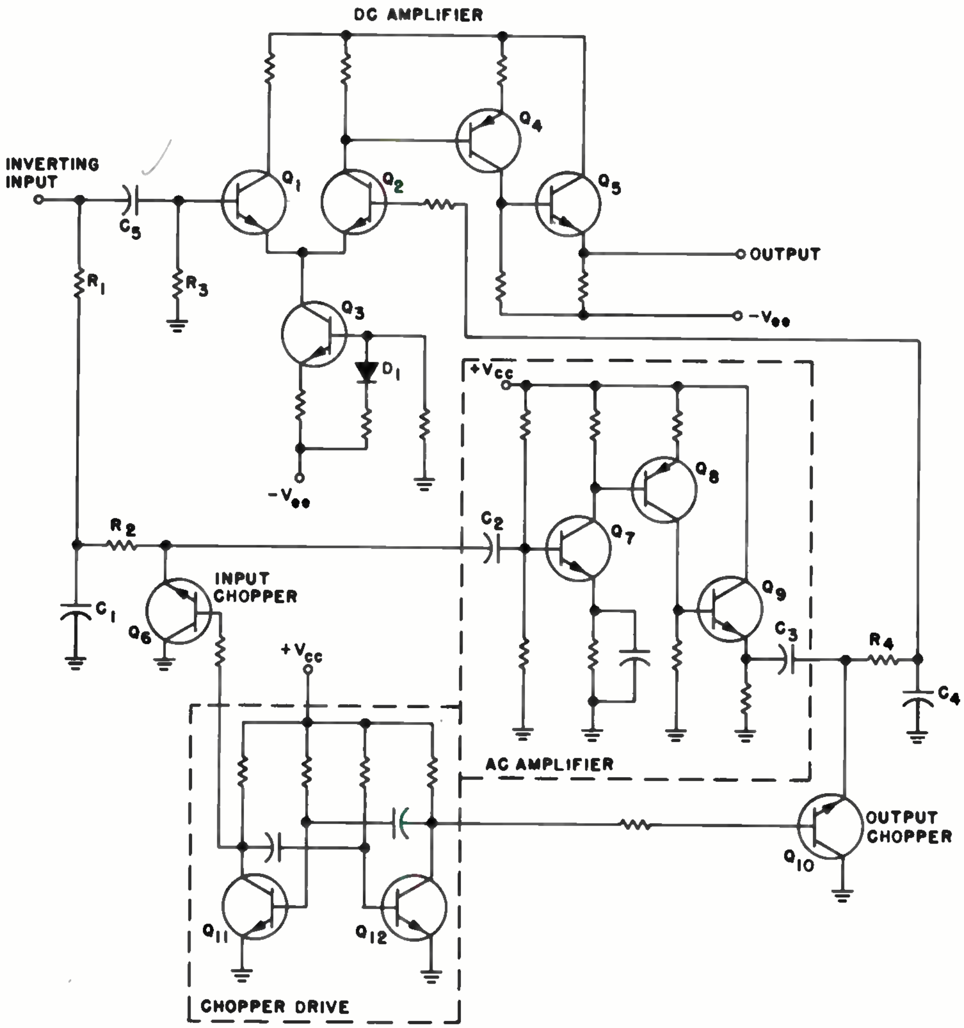

Fig. 28. A chopper-stabilized amplifier.

it has no effect on the circuit and the input voltage is applied directly to the ac amplifier through C_2. When Q_6 conducts, it shorts out the signal so that none is applied to the ac amplifier. Transistor Q_6 is turned off and on very rapidly by a free-running multivibrator circuit used as a chopper driver. This consists of transistors Q_{11} and Q_{12} and their associated components. The outputs at the collectors of Q_{11} and Q_{12} are square-wave signals that switch between ground and $+V_{CC}$. This is used to turn transistor Q_6 off and on. A rate of about 400 Hz is used.

Notice that in this circuit Q_6 is connected in a configuration inverted from that normally used. To turn a transistor on, we usually forward-bias its emitter-base junction. In this circuit we are forward-biasing the collector-base junction. Most transistors are somewhat symmetrical; the collector can be used as the emitter and vice versa. By using this connection, there will be an extremely low voltage drop between the emitter and collector when the transistor is turned on. This permits the transistor to function as an almost perfect on/off switch. When it is on, its resistance is practically zero; when it is off, almost infinite.

The 400 Hz signal appearing at the emitter of Q_6 is passed through the ac amplifier made up of Q_7, Q_8 and Q_9. Here it is amplified and fed to the output chopper, which is another inverted transistor, Q_{10}. Q_{10} effectively rectifies the ac output while R_4 and C_4 filter it into a dc voltage to be applied to the other input of the differential amplifier. Here the dc signal undergoes further amplification in transistors Q_2, Q_4 and Q_5.

Because of the tremendous improvements recently made in electronic components and circuit techniques, chopper stabilized amplifiers are actually being used less. It is now possible to obtain closely matched transistors and stable power supplies that reduce drift effects to a point where chopper stabilization is unnecessary. In fact, many of today's integrated circuit op amps have characteristics which approach those of a standard chopper stabilized amplifier. However, for extremely critical operations, chopper stabilization may be used to completely eliminate the effects of drift.

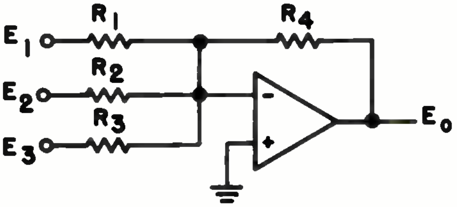
Common Uses

Today amps are used in a wide variety of ways. They appear in almost every phase of electronics because they are capable of performing so many useful functions. The op amp is a key element in the analog computer because it can perform so many useful mathematical calculations. It can perform multiplication and division by a constant simply by selecting the gain. It can also add or subtract. Since one of the major uses for op amp is performing mathematical operations, we will show you several of these useful applications.

MATHEMATICAL OPERATIONS

A typical op amp and summer is shown in Fig. 29. This circuit is basically that of the simple inverting op amp you studied before. The only difference is that we have added more than one input resistance. In this case we have added three, and to each supplied an input voltage. The op amp will sum the three input voltages after multiplying each by a gain that is the ratio of the feedback resistance divided by the associated input resistance.



$$E_0 = -\left[\frac{R4}{R_1}(E_1) + \frac{R4}{R_2}(E_2) + \frac{R4}{R_3}(E_3)\right]$$

Fig. 29. An op amp summer.

The mathematical output expression is shown in Fig. 29. Notice that the negative sign indicates that the sum is inverted. This amplifier circuit can be used to perform algebraic addition or subtraction operations. Any number of input resistances may be connected to the summing junction.

To show how this circuit works, let's assume some values for R_1, R_2, R_3 and R_4 in Fig. 29. Assume that all the resistors are 100K. Next assume the input of E_1 equals 2 volts, E_2 equals 3 volts, and E_3 equals 4 volts. Now, using all of these values, what is the output voltage? Find its magnitude and its polarity.

To solve this problem, all you have to do is fill in the appropriate values in the output expression shown in Fig. 29. We will do this after trying to understand exactly what is happening in this circuit. Keep in mind that each of the input voltages is going to be multiplied by a coefficient that is the gain of the amplifier for that input. Recall that the gain of the op amp is a function of its feedback and input resistance ratio. However, since we have made each input resistor the same size as the feedback resistor, this ratio will be 1:1. Therefore, in this circuit the output voltage is equal to:

$$E_o = -\left[\frac{100K}{100K}(2) + \frac{100K}{100K}(3) + \frac{100K}{100K}(4)\right]$$

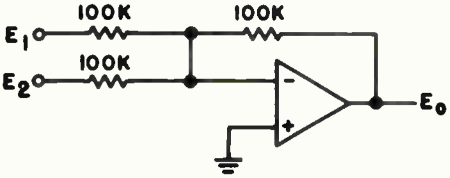
$$E_o = -\left[1(2) + 1(3) + 1(4)\right]$$

$$E_o = -(2 + 3 + 4) = -9$$

The solution to this problem simply involves basic addition. The amplifier performs the addition. Just keep in mind that the amplifier circuit still inverts and that this inversion must be considered when the absolute algebraic or polarity of the signal is important.

In a previous section you were introduced to the differential op amp circuit that is used to take the difference between two input voltages. This circuit could also be used to perform subtraction. However, we can also use a summer circuit to perform subtraction.

Fig. 30 shows a two-input summer that can be used for subtraction. Notice in this circuit that both the input and feedback resistances are equal so that the input voltages are multiplied by 1. To use the summer to subtract, we must feed voltages of opposite polarity into the two inputs. The op amp produces the difference between the two input signals as an output with a polarity opposite to the larger voltage.



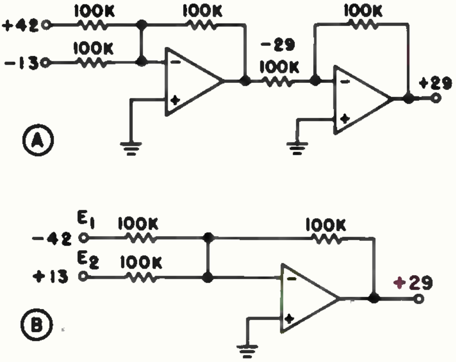
$$E_0 = -(E_1 + E_2)$$

-27 +15

Fig. 30. Two-input summer for subtraction.

As an example, let's subtract 18 from 27. E_1 will be −27 volts and E_2 will be 18. Since the polarities of the two voltages are different, the amplifier is going to produce an output voltage equal to the sum of the two (−9 volts). Because the larger voltage is negative, the output voltage will be inverted by the amplifier to become positive. The op amp performs algebraic addition; with it we can add numbers of any polarity. When we add numbers of opposite polarity we are producing subtraction. In other words, the process of subtraction is a form of algebraic addition. This op amp circuit inverts so that the polarity of the output voltage is significant. Therefore be sure to invert the output voltage that you observe to obtain the true algebraic value.

By properly assigning the polarities of the input voltages the inverting characteristics of the amplifier can be used to provide proper polarity output. For example, if we wish to solve 42 − 13, one way is to make 13 a negative voltage and 42 a positive voltage. As in Fig. 31A, the circuit will produce an output voltage equal to −29. Note that the input and feedback resistances are all equal to one another so that no coefficient multiplication takes place. Although this circuit produces the proper magnitude output voltage of 29, the polarity is algebraically incorrect. The reason for this is simply the inversion of the op amp. We can correct the situation by passing the signal at the output of the summer through a simple unity gain inverter. This will produce the proper output voltage without changing the magnitude.



$$-(E_1+E_2) = -(-42+13) = (42-13) = 29$$

Fig. 31. Two ways of producing correct algebraic subtraction.

However, we can produce the proper polarity output voltage with a single summer amplifier if we correctly assign the polarities of the input voltages. This is shown in Fig. 31B. The two input voltage magnitudes are the same as before, 42 and 13. However, we make the larger of the two voltages the negative so that the polarity of the inverted output will be correct. This way we let the inverting characteristics of the amplifier work for us.

CALCULATING OP AMP NETWORKS

By now you should be able to calculate the output voltage and polarity of an op amp network. Knowing the values and polarities of the input voltages and the values of the input and feedback resistances, you should be able to take a circuit like that in Fig. 32 and compute the output voltage and polarity. Notice that this circuit uses a wide variety of op amp configurations. While at first this network may seem somewhat complex, keep in mind that it uses nothing but the simple individual op amp circuits that you have already studied. By breaking the problem down and calculating the voltage at each point in the circuit, it is very easy to arrive at the correct output voltage and polarity. Let's go through this circuit and calculate the output voltage, assuming the input voltages shown.

Amplifier 1 is a simple inverting amplifier whose gain is the ratio of the feedback to input resistors. This ratio is 40K/25K = 1.6. This amplifier multiplies the input voltage by a gain of 1.6. Multiplying our input voltage of 40 by 1.6 gives us an output voltage of 64 volts. Keep in mind that the amplifier inverts so the output is negative since the input voltage is positive. This means that −64 volts appears across the potentiometer. This pot is set to a coefficient k of .2. This simply indicates that 20% of the voltage applied to the pot is tapped off and appears at the arm. To find the voltage at the arm we simply multiply −64 by .2 to get −12.8 volts. This voltage is applied to one end of a differential amplifier. Notice the differential amplifier uses all 10K resistors so that no gain is provided. Instead, the output voltage will be the difference between the two input voltages.

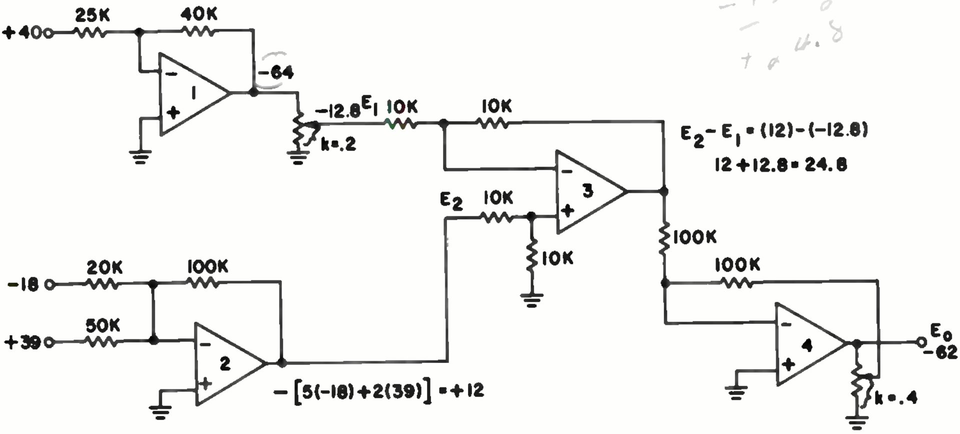


Fig. 32. An analog computing circuit using a variety of op amp circuits.

Amplifier 2 is a summer to which two input voltages are applied. The resistor values in the circuit provide gain multiplication for each input. Again the gain of each input is equal to the ratio of the feedback to the input resistor. The gain of the upper input is 100K/20K = 5. This means that the input voltage, −18, is multiplied by a gain of 5. The gain of the lower input is 100K/50K = 2, meaning that the input voltage, +39, is multiplied by 2. Making the calculation using the standard output formula, we get an output voltage of 12.

Now we have both inputs to the differential amplifier and we can calculate the output. Recall from your knowledge of this circuit that the output is equal to $(E_2 - E_1)$, or the lower input voltage minus the upper input voltage. Plugging our two input voltage values into this formula, we find that the output voltage is 24.8. Notice that since we are subtracting two input voltages of opposite polarity, the overall effect is algebraic addition. The output of amplifier 3 then is a positive 24.8 volts. This is now fed to amplifier number 4, where it is further multiplied in gain. Notice that the circuit used here is the one whose gain is determined by the coefficient of the output potentiometer. The gain of this circuit is equal to 1/k = 1/.4 = 2.5. The output voltage then is the inverted product of 24.8 multiplied by 2.5, or 62 volts.

INTEGRATOR CIRCUITS

In several previous lessons the subject of integrators was discussed. An integrator, in its simplest form, is a resistor-capacitor network whose time constant is made long with respect to the period of the input signal applied to it. This circuit, then, produces an output that is a function of the mathematical integral of the input signal. Integration is a mathematical function; specifically it is a form of calculus. However, we'll take a simpler approach (eliminating a calculus discussion) toward understanding the integrator circuit.

A simple integrator circuit is shown in Fig. 33. The input voltage is applied across a resistor and capacitor connected in series and the output voltage is taken from across the capacitor. If the input signal applied to this integrator network is a sine wave, the output signal will also be a sine wave. Because of the reactance in the circuit, the output voltage will be out-of-phase with the input voltage. Specifically, the output voltage will lag the input voltage by some angle between zero and 90°. The longer the time constant of the circuit, compared to the period of the incoming signal, the closer the output voltage approaches the 90° lag point. At this time the reactance of the capacitor is generally so low, compared to the resistance value, that the output

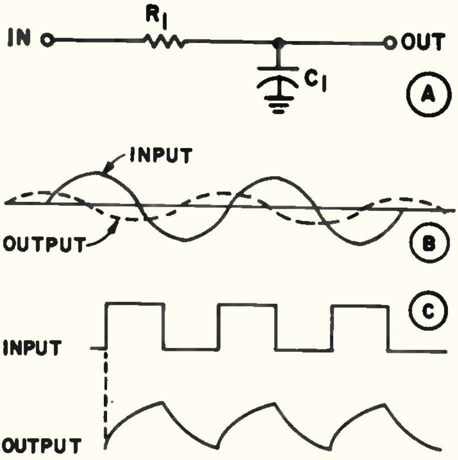

Fig. 33. A simple R-C integrator (A), sine wave input/output (B) and square wave input (C).

voltage is much smaller than the input voltage. Theoretically, if the phase shift were a total of 90°, the output voltage would be zero. However, a practical integrator is one whose phase shift approaches 90° closely, but also one that still has a measurable output voltage.

If the input voltage applied to an integrator is a square wave like that shown in Fig. 33C, the output voltage will be a triangular or sawtooth type waveform. The larger the time constant, the closer the output approaches a linear sawtooth or triangular waveform.

The integrator circuit shown in Fig. 33 is a useful network. It can be used to perform phase-shifting and wave-shaping operations. However, it is limited in that its output voltage is much smaller than its input voltage and it does not provide perfect integration. In many applications it is desirable to have exactly a 90° phase shift, or a perfectly linear sawtooth or triangular wave output. The op amp integrator that we will describe next can be used for such applications.

A typical op amp integrator is shown in Fig. 34. This is the standard op amp configuration except that we use a feedback capacitor instead of a feedback resistor. The result is a nearly perfect integrator circuit. Disregarding amplifier phase shift, the output is shifted exactly 90° when a sine wave is applied to the input of this circuit. The output amplitude can be adjusted to a desired level by choosing the proper values of resistance and capacitance. When a square wave or dc step voltage is applied, the output is nearly a perfect linear sawtooth or ramp waveform. The rate of change of the output voltage depends upon the input voltage and the gain of the integrator which is determined by the R-C values in the circuit.

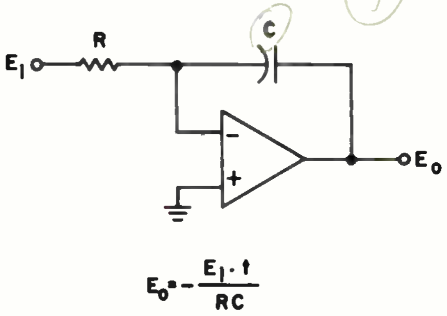

Fig. 34. An op amp integrator.

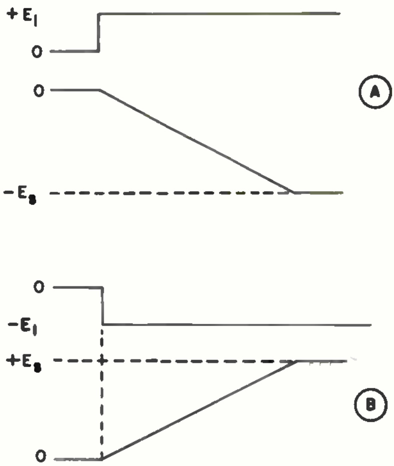

Fig. 35. Integrator input-output waveforms.

Now let's take a look at the operation of the op amp integrator circuit of Fig. 34. We are going to apply a step voltage to the input where the voltage switches rapidly from zero to some dc voltage level and remains there. The output waveform of the integrator, under these conditions, is shown in Fig. 35. In Fig. 35A, both the input voltage (E_I) and the output voltage are zero.

When the input voltage steps rapidly to the positive voltage level E_1, the output begins to rise slowly in a negative direction. The change of voltage is linear with respect to time, producing a straight negative-going ramp. As long as the input voltage is held at the E_1 level, the output will slowly rise due to the charging of the feedback capacitance through the input resistor. Soon we will reach a point where the output voltage can no longer continue to increase due to the saturation of the output amplifier of the op amp. When this occurs the output levels off at an output voltage $-E_S$, which is equal to or slightly less than the negative power supply voltage of the op amp.

Fig. 35B shows the input and output waveforms for a negative-going step voltage input. When the input voltage steps to a negative E_1 level, the output voltage begins to rise linearly from zero. As long as voltage is applied, the output will increase in a straight line to eventually reach the saturation point that is nearly equal to the positive supply voltage of the op amp.

The value of the output voltage is very predictable if we know the values of the input resistor, the feedback capacitor, the input voltage and the time during which the input voltage is applied. All of these factors are related by the formula:

$$E_{out} = -\frac{1}{R\text{-}C}(E_1)(t)$$

This formula tells us the value of the output voltage at a specific time (t) after input voltage E_1 is applied. The 1/R-C value is the gain of the integrator stage. The gain of this circuit is equal to the reciprocal of the time constant. If we are using a 1 mfd capacitor and a 1 megohm input resistance, the integrator gain is $1/(10^6 \times 1 \times 10^{-6}) = 1$. With a gain of 1, the output voltage with a step voltage input is simply equal to $-E_1(t)$.

Let's assume that we have an input voltage of +10 volts and that we allow the circuit to integrate for a period of 5 seconds. To determine the output voltage, we multiply the input voltage by the time and invert the result. In this case, $E_{out} = -10 \times 5 = -50$ volts. We can stop the integration after 5 seconds by removing the input voltage or by shorting the capacitor.

Fig. 36 shows the output waveforms you can expect. The waveform at A shows the step voltage input that switches from zero to +10 volts. The output voltage begins to increase in negative value. If the input is allowed to be present for 5 seconds, the output voltage will go to −50 volts. If we remove the input voltage at this point, the output will remain at its −50 volt level. This is

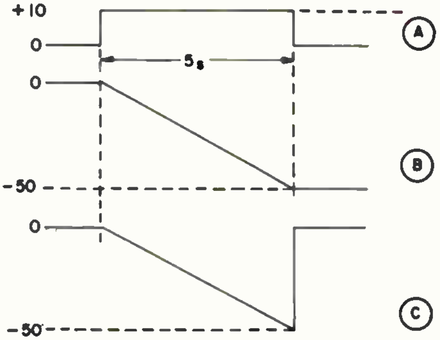

Fig. 36. Integrator step input (A), output where input is removed after 5 seconds (B) and output where feedback capacitor is shorted after 5 seconds (C).

because the capacitor retains the charge it received (−50 volts) while the input was connected. Over a long period of time, the charge on this capacitor will leak off due to the internal resistance of the capacitance, the input impedance of the op amp and other factors.

Fig. 36C shows the result of shorting the output feedback capacitor after a 5 second period. The output voltage again goes negative to reach a value of −50 at the end of 5 seconds. If we short the output capacitor with a switch of some type, the capacitor discharges quickly through the short circuit. The output voltage drops to zero despite the fact that the input is maintained at this value.

What happens to the output voltage when we change the gain of the amplifier? Let's change the values of the input resistor and feedback capacitor and note the effect this has on the output voltage when we integrate the +10 volt dc input for a period of 5 seconds. Assume that our new input resistance is 100K-ohms and our feedback capacitor is .1 mfd or 10^{-7}. The R-C time constant then is 10^5 X 10^{-7} = 10^{-2}. Then the gain of the integrator is 1/R-C = $1/10^{-2}$ = 1/.01 = 100. We now multiply our input voltage by 100 and the time the input voltage appears at the integrator. The output voltage should theoretically rise to a value of 10 X 100 X 5 = 5000 volts. However, this is an unreasonable value because of the output voltage swing limitations. Even if this is a high voltage amplifier where the output voltage swing may be ±100 volts, the output will quickly rise and saturate at its negative level shortly after the input voltage is applied.

The gain of an integrator, the input voltage value and the time the integrator is allowed to observe the input voltage determine the rate at which the output voltage changes. If the gain and the input voltage are high, the output voltage changes rapidly. If we are not careful to control the input voltage, gain and time duration of integration, it is quite easy to saturate the amplifier or to cause it to try to produce an output voltage beyond its capabilities. Fig. 37 shows the output voltage of an integrator with a −10 volt input step. The outputs produced with high, medium and low gains are shown. The high gain is a result of a short R-C time constant. The capacitor charges quickly, so the output voltage rises rapidly and saturates at time t_1. Making the R-C time constant longer lowers the gain. Since it takes the capacitor longer to charge, saturation doesn't occur until time t_2. A very low gain, meaning a long time constant, produces a very gradual output ramp that reaches saturation at t_3.

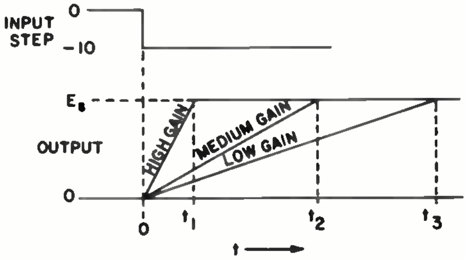

Fig. 37. How integrator gain affects the output ramp.

Fig. 38 shows how the op amp can be used with sine wave signals. If we assume that the feedback capacitor is 1 mfd and the input resistor is 1 megohm, the gain of the op amp is 1/R-C = $1/(10^6$ X $10^{-6})$ = 1. This means that the output will be equal to the input. However, because the circuit is an integrator, the input and output waveforms will be out-of-phase. A perfect integrator would produce an output that lags the input by 90°. Keep in

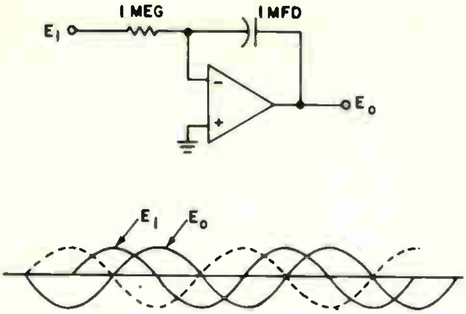

Fig. 38. Integrator operation with sine wave signals.

mind that our op amp integrator also inverts the signal; the output is actually shifted by 90° and then inverted 180°.

The input and output voltages of the integrator are also shown. The output voltage, as it would appear without inversion, is marked by the dashed line. As you can see, it lags the input signal by 90°. However, inversion adds another 180° phase shift, which causes the output voltage to appear as though it is leading the input signal by 90°. We call the output waveform a cosine waveform to distinguish it from the sine wave input. By adjusting the values of input resistance and feedback capacitance, the gain of the amplifier can be adjusted to produce any desired output amplitude within the amplifier's capability.

3-23-72

ELECTRONIC COMPARATORS

An electronic comparator is a circuit that compares one voltage with another and produces an output signal that indicates when the two input voltages are equal. A good electronic comparator will also produce an output signal that will permit you to know whether one of the input signals is less than or greater than the other. One of the input signals to the comparator is the reference signal. It is the standard by which we will compare another input signal, generally a changing or varying signal.

The simplest form of a comparator is the diode circuit shown in Fig. 39. A diode is biased through a resistance with a 20-volt battery which represents the reference voltage. We are going to compare this reference voltage with the input signal, applied to the cathode of the diode that is a positive-going ramp voltage. This could possibly be the output from an integrator being driven from a negative dc source.

With the input voltage at zero, the diode is forward-biased. If we assume this to be a perfect diode that has no voltage drop across it, the output voltage will also be zero. As the input voltage begins to rise, the diode still conducts; therefore, the input is effectively connected directly to the output through the diode.

The output exactly follows the shape of the input signal. The output remains the same as the input only while the input voltage is less negative than the reference voltage, keeping the diode forward-biased. As soon as the input voltage reaches a value of 20 volts, the diode no longer conducts; there is insufficient voltage across it to cause it to be forward-biased. As the input voltage rises beyond 20, the diode is still cut off so the output voltage remains at 20 volts. The

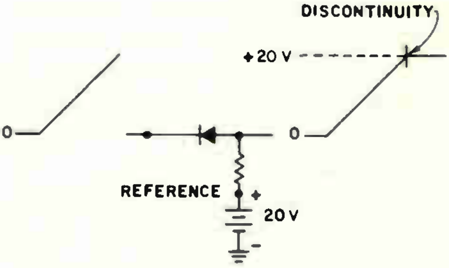

Fig. 39. A simple comparator circuit.

output, in effect, sees the 20 volts from the reference battery through the resistor.

The output signal flattens off at this point. The point where the waveform stops rising in voltage and flattens out is known as a discontinuity. As long as the input voltage is less than the reference voltage, the output follows the input. However, when the two are equal, a discontinuity in the output occurs. This discontinuity represents the point where the reference and input voltages are equal. Beyond this the output waveform flattens out, indicating that the input voltage is greater than the reference.

While the circuit of Fig. 39 is definitely a comparator, its usefulness is somewhat limited. In a practical circuit, there is a finite voltage drop across the diode. For a silicon diode this drop may be .6 or .7 volt. As a result the diode will not stop conducting until the input voltage is approximately .6 or .7 volt above the reference voltage. For this reason there is a substantial error in the comparison. This is particularly true if the reference voltage is a small voltage that is the same order of magnitude as the diode voltage drop. For very large voltages, the percentage error would be much smaller.

In addition, the output waveform is not in the most easily used form. In a practical circuit, the discontinuity point is not a sharp and clearly defined point. Because of the stray capacitance in this circuit, the point is rounded and introduces some ambiguity in the exact point of equality. This circuit is adequate for simple comparisons, but for critical comparisons, a more sophisticated circuit is required.

Consider for a moment how we may use a differential amplifier as a comparator. A differential amplifier is normally designed to handle dc signals. Therefore we may apply the reference voltage to one of the differential inputs. Since the output of the amplifier is equal to the difference between the two inputs multiplied by the gain, applying a varying signal to the other input will make the differential amplifier output indicate when the two are equal. When the two signals are equal, the output of the amplifier will, of course, be zero. The higher the gain of the amplifier, the larger the output voltage swing will be for a small difference between the two input signals. Remember that this circuit amplifies the difference voltage between the two input signals.

According to this principle an op amp operated in the differential mode with no feedback should provide excellent comparison. By using the full open-loop gain of the amplifier, only millivolts (or perhaps microvolts) of difference signal is required to cause the amplifier output to swing between its two maximum output voltage limits.

Fig. 40A shows an op amp connected as a comparator. Notice that absolutely no feedback connection is provided. The reference signal is connected to one of the inputs while the varying signal, to be compared to the reference signal, is applied to the other input.

If we use the input signal assumed earlier for the simple comparator, we can get some idea as to the sensitivity of this circuit. When the input voltage at the inverting input is 0 volts, the reference being 20 volts, the difference signal is 20 volts. With this much input signal multiplied by the full open-loop gain of the amplifier, the output will swing to its positive saturation level.

With an open-loop gain of 10,000, the output voltage would try to swing toward a value of 200,000. However, the ampli-

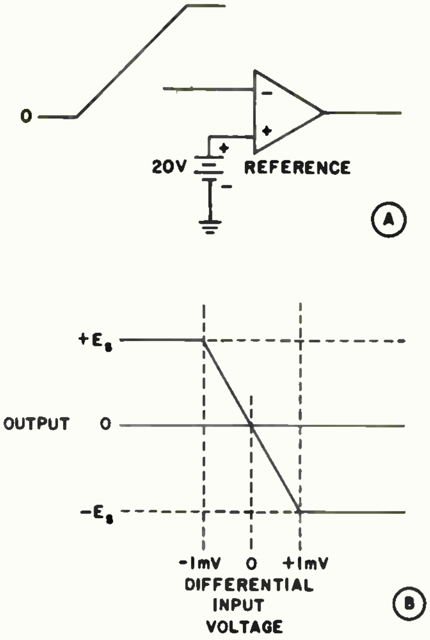

Fig. 40. An op amp comparator (A) and its output voltage (B).

fier will simply saturate at its positive output swing point. You can see this in the graph of Fig. 40B. As the input signal begins to rise from zero in a positive direction, the difference voltage between the two inputs grows smaller. However, during most of the rise, the difference voltage between the two is still large enough to keep the amplifier output in saturation.

Soon we begin to reach a point where the input voltage approaches the value of the reference. When the input voltage becomes equal to the reference voltage, the output of the amplifier will be zero. As you can see from the graph in Fig. 40B, the output voltage drops from its positive saturation level to zero when the two voltages are equal.

As the input voltage continues to swing in a positive direction, it becomes greater than the reference voltage and the difference signal between the two is amplified. As soon as the difference signal reaches a large enough value, the output of the amplifier swings to the negative saturation region. As you can see from the curve, the gain of the amplifier is so high that it takes only a 1 millivolt difference between the two input signals to cause the amplifier output to swing to one of its saturation levels.

For that reason the sensitivity of this circuit enables us to detect the equality between two signals within very close ranges. With only 1 millivolt of error, it is possible to compare very low level signals with good precision. When the output of the comparator sets at one of its saturation levels, it means that the input signal is either greater than or less than the reference voltage. The other saturation level is reached whenever the input signals are again unequal. When the two input signals are equal, the output of the comparator is zero. Simply by looking at the output signal, you can tell whether the input voltage is less than, equal to, or greater than the reference voltage.

There are some very important facts to keep in mind here. The rapid switching of the op amp output is due to its high gain or sensitivity. Remember that we are amplifying the difference voltage between the two inputs. With the high open-loop gain, the output can swing from its negative to positive output saturation level with only an extremely small difference signal. For most typical op amps, a difference voltage in the millivolt region is sufficient to cause the amplifier to swing from one extreme to the other. There is some error introduced, but it is extremely small; it is negligible for almost all practical electronic circuits.

The sensitivity of the op amp com-

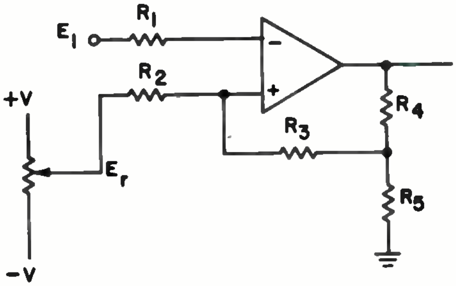

Fig. 41. Adding feedback to raise the trigger level and minimize the effects of noise.

parator can also be a disadvantage. Many times noise signals appearing on the inputs can cause the comparator to trigger falsely, producing undesirable output voltage transitions.

To overcome the noise sensitivity of the comparator, we can add feedback to the circuit. Fig. 41 shows a differential op amp comparator where the input voltage E_1 is applied to the inverting input through R_1. The reference voltage is obtained from a potentiometer that is connected to both positive and negative power supplies. The arm of the pot can be set to any voltage between the upper (positive) and lower (negative) voltage levels and still include the zero volts at the center of the pot. This provides a convenient means of adjusting the reference voltage level for the circuit. The reference voltage is applied through R_2 to the non-inverting input of the op amp.

Let's assume that the op amp has an initial sensitivity of 10 millivolts. This means that a change or difference of 10 millivolts between the two inputs will cause the amplifier to switch from one output level to the other. If noise exceeding 10 millivolts appears on the input line, the comparator output will trigger erratically and give us a false indication of the comparison of the input and reference signals.

To get a true comparison, we apply feedback to the non-inverting input. A small portion of the output voltage is tapped off by the voltage divider made up of R_4 and R_5. The voltage is fed back through R_3 to the non-inverting input along with the reference voltage. Here the feedback voltage effectively adds to the reference voltage, increasing the amount of difference voltage required to cause the amplifier to trigger. If we feed back 15 millivolts from the output, the overall threshold for the circuit becomes 10 + 15 or 25 millivolts. This means that the difference between the two input signals must be at least 25 millivolts in order to cause the output voltage to switch from one level to the other.

This introduces a little more error in our comparison. However, the increased voltage difference required for output switching minimizes the effect that noise has on the circuit. In other words, the circuit can now tolerate a higher level of noise on the input without producing erratic switching. The feedback effectively reduces the sensitivity of the comparator but improves its noise immunity. By replacing resistors R_4 and R_5 with a potentiometer, the sensitivity can be made adjustable.

Fig. 42 shows another way of using an op amp as a comparator. The non-inverting input is connected to ground as it normally is in a standard op amp

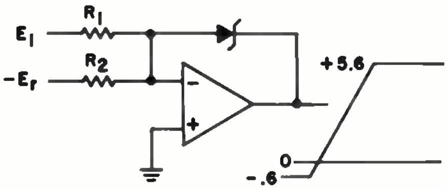

Fig. 42. Comparator made with an op amp summer.

configuration. The input and reference voltages to be compared are applied to the inverting input through summing resistors R_1 and R_2. In order for this circuit to properly perform algebraic addition (subtraction), the polarities of the two voltages to be compared must be opposites.

In the comparator circuit you studied in Fig. 40, the polarities of the input and reference voltages were the same. If the input voltage was positive, the reference voltage would also be positive. In the same way, a negative input voltage and a negative reference could also be used to obtain proper operation. Here we are effectively using the algebraic addition characteristics of the op amp to compare the two input signals. When the two input signals E_1 and $-E_R$ are equal in magnitude, the sum of the inputs at the inverting input will be zero, making the output zero. If the input voltage E_1 is greater in magnitude than the negative reference voltage, the resulting input is positive. This causes the output to swing to its negative saturation level. When E_1 is smaller, the net input voltage is negative and the output voltage swings to its positive output extreme.

In this circuit we are using a Zener diode in the feedback path. This prevents the amplifier from swinging between its two saturation levels, limiting the output voltage levels. When the output swings in the negative direction, it causes the Zener diode to be forward-biased. The output voltage is limited to .6 volt. When the output voltage swings positive, the Zener diode becomes reverse-biased in its Zener mode and holds the output voltage to a level equal to the Zener voltage. In this case we are using a 5.6 volt Zener. This practice of limiting, or clamping, the output voltage to a specific level is often used to make the output voltage of the comparator compatible with other electronic circuits that it will drive.

COMPARATOR APPLICATIONS

The op amp comparator circuits that we have discussed here have a wide variety of applications. They are useful in any situation where you want to compare the voltage level of two inputs and produce an output that detects this comparison. There are many electronic control applications where it is necessary to detect when two voltage levels are equal.

The comparator may be used to monitor the output voltage of a power supply driving a critical instrument. The reference voltage is set equal to the desired power supply output voltage while the output voltage is applied to the comparator input. As long as the output voltage is above the reference voltage, the output of the comparator is considered to be *off*. However, if the power supply voltage should drop, the comparator would detect this change in voltage and cause its output to switch to an *on* condition. The output could then be used to turn on a light that would signal a low voltage condition that may be undesirable in the system. A comparator used in this way is called a threshold detector. Comparators find a wide variety of uses in control applications such as this.

The output voltage of a comparator can also be used to make a decision regarding the *off* or *on* of a specific logic circuit, based upon the relative amplitudes of certain input and reference voltages. For example, if the input voltage is above the reference voltage, a particular electronic circuit may be permitted to operate. However, if the input voltage drops below the reference voltage, the output of the comparator either turns off the electronic circuit to prevent its operation or enables another electronic circuit to perform an alternate function.

A very common application for the voltage comparator is waveform generation. For example, the comparator can be used to change a sine wave signal into a square wave. Fig. 43 shows a sine wave signal applied to the input of a comparator. The sine wave varies symmetrically above and below zero. The dashed line in the figure represents an applied dc reference voltage. Whenever the sine wave and reference voltages are equal, the output of the comparator will switch and produce a square wave output signal. Also notice in Fig. 43 that each time the sine wave and reference voltages are equal, the output of the comparator switches to produce a clean square wave. The frequency of the square wave is the same as that of the input sine wave. However, the duty cycle of the output waveform depends upon the setting of the reference voltage. A 50% duty cycle square wave can be generated from the sine wave by making the reference input equal to zero. Whenever the sine wave voltage crosses the zero axis, the comparator will switch and produce a 50% duty cycle square wave. Remember that output clamping with a Zener diode can be used to produce desired, limited voltage levels for driving other circuitry.

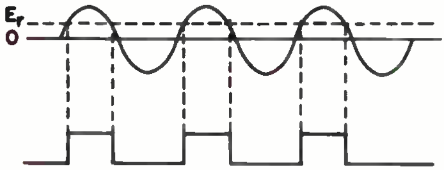

Fig. 43. Input-output waveforms of a comparator used for wave-shaping.

SELF-TEST QUESTIONS

(aa) A 3-input summer amplifier has input resistors R_1 = 10K, R_2 = 5K, and R_3 = 2K to which are applied voltages of $E_1 = -10$, $E_2 = +6$ and $E_3 = +8$. The feedback resistor R_f is 20K. What are the amplitude and polarity of the output voltage?

(ab) True or false: An op amp summer can perform any algebraic addition problem.

(ac) True or false: A summer can have any number of inputs.

(ad) True or false: The output voltage rate of change in an integrator can be varied by changing the size of the feedback capacitor.

(ae) True or false: An op amp integrator does not invert.

(af) An integrator has a feedback capacitor of 1 mfd and an input resistor of 100K. What is the gain?

(ag) If the integrator in (af) is allowed to integrate a –.3 volt input for 7 seconds, what will the output voltage be?

(ah) True or false: In a summer type comparator the input and reference voltages must be of opposite polarity.

3-22-76

Tests and Measurements

The ultimate test of an op amp is its performance in the particular application for which it was selected. However, there are individual tests that can be made to test the individual specifications to determine its suitability for a given job. In this section we are going to discuss measurements of op amp characteristics. Adequate prediction of performance requires measurement of many of the parameters that will be discussed in this section.

MEASURING OPEN-LOOP GAIN

Open-loop gain of op amps can be a difficult parameter to measure; gain is usually very large and oscillation problems are often encountered. As you know, the dc gain of op amps is fairly large. At low frequencies it starts to decrease, or roll off, at a fixed rate. Therefore, we must measure open-loop gain at a very low frequency or at dc. Measurement at dc poses difficult problems because the offset voltage also gets amplified. If the offset voltage is too large, it could cause the output voltage to swing to either its positive or negative saturation level. Therefore, it is better to measure the open-loop gain using ac at some low frequency.

A common circuit used for the measurement of open-loop voltage gain is shown in Fig. 44. The input source is a sine wave at 10 Hz that is applied to the non-inverting input through a resistive divider formed by R_1 and R_2. This resistive divider is designed to reduce and accurately control the input voltage to the circuit. The op amp input voltage is adjusted to some low value such as 100 microvolts.

At first glance it may seem as if the amplifier is not in the open-loop mode because there is a 1 megohm resistor connected from the inverting input to the output and a capacitor of 1,000 microfarads connected from the input to ground. Notice that this test circuit has the same configuration as a non-inverting amplifier circuit: the input signal is applied to the non-inverting input while a feedback network is connected between the output and the inverting input. The only exception here is the use of a capacitor between the input and ground rather than a resistor. This capacitor is an effective impedance with ac signals so it works just as well as a resistor. The value of its reactance at 10 Hz is used with the 1 megohm feedback value to determine the gain. The gain called for by this feedback configuration at 10 Hz is equal to

$$\frac{E_o}{E_i} = \left(1 + \frac{R_f}{X_c}\right)$$

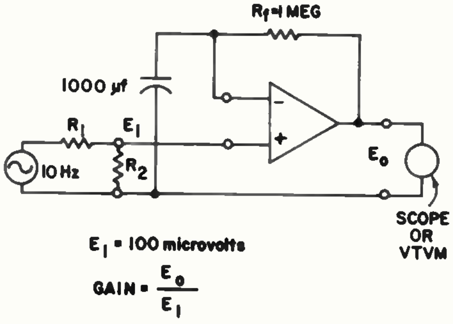

Fig. 44. Open-loop gain measurement.

The capacitive reactance of a 1,000 mfd capacitor at 10 Hz is

$$X_c = \frac{.159}{fC} = \frac{.159}{10 \times 1000 \times 10^{-6}} = \frac{.159}{10^{-2}} =$$

$$.159 \times 10^2 = 15.9 \text{ ohms}$$

Rounding off this value to 16 and using the other values given, we find that this feedback yields a gain of

$$\left(1 + \frac{R_f}{X_c}\right) = \left(1 + \frac{1{,}000{,}000}{16}\right) = 62{,}500$$

or approx. 96 db

In all probability, however, this gain is beyond the capability of the circuit. In other words, even though we have what appears to be closed-loop gain, it is high enough so that the limiting factor will be the open-loop op amp gain. If the op amp has a very large open-loop gain, the values of R_f in Fig. 44 should be further increased. Op amp, open-loop, frequency response is usually flat up to about 100 Hz. Therefore the low-frequency measurement is valid and convenient for measurements with standard instruments.

To measure the gain, we first connect a signal generator, whose output is 10 Hz, to the input and adjust it until the input voltage to the amplifier is 100 microvolts. This can only be done with knowledge of the value of the voltage divider formed by resistors R_1 and R_2. Since 100 microvolts is usually too small to observe directly, you can set the generator output to some more easily measured value and then rely upon the voltage divider ratio to produce an input voltage of 100 microvolts. Next, a high impedance voltmeter or an oscilloscope is connected to the output and the output voltage is measured. The gain is the ratio of the output to input voltage.

If an oscilloscope is used for output measurement, the peak-to-peak value is normally recorded. This must be converted to rms, or the same input voltage units, to obtain the correct value of gain. It is important that the power supply be properly decoupled, or filtered, with large capacitors to ground as close to the amplifier as possible. Should it be required, it is also important to compensate for amplifier oscillation. These precautions should be taken in almost all the measurement circuits we describe.

Gain Stability vs. Temperature. The temperature coefficient, or variation of the gain with temperature, can be measured with the same circuit as Fig. 44. All you have to do is vary the temperature of the amplifier and measure the gain at the various temperatures. A gain vs. temperature curve can then be plotted. The stability factor is a number obtained by dividing the change in gain by the change in temperature. The smaller this number, the better the stability.

Gain Stability vs. Power Supply Changes. The same procedure can be used to measure the variation of gain with changes in power supply voltage. This is often very important because the amplifier specification sheet may call for a gain with a given power supply setting different from the setting being used. To do this measuring, we must know the typical and worst case values for the various power supplies. In general, the gain of the op amp increases as the power supply voltage increases. However, we must be careful to see that the maximum rating of the op amp is not exceeded. The stability factor is a number obtained by dividing the change in gain by the change in power supply voltage setting. The lower this number is, the better the stability.

IMPEDANCE MEASUREMENTS

Open-loop Input Impedance. The open-loop input impedance is measured in a circuit like the one used for the open-loop gain test. The only exception is that a variable resistor (R_3) is placed in series with the input. Refer to Fig. 45. The input voltage is again adjusted to be 100 microvolts at about 10 Hz. With the value of resistor R_3 reduced to zero, the output voltage is measured. The second step is to increase the variable of R_3 until the output drops by 10%. In other words, if the output swings 10 volts peak-to-peak, we increase the value of R_3 until the output drops to 9 volts peak-to-peak. We are decreasing the output by decreasing the value of the input with a voltage divider, formed by the series R_3 and the input impedance to the amplifier. Since the output of the amplifier has dropped 10%, we conclude that the resistance into the input terminal is equal to 9 times the value of R_3 at that setting. All you have to do now is measure the value of R_3 and multiply it by 9. This will give you the input impedance of the amplifier.

The key to understanding this method of measuring the input impedance is to realize that the output voltage of the amplifier drops because of the introduction of variable resistor R_3. When it drops 10%, the relationship between R_3 and the input impedance of the amplifier is 9 to 1.

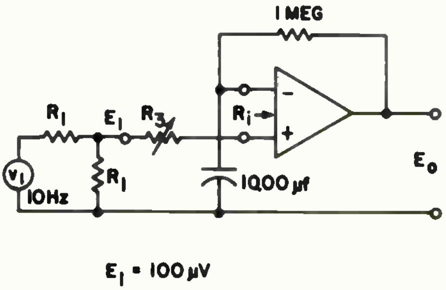

Fig. 45. Measuring input impedance.

In order to use this method, we must have an initial idea of what the input impedance is going to be so we can choose the right magnitude for R_3. For example, this input impedance can be as large as 1,000 megohms in FET input amplifiers. This would mean that the value of the resistor must also be extremely large. Therefore, this method may be impractical for some high input impedance op amps.

Output Impedance. The output impedance measurement is similar to the measurement of the input impedance, but simpler. We'll use the circuit shown in Fig. 46 to illustrate.

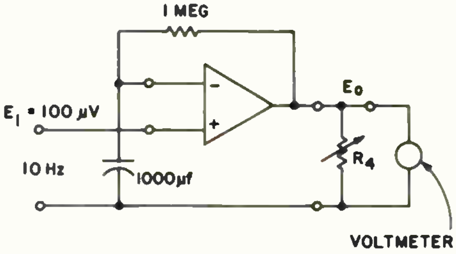

Fig. 46. Measuring output impedance.

We again adjust the input voltage to 100 microvolts but, this time, connect a variable load resistance (R_4) to the output. With the load resistance disconnected, we measure the output voltage. We then connect R_4 to the output and adjust its value until the output voltage drops 10%. For this procedure we must be sure that the output signal is not clipped or otherwise distorted. We are using the output impedance of the amplifier and R_4 as a voltage divider whose output voltage drops as we decrease R_4. When the output voltage drops 10%, the output impedance of the amplifier is equal to the value of the load resistance divided by 9.

INPUT VOLTAGE MEASUREMENTS

Input Offset Voltage. The input offset voltage is very conveniently measured at dc using the circuit shown in Fig. 47. In this circuit we have an amplifier connected in the inverting configuration with an input resistance equal to 100 ohms and a feedback resistance equal to 10K. Therefore, the gain of the circuit is 10K/100 = 100.

With the input shorted to ground, the input to the circuit is equal to the input offset voltage of the amplifier. Since this input offset voltage is usually in the millivolt region, it is difficult to measure; it is best to amplify it and measure the enlarged version at the output. This is what this circuit does. The output voltage, if measured with a suitable voltmeter, will be equal to the input offset voltage multiplied by the gain of the amplifier. What we have done is to use the amplifier to increase its own input voltage by shorting the inputs. Now, if the input voltage is as small as 1 millivolt, it will appear in the output as a more conveniently measured voltage of 100 millivolts.

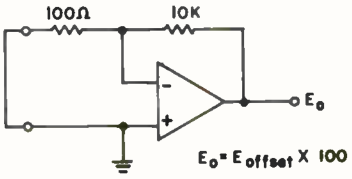

Fig. 47. Input offset voltage measurement.

Input Offset Voltage Drift vs. Temperature. The input voltage drift versus temperature can also be measured in the circuit of Fig. 47. All you have to do is vary the temperature of the amplifier and note the offset voltage change. Then compute the change in offset voltage divided by the change in temperature. The smaller this ratio, the better the matching of V_{be} of the input transistors with temperature.

Input Voltage Drift vs. Supply. The variation of input offset voltage with power supply voltage changes is commonly called the power supply rejection ratio. We measure the input offset voltage with different values of power supply voltages. Then we divide the change in offset voltage by the change in power supply voltage producing that change. The resulting ratio tells us the stability. A low ratio value is desirable. In some cases it is best to vary only one of the two supply voltages at a time.

Input Voltage Drift vs. Time. To measure the input voltage drift versus time, attach a strip chart recorder to the output and let the amplifier run. Then, checking the strip recorder output, we find the maximum output change for the prescribed time.

A strip chart recorder is a special type of voltmeter that records the output voltage in ink on a strip of graph paper. The paper is moved very slowly past the pen that marks a line or curve on it. The position of the pen is determined by the input voltage; the position of the mark on the paper shows the voltage variation with time.

Input Bias Current. The measurement of the input bias current is done best as in Fig. 48A. Rather than measuring the

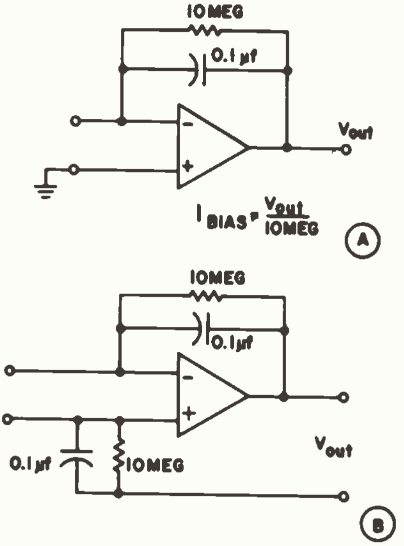

Fig. 48. Input bias current measurement (A) and input offset current measurement (B).

input bias current directly at the input with some form of current meter, we insert a 10 megohm resistor from the input to the output. The other input of the amplifier under test is returned to ground. This circuit takes advantage of the fact that the input bias current, the current that flows into or out of the input terminal, must flow through the 10 megohm resistor and appear as an output voltage. So the approach here is very similar to the one used for the input offset voltage. We convert the current into a fairly large voltage rather than a current of a few nanoamperes, which is very difficult to measure.

To use the circuit shown in Fig. 48A, measure the output voltage (E_o) with a suitable oscilloscope or voltmeter. The input-output current will be equal to the magnitude of the output voltage divided by 10 megohms. The reason for this is that the input bias current is flowing through the 10 megohm resistor. We can use Ohm's Law to determine this current. Let us assume that the output voltage of the amplifier (which we are testing under the conditions of Fig. 48A) equals 1 volt. When we divide this voltage by 1 megohm, we get .1 microampere, or 100 nanoamperes. This is the value of the input bias current flowing into the inverting input.

Using this method we can obtain the current flowing into only one of the input terminals. The current flowing into the other terminal could have a different value. Therefore in order to find the non-inverting input bias current, we must do a similar measurement. To do this we must ground the inverting input previously used and connect the 10 megohm resistor between the other input and ground. Now we obtain another value for input bias, different from the first one. The .1 mfd capacitor across the 10 megohm resistor is used to eliminate any noise or ac signal that could occur.

Input Offset Current. As you know, the average of the two input bias currents is called the input offset current. One way we could measure the input offset current is to individually measure the two input bias currents, add them and divide by two. However, the circuit shown in Fig. 48B shows a more direct way of obtaining the input offset current in one measurement.

We have a balanced input with a 10 megohm resistor and a .1 mfd capacitor connected to both inputs. This way we obtain an output voltage that is proportional to the difference between the two bias currents. To obtain the true input offset current, the value of this output current must be divided by two. In this circuit, the input offset current equals the output voltage divided by 10 megohms, as before.

In order to measure the input bias current drift and input offset current drift with temperature, we place the amplifier in a temperature-controlled environment and note the change in input offset current divided by the change in temperature. That way we get what we call the "temperature coefficient" of the input bias current and of the input offset current.

Often it is important to find the input current drift with power supply voltage changes. Depending upon the amplifier requirements, we vary the power supply output ±10, or 20%, while we monitor the input offset current. We then divide the change in input offset current, caused by the power supply variation, by the change in power supply magnitude. The resulting ratio gives an indication of the stability. A low ratio is most desirable.

FREQUENCY RESPONSE

In order to measure the frequency response, we normally connect the amplifier in the desired configuration. Then we apply a sine wave of varying frequencies to the input while we monitor the output voltage and the gain. However, in order to find the maximum frequency response, it is better to connect the amplifier in the unity gain configuration shown in Fig. 49A.

As we explained before, if feedback is used in an amplifier, the magnitude of the gain decreases and the bandwidth increases. In the extreme case of unity gain, the amplifier frequency response curve extends all the way to the point where it meets the open-loop roll-off curve. This is shown in Fig. 49B. In this figure we show the frequency response for open-loop gain, a gain of 100, and the frequency response of the unity gain amplifier which intersects the axis at the maximum frequency at which the amplifier can be used (F_{max}).

To find the maximum frequency response, we use a signal generator with a variable frequency output. The generator should be set at a fairly low output, e.g., 30 millivolts. The output of the amplifier is monitored with an oscilloscope or voltmeter and the frequency is increased until the output voltage drops 3 db. At this frequency the response will equal the F_{max} of the amplifier. Of course, if some gain is required the procedure will be the

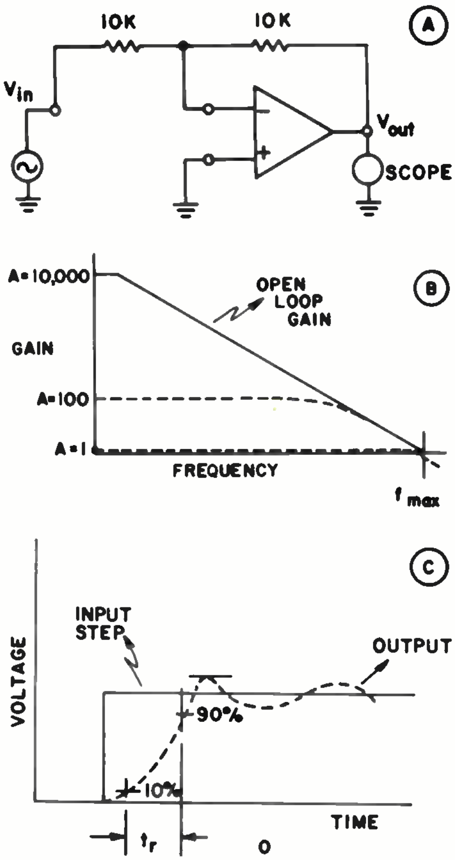

Fig. 49. Frequency response measurement.

same. The frequency response is always taken when the gain drops to 3 db below the low-frequency or dc value. As you can see, this frequency will decrease as the closed-loop gain of the amplifier increases.

Rise Time and Delay Time. The same circuit that was used for the frequency response measurement is also used to find the rise time of the amplifier. However, instead of connecting an input sine wave, we connect a square wave of about 100 millivolts peak-to-peak. We then monitor the output with an oscilloscope. The procedure is to observe the output on an expanded time scale and measure the output rise time from 10% to 90% of its rise. If the square wave input rise is fast compared to the rise time of the amplifier, the rise time of the square wave input can be neglected. For example, if we use a generator with a rise time of 10 nanoseconds and the rise time seen on the oscilloscope is 1 microsecond, the 10 nanoseconds can be neglected.

In Fig. 49C we show a picture of what can be seen on a dual channel oscilloscope. The first signal is the input step, or square wave, which we have shown as an ideal condition with zero rise time. The dashed line is what could be the amplifier output. As we mentioned before, the rise time is measured from the 10% point to the 90% point.

It is also possible that some degree of overshoot will be noticed rather than a smooth signal that simply follows the input. In many cases the overshoot limits must be specified by expressing the amount of overshoot as a percentage of the output voltage. Take the case where the input voltage is 100 millivolts and the output voltage is also 100 millivolts because the circuit is connected with the unity gain configuration. If the output in this situation overshoots to 110 millivolts and then comes back down, the amount of overshoot is 10% (10 millivolts/100 millivolts). In the case of many high-frequency amplifiers, the overshoot can go up to 40%.

The frequency response and rise time characteristics of an op amp are intimately related. In general, amplifiers with very high-frequency response have much faster rise times than amplifiers that have a low-frequency response. The rise time and frequency response are closely related; if one is known, the other can be calculated. The formula F = .35/tr shows this relationship. F is the 3 db down frequency, or the amplifier bandwidth in MHz, where the t_r is the rise time expressed in microseconds. For example, if the rise time is .5 microsecond, the bandwidth, or 3 db cutoff, is .35/.5 = .7 MHz. By turning the formula around (t_r = .35/f), you can calculate the rise time for a given bandwidth.

SUMMARY

In this section we have attempted to describe the procedures for testing, measuring and evaluating some op amp parameters. In many cases such comprehensive tests are not necessary. The most important tests that guarantee op amp performance are:

1. Open-loop gain.
2. Input offset voltage and input offset voltage drift with temperature.
3. Input offset current.
4. Input impedance.

In applications where we are interested in specific characteristics, they must be measured. If we have an op amp that will change very much with time, the variations of gain, offset voltage and current with power supply voltage change become very critical. However, in most applications the parameters given are all that are needed to guarantee good op amp performance.

A lot of these test circuits can be combined with switching arrangements to form a piece of test equipment that can quickly perform all of the op amp tests given here. These automatic test sets for op amps are able to sequence from one test to the other by themselves. By using comparators they provide a light signal of whether all the tests have been passed; if any test was not passed, a red light indicates a no-go condition.

A photograph of one of these units is shown in Fig. 50. The square push buttons are used to select the desired test while the rotary switches select various input parameters. The meter is used for voltage and current measurements. This unit tests integrated circuit op amps that are plugged into the test socket below the push buttons. You are going to study integrated circuits in detail in a later lesson. You will see then how useful this device is in testing integrated circuit op amps.

SELF-TEST QUESTIONS

(ai) Why is the open-loop gain measurement made at a very low frequency?

(aj) The output rise time of an op amp is 400 nanoseconds (.4 microseconds). What is the 3 db bandwidth?

Answers to Self-Test Questions

(a) True.

(b) False. The gain is the ratio of the feedback to the input resistor.

(c) True.

(d) True.

(e) False.

(f) Gain = $R_f/R_1 = 84K/12K = 7$.

(g) $E_o = -$ gain $\times$ $E_1 = -4(-3.5) = +14$ volts.

(h) High open-loop gain, high input impedance, low output impedance, wide frequency response, direct coupling, low drift, low power consumption, differential inputs.

(i) Gain = $1 + R_f/R_1 = 1 + 120K/30K = 1 + 4 = 5$.

(j) $E_o = R_f/R_1 \ (E_2 - E_1) = 75K/15K \ [-23 - (-16)] = 5(-23 + 16) = 5\ (-7) = -35$ volts.

(k) False.

(l) False. The load is connected between the output and the inverting input.

(m) $k = E_o/E_1 = 9/27 = .333$.

(n) Gain = $1/k = 1/.004 = 250$.

(o) Unmatched emitter-base voltage drop in the differential input transistors is the basic cause of input offset voltage.

(p) Unmatched leakage and Beta in the input transistors cause input offset current.

(q) A high input impedance does not load the driving source.

(r) Rise time is the time it takes the amplifier output to rise from 10% to 90% of its final amplitude in response to a step input.

(s) The power supply voltages determine the output swing limit.

(t) Drift is caused by changes in component characteristics with temperature, time and power supply variations.

(u) No. This circuit can adjust the offset to produce a zero output for zero input, but drift will change the characteristics and make the output above or below zero.

(v) Six db per octave is equivalent to 20 db per decade. 100 Hz to 1 kHz is a decade change so the gain drops by 20 db or from 120 db to 100 db.

(w) Frequency compensation networks insure a 6 db per octave roll-off to prevent oscillation.

(x) High input impedance can be obtained by using FET input transistors, the Darlington connection or super-high Beta transistors at low current levels.

(y) A booster amplifier is used with an op amp to permit it to develop its normal output voltage across a low resistance load. It is a power amplifier.

(z) The internal self-bias, due to the depletion layer, causes crossover distortion.

(aa) $E_o = -\left[E_1(R_f/R_1) + E_2(R_f/R_2) + E_3(R_f/R_3)\right]$

$E_o = -\left[-10(20K/10K) + 6(20K/5K) + 8(20K/2K)\right]$

$E_o = -\left[-10(2) + 6(4) + 8(10)\right]$

$E_o = -(-20 + 24 + 80) = -84$.

(ab) True.

(ac) True.

(ad) True. Changing the feedback capacity varies the gain so the rate of output voltage change can be controlled.

(ae) False. The op amp integrator does invert.

(af) Gain = 1/R-C = 1/(100K X 1 mfd) equals
$1/(100{,}000 \times 1 \times 10^{-6}) =$
$1/(10^5 \times 10^{-6}) =$
$1/10^{-1} = 1/.1 = 10.$

(ag) $E_o = -1/R\text{-}C \cdot E_{in} \cdot t = -10 (-.3)(7) = 21$ volts.

(ah) True.

(ai) Since the gain begins to roll off at a very low frequency, to obtain a measurement of the maximum open-loop gain, the test should be performed at dc or some low frequency before this roll-off occurs.

(aj) Bandwidth $f = .35/t_r = .35/.4 =$ .875 MHz or 875 kHz.

Lesson Questions

Be sure to number your Answer Sheet K309.

Place your Student Number on every Answer Sheet.

Most students want to know their grades as soon as possible, so they mail their set of answers immediately. Others, knowing they will finish the next lesson within a few days, send in two sets of answers at a time. Either practice is acceptable to us. However, don't hold your answers too long; you may lose them. Don't hold answers to send in more than two sets at a time or you may run out of lessons before new ones can reach you.

1. What three transistor characteristics affect input offset voltage and current?

2. What two external conditions are most responsible for changes in op amp characteristics?

3. A two-input op amp summer has input resistors R_1 = 50K, R_2 = 40K to which are applied input voltages of E_1 = −30 volts and E_2 = +40 volts. The feedback resistor R_f is 200K. What are the output voltage amplitude and polarity?

4. Name two ways of getting high input impedance in an op amp.

5. An input voltage of −2.3 volts is applied to an op amp follower. What is the output voltage?

6. A triangular waveform is applied to a comparator whose reference input is grounded. The output signal will be:

   (a) A triangular wave
   (b) A sine wave
   (c) A square wave
   (d) A fixed dc voltage

7. The output saturation limit on an op amp integrator is ±50 volts. The integrator gain is 5, the input voltage is +2 and the circuit integrates for 4 seconds. Is the output in saturation?

8. The 10% to 90% output rise time of an op amp is .08 microseconds. What is the upper 3 db down bandwidth?

9. As the closed-loop gain of an op amp circuit increases, the bandwidth

   (a) increases
   (b) decreases

10. Name five mathematical operations that an op amp can perform.

3-25-76

$E_o \quad R_c\,(E_i)(T)$

$E_o \quad 5(+2)(4)$

$E_o = 40v$

$F = \frac{1.3}{tn}$

$1 \quad \frac{22}{.05} = 4.375$ n Hz

COMPETITION

When a competitor opens a shop in your neighborhood, your first reactions are probably the same as those of most people – you feel that he is "cutting in" on your trade and that, by fair or foul means, he may run you out of business. However, there is another view to take of this problem.

First, forget your fears! A mind frozen by mistrust and hate is incapable of reasoning; it will lead you to the very downfall you fear. Face the facts: someone else is in the same business, so you must make your services so much better than his that you get your share of the work.

Welcome the competition as a spur – something to force you to your best efforts – something to make you become more careful, more efficient, more alert. You will find that honest competition adds enjoyment to your work.

And, another thing, force your competitor to rise to your level to survive – don't stoop to his. Do your best work and you'll find that your fears were not justified – there is plenty of business for the man who can deliver the goods!

INTRODUCING YOU
TO ELECTRONICS

B101

STUDY SCHEDULE

By dividing your study into the steps given below, you can get the most out of this part of your NRI Course in the shortest possible time. Check off each step when you finish it.

☒ 1. **Introduction** .... **Pages 1 - 4**
This section gives you a glimpse of the opportunities in store for you, and also some helpful suggestions on how to study.

☒ 2. **Electricity** .... **Pages 5 - 12**
You get a basic idea of what electricity is.

☒ 3. **Current Flow** .... **Pages 13 - 17**
You learn how current is made to flow in a circuit, and the relationship between current, voltage and resistance.

☐ 4. **Magnetism** .... **Pages 18 - 24**
You learn about the importance of magnetism in electronics.

☐ 5. **Electronic Components** .... **Pages 25 - 37**
We look at a number of basic parts; conductors, insulators, batteries, coils, transformers, resistors, vacuum tubes and transistors.

☐ 6. **Answers to Self-Test Questions** .... **Pages 38 - 39**

☐ 7. **Answer the Lesson Questions.**

☐ 8. **Start Studying the Next Lesson.**

PII3M1174 1974 EDITION Litho in U.S.A.

INTRODUCING YOU TO ELECTRONICS

Deciding to study the NRI course is one of the wisest decisions of your life. Why? Because this course has been planned and written from beginning to end especially for men who must do their studying at home, usually after their regular day's work. Each of NRI's bite size lessons has been programmed into small sections. Most of these sections can be mastered with little over an hour's diligent study.

The amount of education you now have is of less importance than an unswerving ambition to succeed. The first lesson starts right at the beginning assuming that you know nothing about electronics, and prepares you for the more advanced second lesson. If you will make a firm resolution now to work on your course regularly, you can be assured of success. The rewards that can be yours by satisfactorily completing your course are within your grasp. You've taken the first step by enrolling, now the next step is to set up a study schedule, and then stick to that study schedule at all costs.

Since in the second book, and in each of the following books that you will study, you will be building on what you have learned in previous books, it is important for you to understand each new idea as it is presented before going on to the next subject. Do not make the mistake of skipping over a section that you do not at first understand. Usually if any section of a lesson at first seems difficult, you will be able to understand it completely by rereading it several times. If after you have carefully studied a section of a lesson, you find there are still some points puzzling you, take advantage of the NRI Consultation Service to ask for extra help. Try to be as specific as possible about exactly what is not clear to you -- we will be glad to assist you; we are here to help you.

The surest way to succeed is to be determined to succeed. Make a sincere promise to yourself right now, that you are going to complete your NRI course and succeed in electronics.

OPPORTUNITIES

Let us look at a few of the opportunities that are available to the qualified technician. As an NRI graduate you will be in a position to choose your opportunity, instead of waiting for it to come to you.

In radio, for instance, there are hundreds of different job opportunities in entertainment broadcasting alone. You might think that television has eliminated the opportunities in this field of radio. The actual facts are that almost every week new radio stations are licensed by the FCC and that the annual radio receiver production in this country is close to 10,000,000 receivers.

Television has not eliminated opportunities in the radio field; instead it has created new opportunities of its own. The demand for broadcast technicians and television servicemen has never been fully satisfied since television first swept across the country. Now color television is here, and it is creating still greater demands for trained men. You can be one of them.

Another fact that people fail to realize is that there are many opportunities outside the entertainment broadcasting field. There are thousands of fascinating well-paid jobs for men in communications systems on land, on sea, and in the air. Fire and police departments, telephone companies, power companies, gas companies, railroads, and airlines are only a few of the many organizations using radio communications equipment. The use of radio in industrial communications is in fact increasing so fast that finding frequency assignments for all the new stations is becoming a serious problem.

Electronic equipment is also becoming more and more important in industry. Electronics in industry represents a tremendous new field, the surface of which has just been scratched. Electronic equipment is used to count finished components coming off assembly lines, it is used to inspect manufactured parts, it is used to control precision machines, automatically making possible the high-speed production of items that could formerly be made only manually by highly skilled operators. Electronics is used in oil refineries, in the manufacturing and quality-control of new cars, in the new plastics industry and in many other fields, too numerous to mention. As a matter of fact, there is hardly an industrial process in which electronics cannot be put to use advantageously. Here is a field of unlimited opportunities; a field that is just developing.

From the preceding list of opportunities you might think that this is an industry already fully developed. Actually we have barely scratched the surface. You are going to see breath-taking new developments which far outshadow even the miracle of color television. Because your NRI training is built upon a sound foundation, you will be prepared for the undreamed-of jobs that will soon be created by new developments. You will not only learn about equipment in use today, but you will also learn the fundamental ideas in back of the operation of tomorrow's equipment. Once you understand this basic theory, you will be able to understand new developments as they come along. You will understand how they work, because you will know the fundamentals. New electronic equipment will not use new circuits, it will use the basic circuits you will be studying, but in new ways.

HOW TO STUDY

Naturally, you want to complete your course and become an expert technician as quickly as possible. To help you do this, here are a few suggestions on how to study.

A Study Schedule.

The first suggestion is that you plan a study schedule. Decide how many hours you'll study each week. Then decide on which days you will be able to work on your course. Finally, decide the time during the day or evening that will be best for studying.

How Often to Study.

Space your study periods close together. The ideal arrangement is to devote some time to your course each day. If you can't spare one or two hours, study for 45 minutes, half an hour, or whatever you can spare.

Regular study is the key to learning effectively. You can learn and remember much more from studying 30 minutes daily than from longer sessions spaced several days apart. Studying daily, or every other day, keeps the instruction fresh in your mind. If three or four days pass between study periods, you may forget most of what you learned from your last session. It's hard to pick up where you left off, and you often have to do a lot of "back-tracking" to refresh your memory.

Take a Break.

Unless you're accustomed to studying regularly, you may find that you tire easily. This isn't unusual. It will take time for you to get the "study habit".

In the beginning, make your study periods short and break them up with periods of rest. After you've completed several lessons, you will be able to study longer without getting tired.

Be Fair to Yourself.

Most of us have asked for that second slice of apple pie only to discover we are too full to handle it. An over-ambitious study schedule can be like that second slice of pie. Be sure your study schedule is reasonable, one that you will have no trouble following. This schedule need not deprive you of time for other activities. A well planned schedule will see to it that each activity gets its fair share of your attention.

If possible, have a regular place to study, and get used to going to the same place each time you study. Naturally, this place should be relatively free of distracting noises. If the noise around you can't be controlled, consider going to a Public Library. Libraries are quiet and have an ideal study atmosphere.

When you sit down to study, be sure to have everything you need. Then you won't have to stop in the middle of a lesson to get a pencil, paper etc. Keep these materials near your place of study at all times so that once you sit down, you can go right to work.

Here are some suggestions to help you study your lesson texts systematically. These suggestions are the result of years of experience with well over 600,000 students and will enable you to learn effectively.

Survey the Lesson.

Begin each new lesson with a survey. First, read the Study Schedule to get a general idea of the subjects and their order of presentation. Next, thumb through the lesson and look at the different main headings. The main headings are the same as each step in the Study Schedule.

Now carry the survey further. Look at the smaller headings under each main heading to get a more detailed idea of what the lesson covers. In fact, you should glance at the first two or three sentences under each heading.

The survey acquaints you with the lesson. When you begin a thorough study, you will know what to expect.

Read and Recite.

After the survey, you are ready to study the lesson. Remember, the text is full of facts and explanations. To absorb them, you should read every sentence carefully, turning over in your mind what it says and means.

Stop periodically and try to recall what you've read. Actually recite to yourself the main headings and the important ideas under each. Then check back to see whether you've covered everything. If you've left something out, restudy those points and again try to repeat them to yourself.

Answering the Test Questions.

On the last page of each lesson are ten questions covering subjects in the lesson text.

You'll probably find many of the questions easy to answer. Some will require a good deal of thought. A few may seem difficult but will help you develop the ability to work out problems you'll encounter in the field.

If you come to a question you can't answer, find that part of the lesson where the subject is covered. Reread that portion carefully, fixing the answer to the question firmly in mind. Then write out the answer in your own words.

You will find it helpful to review periodically. A good system is to review completed lessons at about the same rate you study new lessons.

For example, when you finish six lessons, go over the first two again. When you finish your next new lesson, review the third and fourth lessons. After your review catches up to your new lessons, start the review over again. Naturally, when you review, you will not have to be as thorough as when you study the lesson. However, just skimming through the lesson you are reviewing will help recall the important points in that lesson.

Your lessons contain a series of self-test questions which are related to the major topics of each text. You should try to answer each question, in writing, as you come to it in your studies. Before continuing, check your answer against the "Answers to Self-Test Questions" on pages 38 and 39. If you have answered the questions correctly, go on to the next section. If any of your answers are incorrect, review the topic just covered.

These Self-Test Questions are for your own use so you can see how well you understand the material. Do NOT Send the Answers to the Self-Test Questions to NRI for Grading. This will only slow down your instructor.

Now you are ready to go -- ready to start your study of electronics. At first we will study a few basic ideas and then we will use these ideas in building up some simple circuits. Make sure you fully understand the ideas and circuits as they are presented. Even the most complex electronic equipment is made up of nothing more than a large number of the simple circuits that you will study in your early lessons.

Electricity

Electricity and magnetism play an important part in the operation of all electronic equipment. But what is electricity? What is magnetism? If you learn the answers to these two questions once and for all now, you will have the foundation for everything else you will study and work with in your electronics career. Let us take up electricity first.

WHAT ELECTRICITY IS

We will start our discussion of what electricity is by describing a few simple experiments that were performed by scientists many years ago. These experiments helped lead to the understanding of electricity that we have today. You do not have to perform these experiments. We are describing them only to help you understand electricity.

If two small glass balls are suspended by threads as shown in Fig. 1, the weight of the glass balls will cause them to hang straight down as shown. Now if we take a piece of silk cloth and rub the balls with the cloth and then suspend them, instead of hanging straight down as they did before, the balls will tend to swing out as shown in Fig. 2 as though some force were pushing them apart.

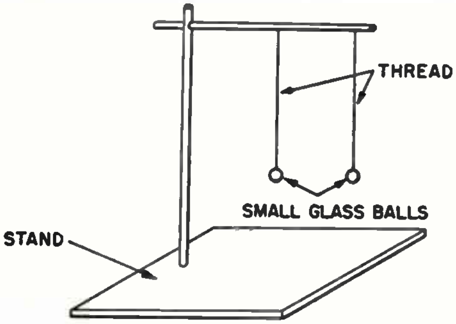

Fig. 1. Two small glass balls suspended by threads will hang vertically because of the weight of the balls.

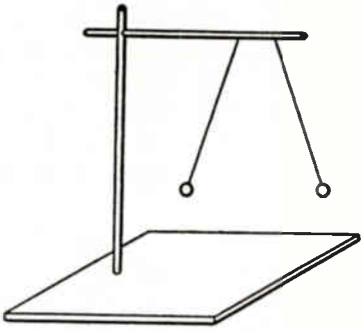

Fig. 2. Two glass balls that have been rubbed with a silk cloth move apart.

Actually, there must be some force pushing them apart; rubbing the balls with the silk cloth has produced the force.

The same experiment can be performed using two small hard-rubber balls. Again, before the balls have been rubbed with the silk cloth they will hang vertically, but once they have been rubbed with the silk cloth they will push apart. Again rubbing the small balls with the silk cloth has produced a force which pushes the balls apart.

There are two important points illustrated by these experiments. First, rubbing the balls with the silk cloth produced a force that pushed the balls apart. We call this force a "charge". The act of producing this force is called "charging". We say that the balls are "charged."

Second, let us consider what happened when we rubbed the glass balls with the silk cloth. When we rubbed the two balls, we charged them. Since both balls were charged in the same way, it is logical to assume that we have placed the same kind of a charge on the two balls. But the two balls pushed each other apart. We had similar results when we charged the two rubber balls. They also repelled each other. From these experiments we can conclude that if two objects are charged with the same kind of a charge, they will repel each other. This is a basic electrical law, and it is usually stated:

like charges repel.

Now, if the same experiment is performed using one small glass ball and one small rubber ball, we would observe an entirely different effect. When the balls are rubbed with the silk and then suspended, instead of moving apart, the two balls would move toward each other as shown in Fig. 3. If they are placed close enough together, they will move toward each other until they touch. Once the two balls touch each other, they will begin to move apart to hang straight down. They will probably swing past the straight-down point and then swing back together and touch again. This cycle may be repeated several times until eventually the balls will hang straight down as they would if they had not been charged in the first place. Now let us see what conclusions we can draw from this experiment.

We have seen that rubbing the two balls with the silk cloth charged them as before. This we know is true because a force was produced on the two balls, otherwise they would simply hang straight down. We also know that the forces produced on the two balls were such that the balls did not repel each other, at least at first, because the two balls moved together and touched. Since we have seen from the previous experiments that like charges repel, these charges must have been unlike. In other words, there must be a different kind of charge on the glass ball from the one on the rubber.

These simple experiments lead us to a fundamental important rule,

"like charges repel;
unlike charges attract."

Remember this rule, it is important. You will use it throughout your entire career in electronics. You will soon use this simple rule to help explain the operation of many electronic devices.

Now let us proceed with our study of electricity to see if we can explain more fully what happened in the experiments we have just described. To do this we must study the electron theory.

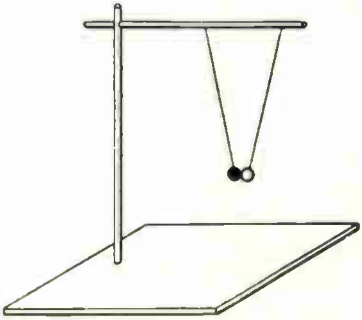

Fig. 3. The charged glass and rubber balls will move together and touch each other.

THE ELECTRON THEORY

Everything on this earth is made up of tiny particles. You can see for yourself that the earth is not one solid piece of material, it is made up of tiny particles of sand and stone and rock. Even the smallest grain of sand is itself made up of millions of still smaller particles, so small that they cannot be seen even with the most powerful microscope.

The smallest particle of a substance that retains the original properties of the substance is called an "atom." All atoms of a given substance are alike. In other words, the smallest particle of a piece of copper that still is and resembles copper is called an atom. These atoms are so small that a piece of copper the size of the head of a pin would contain millions of atoms.

But the atom is not the smallest particle, the atom itself is made up of still smaller particles. Scientists have identified a number of different particles from which the atom is made. However, we are interested in only two of these particles, the nucleus* and the electron. We are more interested in the electron than we are in the nucleus.

The nucleus is the center of the atom. Travelling around the nucleus in elliptical paths (a somewhat circular path that has been squashed, like an egg or football) will be one or more electrons. The number of electrons will be different for atoms of different elements.

The nucleus of an atom has a positive charge. The simplest atom is the hydrogen atom and the nucleus of this atom has one positive charge. Travelling around this nucleus in an elliptical path is one electron which has a negative charge. The negative charge on the electron exactly balances the positive charge on the nucleus so that electrically the atom is neutral. The most complex atom found in nature is the uranium atom. The nucleus of the uranium atom has 92 positive charges and travelling around the nucleus of this atom are 92 electrons which will exactly balance the 92 charges on the nucleus, so that the net electrical charge on the atom is zero.

Between the simplest atom, which is the hydrogen atom, and the most complex atom are 90 other materials. They range from the helium atom which has two positive charges on the nucleus and two electrons travelling around it up to the protactinium atom which has 91 charges on the nucleus and 91 electrons travelling around it.

In their natural state the electrons travelling around the nucleus of an atom exactly balance the positive charges on the nucleus. However, under some circumstances an atom might loose one of its electrons. When this happens, the electron, which carries a negative electrical charge, moves off into space or over to a nearby atom. Meanwhile, the atom which has lost the electron now does not have enough electrons to completely balance the positive charge on the nucleus. As a result, the atom has a positive charge.

Under some circumstances the opposite might happen, and an atom might pick up an extra electron.

---

* To be strictly correct we should not call the nucleus a particle, because it is made up of smaller particles. However, for our purposes we can consider the nucleus as one particle.

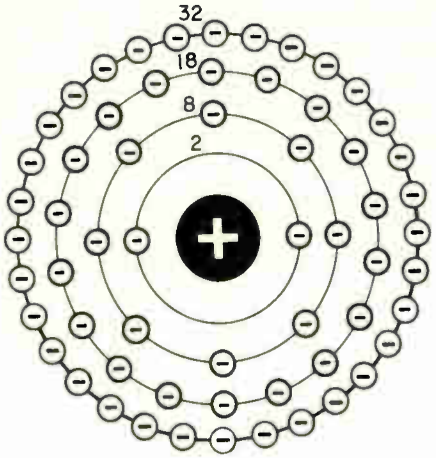

Fig. 4. The maximum number of electrons there can be in each of the first four rings of any atom.

When this happens the atom has more electrons than it needs to completely neutralize the charge on the nucleus. As a result, the atom will have a negative charge.

The electrons around the nucleus of an atom travel around it in rings. There is a maximum number of electrons that can be in each ring. In Fig. 4 we have shown the maximum number of electrons that can be in each of the first four rings surrounding the nucleus of an atom. As the atoms go from hydrogen, the simplest atom, to uranium, the most complex atom, the electrons fill the inner rings first. For example, the hydrogen atom shown in Fig. 5A has one electron traveling around the nucleus. The helium atom shown in Fig. 5B has the first ring filled with two electrons travelling around the nucleus. The lithium atom has three electrons as in Fig. 5C, two electrons fill the first ring and the third electron appears in the second ring. Subsequent elements will have electrons in the second ring until a maximum of eight electrons is reached in this ring. The next element will have two electrons in the first ring, eight in the second and the eleventh electron in the third ring.

When the outer ring of electrons in an atom is filled, the atom is very stable electrically and chemically. It is almost impossible to get an electron to move out of the atom or to force another electron into the atom. On the other hand, if the outer ring has all the electrons it can hold except one, it is very easy to force an electron into that outer ring to fill the ring. By contrast, if the outer ring has only one electron in it, that electron is not held very closely to the atom and therefore it can easily move out of its position into space

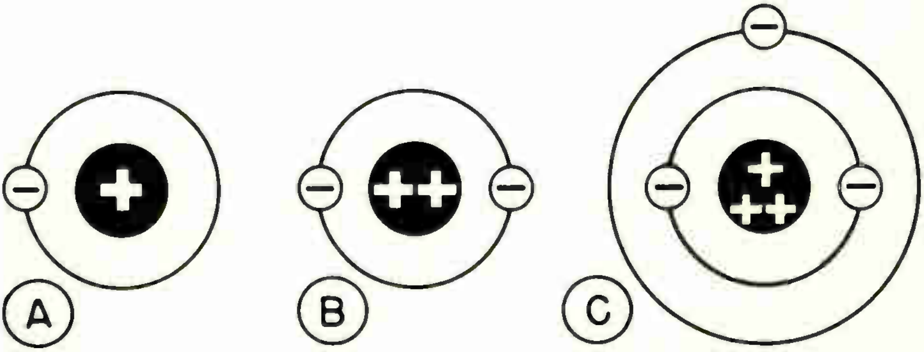

Fig. 5. The hydrogen atom is shown at A, the helium atom at B, and the lithium atom at C.

or to another atom.

The copper atom is an excellent example of an atom with one electron in its outer ring. The positive charge on the nucleus of the copper atom is 29 as shown in Fig. 6. The first three rings of the atom are filled, they hold all the electrons they can. However, the 29th electron required to neutralize the charge on the nucleus is in the fourth ring by itself. This electron is not held very closely to the nucleus. As a result, it can move easily from one atom to another. This is the reason why copper wire is so widely used in electronic equipment and in electric power distribution.

If we apply some external force to a copper atom, we can easily knock the outermost electron loose and it might move to an outer ring of a nearby atom. This atom will then have two electrons in the fourth ring. It then has one more electron than it needs to neutralize the charge on the nucleus. The tendency is for this atom to get rid of this extra charge as quickly as possible. Either the new electron that moved into the fourth ring will be forced out of this ring, or the original electron in the fourth ring will move out. In any case, whichever of the two electrons leaves this fourth ring will move over to a nearby atom, and it in turn will upset the balance of this atom and either move on itself, or force the electron in the outer ring of this atom out.

Now if you will remember when we rubbed the two glass balls and the two rubber balls with a silk cloth and placed like charges on them they repelled each other. Electrons have a negative electrical charge. All electrons have exactly the same charge. Since the charges on electrons are like charges they tend to repel each other.

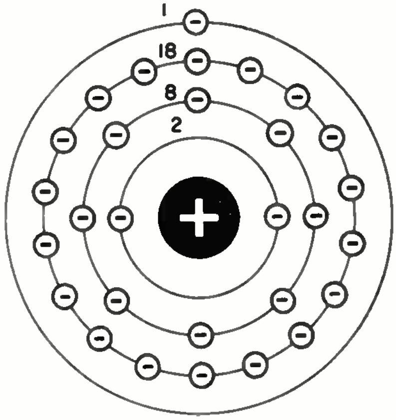

Fig. 6. The nucleus of the copper atom has a positive charge of 29. Around the nucleus there are normally 29 electrons arranged as shown above.

In a piece of copper there will be millions of atoms. Each of these atoms will have a nucleus that has a positive charge of 29 on it and around it 29 electrons that neutralize this positive charge. The electrons are held in the atom by the positive charge on the nucleus which attracts them. At the same time the electrons are repelling other electrons in the atom and electrons in nearby atoms. There is more or less a condition where there is a balance between the nucleus holding or attracting its electrons and at the same time the electrons repelling or pushing away other electrons.

If we take a piece of copper wire and connect something to it that will try to pull electrons from one end of the wire and push them into the other end we will set up an instantaneous chain reaction along that wire. The instant an electron starts to move out of the fourth ring of one of the copper atoms the negative charge on

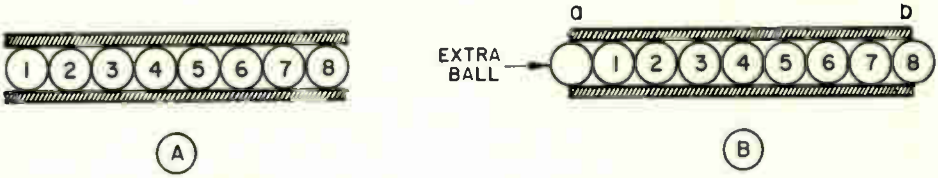

Fig. 7. The hollow tube shown at A is full of ping pong balls. When an extra ball is pushed into end a at B, the effect is to push all the balls at once and a ball starts to to fall out at end b.

that electron will push an electron out of the fourth ring of a nearby atom. At the same instant, it in turn will start pushing an electron out of the fourth ring of an atom adjacent to it. This will happen all the way along the wire so that at the instant an electron starts moving at one end of the copper another electron will start moving at the other end. The motion of the electrons will be the same all through the length of the wire.

You might get a better idea of what is happening if you took a hollow tube such as shown in Fig. 7A and filled it with ping pong balls so that the balls are all touching each other. The minute you start to force an extra ball into the one end, a, all the balls in the tube start to move and a ball starts to fall out of the end b as shown in Fig. 7B. The movement is instantaneous through the entire length of the tube.

The same situation exists when you start an electron moving at end a of the wire shown in Fig. 8. Although the electrons are not touching each other there is a force between them as shown, so that this force causes electrons all down the wire to start to move at the same instant. If you were to apply a greater force so that two electrons started moving at end, a, of the wire as shown in Fig. 9A, this force would cause two electrons to start moving all the way down the wire as shown. Similarly if you increase the force still further and start three electrons moving at end, a, as shown in Fig. 9B, then you have this chain reaction of three moving the entire length of the wire. The motion of electrons will be the same throughout the length of the wire.

The movement of electrons along the wire is called current flow. This is what an electric current is. We will go into this in detail in the next section of this lesson. However, be-

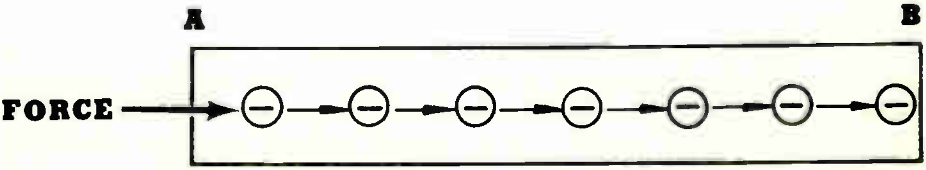

Fig. 8. When force is applied at end A of wire and an electron is pushed towards B, there is an instantaneous reaction all along the length of wire pushing a line of electrons towards B.

fore going to the next section let us explain the action of the charged rubber and glass balls. When the glass ball is rubbed with the silk cloth, the friction of rubbing the ball removes some of the electrons from the ball. Once the electrons have been removed, there are not enough electrons left to completely neutralize the charges on the nuclei of the atoms. Therefore the glass balls will have a positive charge on them.

When we rub the rubber balls, the rubber balls take electrons from the silk cloth so they will have more electrons than are needed to completely neutralize the positive charges on the nuclei of the atoms. Therefore the rubber balls will have a negative charge on them.

Since the two similarly charged glass balls repelled each other and likewise the two charged rubber balls repelled each other, we assumed that like charges repelled. Indeed, two positive charges will repel each other, and two negative charges will repel each other.

When we charge one glass ball and one rubber ball and suspend them near each other, they will be attracted because they have unlike charges; one is charged positive and the other is charged negative and unlike charges attract. When they move together and touch, some of the extra electrons on the rubber ball will leave the rubber ball and move over to the glass ball and partly make up for the shortage of electrons on the glass ball. When this happens, the balls may swing apart, but the charges will not be completely neutralized, so the balls will swing back together again and a few more electrons will move from the rubber ball over to the glass ball. This swinging back and forth will continue until enough electrons have moved from the rubber ball to the glass ball to reduce the force of attraction between the two balls until it is no longer strong enough to cause the balls to swing together.

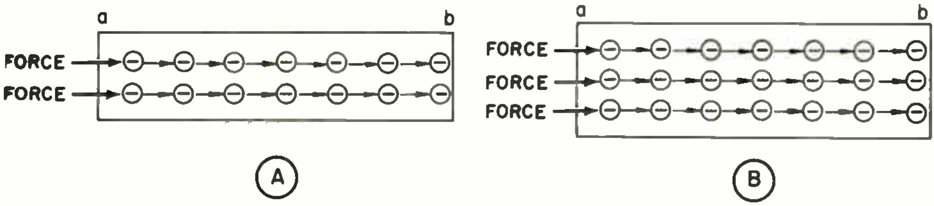

Fig. 9. Number of electrons set in motion along a wire depends on the force applied.

SUMMARY

We have covered a great deal of material in this section, and chances are you will not be able to remember all of it. We do not expect you to remember all of the details, but you should remember the important points such as:

1. Like electric charges repel, and unlike electric charges attract.
2. All material is made up of extremely small particles called atoms.
3. All the atoms of a given substance are identical.

4. Atoms are made up of a nucleus in the center, which has a positive charge, and a number of electrons, which have negative charges. Normally the atom will have enough electrons to exactly neutralize the charge on the nucleus.
5. The electrons arrange themselves in rings around the nucleus of the atom. There is a maximum number of electrons that can be in each ring.
6. In some atoms, such as the copper atom, an electron can be easily displaced.

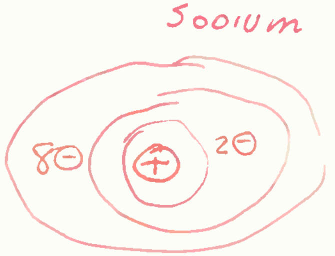
SELF-TEST QUESTIONS

Before going on with the next section of this lesson be sure to answer the following self-test questions. Write out the answer to each question carefully. After you have answered all of the questions, check your answers with those on pages 38 and 39. We do not expect you to give the same answer, but be sure that you understand the point brought out by the question before going on to the next section. Remember, do NOT send your answers to the Self-Test Questions to NRI for grading.

(a) State the law of charges.
(b) What is an atom?
(c) Which two parts of the atom are we interested in?
(d) Which part of the atom has a positive charge? Which part has a negative charge?
(e) If the copper atom which normally has 29 electrons loses one of its electrons, what kind of a charge does the atom have?
(f) Why do electrons in adjacent atoms repel each other?

If you can answer the preceding self-test questions you can be sure that you understand the important points covered in the preceding section of this lesson. However, before going on, here is a real tough question for you to think about. Don't spend more than five or ten minutes thinking about it, but try to answer it because this will stick in your mind and help you to remember some of these important points later.

(g) One atom has ten electrons and another atom has eleven electrons. Which of the two atoms would you expect would most readily give up an electron?



1⊖ the 11-electron atom

Current Flow

In the preceding section you have seen how an electron being knocked out of its atom forces additional electrons out of their atoms and sets them in motion. We have also pointed out that if we apply some force to push the electrons at one end of a wire and another force to pull the electrons from the other end we can start an instantaneous motion of electrons along the wire with the electrons moving from one end towards the other.

A device that is capable of doing this is a flashlight cell. A flashlight cell, by means of the chemical action that occurs inside it, will push electrons from one terminal and pull them into the other. If we connect a wire between the two terminals of a flashlight cell, electrons will immediately be set in motion through the wire and through the cell as shown in Fig. 10. Electrons will be moving from the one terminal of the flashlight cell through the wire and back to the other terminal of the cell, and through the cell back towards the terminal from which they started. This is called an electric circuit.

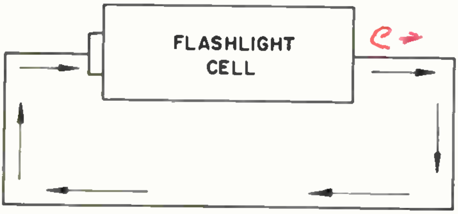


Fig. 10. A wire connected between the two terminals of a flashlight cell provides an electric circuit through which electrons can flow.

Electrons will continue to follow this circular path until the path or circuit is broken by disconnecting the wire from one terminal of the cell or until the chemical action of the cell is exhausted.

Notice that there must be a complete path for the electrons to travel. An electron leaving one terminal of the cell must be able to travel through a complete circuit, through the wire, through the cell and back to the terminal from which it left. If you simply connect a wire to one terminal of the cell, nothing will happen.

A flashlight cell has two terminals. One terminal is a small round terminal in the center of one end of the cell. This is the positive of the cell. The other end of the cell is the negative terminal of the cell. Now, can you tell from which terminal the electrons are going to leave the flashlight cell? Remember the experiment with the glass balls. When we charged the glass balls we placed a like charge on the two balls and they pushed each other apart. Now an electron has a negative or minus charge. Which terminal is going to push electrons away, and which terminal will attract them? The answer to these two questions is just what you might expect from the law of charges. We said that like charges repel, and therefore the negative terminal of the battery will push the electrons out of the battery. The positive terminal of the cell will attract the electrons, because it has the opposite charge on it.

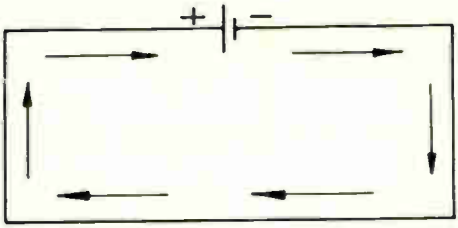

Fig. 11. The schematic diagram of a simple circuit.

In Fig. 11 we have repeated the circuit shown in Fig. 10; however, this time we have used the symbol that is used in electronics to identify a single cell such as a flashlight cell. Notice that we have used one short line and one longer line to represent the cell. The short line identifies the negative terminal of the flashlight cell and the long line the positive terminal. We have also marked the terminals with - and + signs so that there will not be any confusion. Remember the symbol used for the cell, you will see it many times in your electronics career.

Symbols like these are used on all electronic diagrams to indicate the various parts. There is a different symbol for each part. Using a simple symbol instead of trying to show the actual part makes the diagram much easier to understand. These diagrams using symbols are called "schematic" diagrams and the individual symbols, schematic symbols. We will teach you each symbol as you come to it so you will not have to learn a lot of them at once.

In the circuits shown in Fig. 10 and 11, the electrons leaving the negative terminal of the battery simply flow through the wire back to the positive terminal - they are not doing anything useful. Usually we will have some other device connected in the circuit so that the electrons flowing in the circuit will do something useful. For example, in a flashlight we have the flashlight bulb connected between the two terminals of the flashlight cell. The flashlight bulb is simply made of a piece of wire, usually some very hard wire such as a tungsten wire which is placed inside of the glass envelope from which all the air has been evacuated. When we connect the flashlight cell in the circuit such as shown in Fig. 12, the electrons will be set in motion instantaneously throughout the entire circuit as before. However, the movement of electrons through the tungsten wire produces a great deal of heat in the wire; in fact the wire gets so hot that it reaches "white" heat and gives off light. Here we have put the movement of electrons to work, and have used it to produce light. Circuits such as shown in Figs. 10 and 11 where the electrons simply travel from one terminal of the battery to the other are usually avoided. Sometimes they occur accidentally due to a parts failure and they are then referred to as short circuits. You will learn more about this in later lessons.

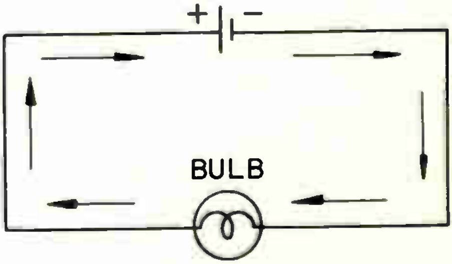

Fig. 12. A simple circuit showing a bulb connected across a flashlight cell.

THE AMPERE

The movement of electrons through an electric circuit is called an electric current. The strength of the current depends on the number of electrons in motion at any point in the circuit. As we pointed out previously, the number of electrons in motion will be the same at all points in the circuit. In the circuits shown in Figs. 11 and 12 the number of electrons leaving the negative terminal of the battery at a given time will be exactly equal to the number of electrons flowing through the flashlight bulb at the same time and also equal to the number of electrons reaching the positive terminal of the battery.

The number of electrons set in motion depends upon the force applied to the circuit, and also on the material used in the circuit. Some materials give up one or two electrons more readily than others, and as a result it is easier for the electrons to move through circuits made of these materials than in circuits made up of other materials that will not give up their electrons so easily.

We must have some way of knowing how much current there is flowing in a circuit. A movement of one or two electrons past a point in a circuit in a period of one second represents an extremely small current, so small in fact that it would be of no useful value. Before a current can be useful, there must be a tremendous number of electrons moving past each point in the circuit. It would be impractical to try to count the number of electrons, so instead, a unit of current called the "ampere" has been devised. The ampere represents a useful number of electrons flowing past a given point in the circuit per second. The actual number of electrons that will pass the point is unimportant. However, a standard ampere has been set up, and all current measurements are made in relationship to this standard ampere. If the number of electrons flowing in the circuit is twice the number represented by one ampere, then the current flowing in the circuit is two amperes. If it is ten times the standard ampere, the current flowing is ten amperes. The word ampere is used so often in electronics that we abbreviate it "amp". To make it plural, we simply add an "s", for example 10 amperes is written 10 amps.

THE VOLT

When we were discussing the ampere, we said that the amount of current that will flow in a circuit depends upon the force applied to the circuit. We should have some means of measuring this force. The force is called the "electromotive force", or "voltage", and it is measured in volts. Often you will see electromotive force abbreviated "emf".

You do not have to be concerned about exactly how much force there is in one volt; the important thing is to know that the number of volts indicates the amount of force applied to the circuit, and the higher the voltage, the more force is being applied to the circuit. In other words, two volts represents twice as much force as one volt. Ten volts represents ten times as much force as one volt.

By way of interest you might like to know that the voltage of a conventional flashlight cell is approximately one and a half or 1.5 volts. The storage batteries used in modern automobiles are made up of six cells connected so that the voltage of the six cells adds. Each cell has a voltage of about 2 volts so that the total battery voltage is 12 volts. Older automobiles may have 3 cell storage batteries - the voltage of these cells is 6 volts. Electric light bulbs and most appliances in homes are designed to operate on a voltage of about 120 volts.

THE OHM

The amount of current that will flow in a circuit depends on one other thing besides the force applied to the circuit. This is how readily the material will give up electrons and let them move in the circuit. Some materials will give up electrons quite readily and let them move through the circuit with little or no opposition. However, other materials will not give up electrons so readily, and may offer considerable opposition to the flow of current. This opposition to current flow is called "resistance". The resistance of a material depends upon how readily it will allow electrons to move through it. Resistance is measured in "ohms". Again, you need not know the exact definition of a standard ohm, the important thing to know is that resistance is the opposition to current flow in a circuit and that it is measured in ohms.

V=IR

OHM'S LAW

E=IR

We have said that the current that flows in a circuit depends upon the force or voltage applied to the circuit and on the opposition or resistance in the circuit. This means that the current depends both on the voltage and on the resistance.

If in an electrical circuit a voltage of 1 volt is applied to a circuit having a resistance of 1 ohm, a current of 1 ampere will flow in the circuit. If we double the voltage so that the voltage is 2 volts and the resistance is still 1 ohm, the current that will flow in the circuit will be 2 amps. On the other hand, if the voltage is 1 volt, and we double the resistance to 2 ohms, the current that will flow in the circuit will be only 1/2 amp.

This relationship between current, voltage and resistance is known as "Ohm's Law". We will use Ohm's Law many times in future lessons. For the present, all you need to remember is that the current depends upon the voltage and the resistance. If you double the voltage and keep the resistance constant, the current will double. If you cut the voltage in half and keep the resistance constant the current will be cut in half. On the other hand, if you keep the voltage constant but double the resistance the current will be cut in half but if you keep the voltage constant and cut the resistance in half the current will double. Increasing the voltage increases the current, reducing the voltage reduces the current. Increasing the resistance reduces the current and reducing the resistance increases the current.

SUMMARY

Here are the important points you should remember from this section of the lesson:

1. If a flashlight cell is connected to a wire made up of a material from which some of the electrons can be displaced, electrons will move from the negative terminal of the cell through the wire to the positive terminal, and through the cell back to the negative terminal making a complete circuit. The

cell provides the force that sets the electrons in motion.

2. A movement of electrons through the circuit is called a "current". In a simple circuit such as shown in Figs. 10 and 11, the movement of electrons is the same at all points in the circuit. Also, remember that once the wire is connected to the two-battery terminals and the electron movement starts, it starts the same instant in all parts of the circuit.
3. The unit used to measure the strength of an electric current is the ampere.
4. The unit of force that sets the electrons in motion is the volt.
5. The unit of resistance is the ohm.
6. The relationship between current, voltage and resistance is known as Ohm's Law.

SELF-TEST QUESTIONS

(h) Which terminal of a flashlight cell has a surplus of electrons? Which terminal has a shortage of electrons?

(i) When an electric circuit is completed do the electrons start in motion at the negative terminal of the battery first? At the positive terminal of the battery? Or do they start in motion instantaneously throughout the entire circuit?

(j) What is the unit in which we measure electric currents?

(k) What is the unit used to measure the electromotive force applied in an electric circuit?

(l) What unit is used to measure the opposition to current flow in an electric circuit?

(m) According to Ohm's Law, what effect on the electric current flowing in the circuit will increasing the voltage have?

INCREASED

(n) If we reduce the resistance in an electric circuit, will the current in the circuit increase or will it decrease?

Magnetism

Magnetism is as important in electronics as electricity. Without magnetism there would be no electronics industry at all, for magnetism and electricity work together to make our modern electronic devices possible.

PERMANENT MAGNETS

A magnet will pick up or attract small pieces of steel or iron. Minerals that have this property are found buried in the ground in some parts of the world. These minerals are called natural magnets. A piece of iron or steel can be made into a magnet by stroking it in one direction with a magnet. When we make a magnet in this way, we say that the metal is "magnetized". These magnets are called "permanent" magnets, because they will retain their magnetism almost indefinitely.

Originally, permanent magnets were made of iron or steel, but modern permanent magnets are usually made of an alloy called "Alnico". Alnico is a mixture of aluminum, nickel and cobalt. Very strong lightweight magnets, which retain their magnetism much better than magnets made of iron or steel, can be made from Alnico.

When a magnetized steel needle is suspended at its balance point by a light thread, as shown in Fig. 13, the needle will always line up in a direction corresponding closely to north and south. This phenomenon led to the first practical use for magnets, in compasses used by early sea voyagers and travellers. Compasses are made simply of a magnetized piece of steel that is mounted on a delicately pivotted bearing that will turn as easily as the needle suspended by the thread.

POLES OF A MAGNET

The ends of a permanent magnet are called "poles". This name was given to the ends of a magnet because the ends point toward the poles of the earth when the magnet is free to pivot on an axis. The pole that points toward the north pole of the earth was originally called the "north-seeking" pole. However, for simplicity the name has been shortened to the "north pole". The magnetic pole that points to the south pole of the earth is called the "south pole".

If two magnets are brought near each other, the north pole of one

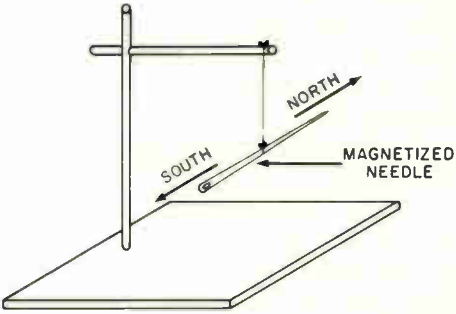

Fig. 13. If a magnetized needle is suspended at its balance point by a thin thread, the needle will line up in a north and south direction like a compass, because it lines up with the magnetic field of the earth.

magnet will repel the north pole of the other. Similarly, the south pole of one magnet will repel the south pole of another magnet. However, the north pole of one magnet will attract the south pole of the other magnet. The reason why a compass always points in a north-south direction is that the earth itself is a magnet, and one pole of this large magnet is near the north geographic pole, and the other pole is near the south geographic pole. The north pole of the earth attracts one of the poles of the magnet and repels the other. The south pole of the earth attracts the pole that is repelled by the north pole, and repels the pole that is attracted by the north pole. Therefore, the magnet will point in a direction so that one pole points toward the north magnetic pole and the other pole points toward the south magnetic pole.

Notice the similarity between the attraction and repulsion of magnetic poles and the attraction and repulsion of electric charges. You already know that "like charges repel and unlike charges attract". In magnets, "like poles repel and unlike poles attract". This is a fundamental law of magnetism; you should remember it.

MAGNETIC LINES OF FORCE

There are lines of force surrounding a magnet. You can trace out the lines of force around a magnet by using a small compass. If you bring the compass near the north pole of the magnet, the south pole of the compass will be attracted to the north pole of the magnet. The compass needle will line up with the magnetic lines of force. If you move the compass as shown in Fig. 14, you will be able to trace out the lines of force. The lines of force are shown coming from the north pole of the magnet and going to the south pole. We do not know for sure whether or not this is true, but there is considerable evidence that the lines of force actually do go from the north pole to the south pole and therefore we will base our explanations on this assumption.

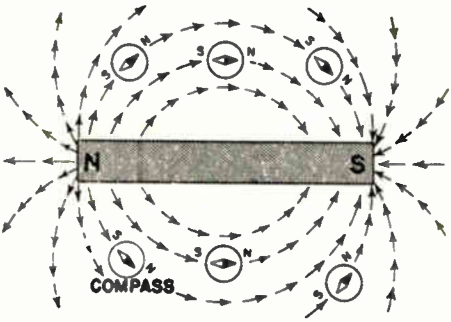

Fig. 14. A small compass can be used to trace magnetic lines of force near a permanent magnet.

Another experiment that can be performed to show the lines of force around a magnet is to place a thin sheet of cardboard over a magnet and then sprinkle iron filings evenly over the sheet of cardboard. Tap the cardboard gently, and the iron filings will arrange themselves in definite lines, producing the pattern shown at the top in Fig. 15.

If two magnets are arranged so that their north poles are placed close together and then iron filings are sprinkled on a cardboard placed over the magnet, the iron filings will arrange themselves as shown in the center of Fig. 15. Notice that you can see the lines of force from the north poles of the two magnets actually repelling each other.

You would get a third pattern by

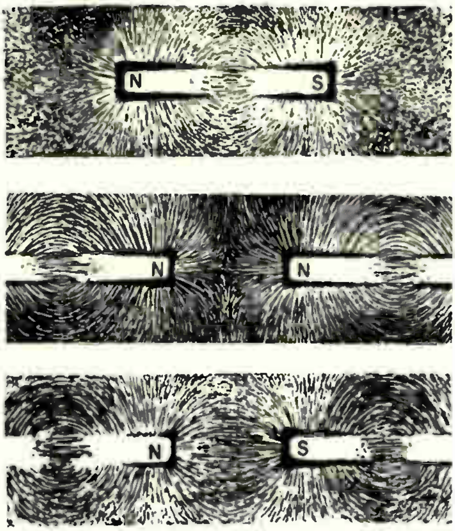

Fig. 15. If iron filings are placed on a sheet of cardboard over permanent magnets, they will trace out lines of force as shown here.

placing the north pole of one magnet toward the south pole of another and sprinkling iron filings on a cardboard. The pattern you would get in this case would be like the one shown at the bottom in Fig. 15. Here you can see the attraction between the north pole and the south pole of the two magnets.

The lines of force coming from a magnet are called "magnetic lines of force". They are similar to the lines of force surrounding electrically charged objects. The lines of force around an electrically charged object are called "electric lines of force".

ELECTRO MAGNETS

An electric current flowing through a wire produces a magnetic field in the space around the wire. This is called "electro magnetism". The circular lines of force around the wire can actually be traced out with a compass. There will be many of these magnetic rings surrounding the entire length of the wire. The magnetic lines of force close to the wire will be much stronger and more easily detected than those at some distance from the wire as shown in Fig. 16. However, even with a weak current flowing through a wire, magnetic lines of force can be detected some distance from the wire, with sensitive equipment.

Even though the magnetic lines of force around a current-carrying wire can be detected, the magnetic field will be weak unless the current flowing through the wire is very strong. However, by winding the wire in the form of a coil, a strong magnet can be made. When the wire is bent into a loop, the circular magnetic rings pass through the center of the coil in the same direction and reinforce each other as shown in Fig. 17.

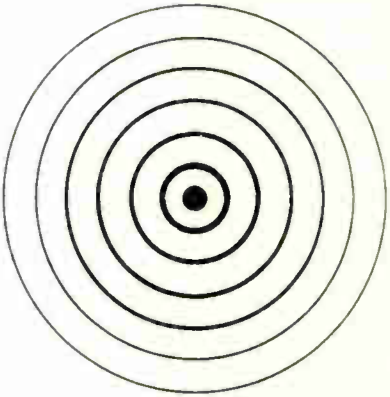

Fig. 16. When electrons flow through a wire, magnetic lines of force surround the wire. This is a cross-sectional view.

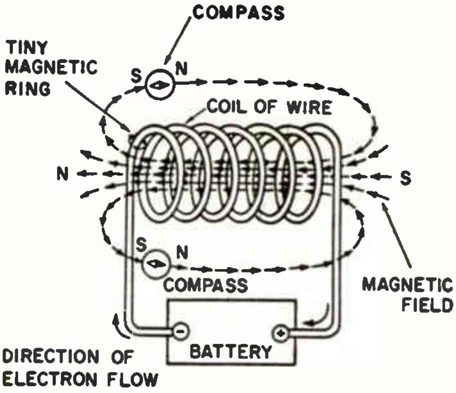

Fig. 17. The more turns of wire we have in a coil, the stronger the magnetic field will be when electrons flow through the coil.

This type of magnet is called an "electromagnet". The magnetic effect exists only as long as the current is flowing through the wire. Once the current is stopped by opening the circuit, the magnetic effect will disappear. Many parts used in electronic equipment depend upon the basic principles of electromagnetism to operate.

The electromagnet shown in Fig. 17 can be made much stronger by inserting an iron bar or a bar of some magnetic material inside the coil. The iron bar is called a "core". The actual increase in the strength of the magnet will depend upon the type of core material used.

You probably wonder why inserting a core inside the coil makes the magnet stronger. The answer to this question is that the iron core is made up of millions of tiny particles of iron. Each of these particles is itself a magnet having a north pole and a south pole. Ordinarily, these tiny magnets are not arranged in any definite pattern. One might point in one direction and another in a second direction, and a third in still another direction as shown in Fig. 18A. As a result of the random arrangement of these small magnets, the magnetic field of one magnet is cancelled by the magnetic field of another. However, when the iron core is placed in the magnetic field inside the current-carrying coil, the magnetic field produced by the coil causes the particles to line up and all point in the same direction as shown in Fig. 18B. When this happens, the entire bar becomes one strong magnet. However, most of the tiny particles are kept lined up only by the magnetic field produced by the current flowing in the coil. Once this field is removed by opening the circuit so that the current can no longer flow through the coil, most of the tiny particles will return to their random arrangement so that they will no longer be pointing in one direction, and most of the magnetic field will disappear.

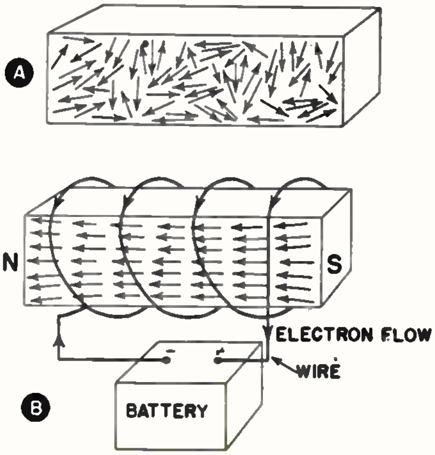

Fig. 18. In an unmagnetized bar of iron at A, the tiny magnets in the iron do not line up; if the bar of iron is magnetized, they will line up as at B.

INDUCED CURRENTS

We have seen that there is a magnetic field around a current-carrying wire, and that if a current flows through a coil, an electromagnet will be produced. Now, is the opposite true? If a coil is placed inside a magnetic field will a current flow through the coil? Let us look in the experiment illustrated in Fig. 19. Here we have a coil wound on a hollow form. The ends of the coil are connected to a small flashlight bulb. We have used a combination of a pictorial drawing for the coil and a schematic symbol for the bulb.

If a magnet is moved quickly inside the hollow form, the bulb will light while the magnet is being moved into the coil. Once the magnet is completely inside the coil and no longer moving, the bulb will no longer light. When the magnet is moved quickly out of the coil, the bulb will light again. If the magnet is moved quickly in and out of the coil, the bulb will light and remain lighted as long as the magnet is in motion. As long as the magnet is moving inside the coil, a current will flow in the coil and through the flashlight bulb.

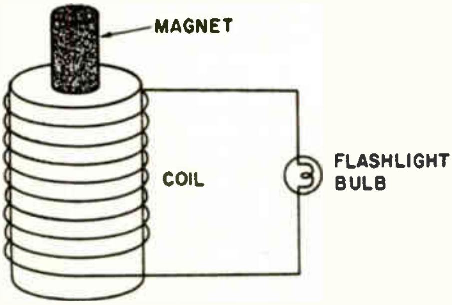

Fig. 19. If a magnet is moved in and out of a coil connected to a flashlight bulb, the magnetic lines of force cutting the turns of wire on the coil will induce a voltage in the coil, and the voltage will cause a current flow through the flashlight bulb.

This current flows because a voltage is induced in the coil. The magnetic lines of force moving through the turns of wire on the coil are said to cut the turns of wire on the coil. A small voltage is induced in each turn on the coil as long as the number of magnetic lines of force cutting the turn is changing. The voltages induced in the various turns of wire on the coil add together. This total voltage produces a current flow through the coil and through the flashlight bulb. We call the voltage produced an "induced" voltage and the current an "induced" current.

A second demonstration of an induced voltage is shown in Fig. 20. Two coils are wound on the same form and placed near each other. It is customary on schematic diagrams to use letters to designate the various parts. L is usually used for coils. We have marked the coils L1 and L2 to make them easy to refer to. One coil, which we have marked L1, is connected to a flashlight cell through a switch, and the other coil marked L2 is connected to a flashlight bulb. Inserted through the form on which the coils are wound is an iron core to increase the strength of the magnetic field. We have shown the schematic symbol for the switch, and labelled it SW. This makes three schematic symbols you should know now, the flashlight cell, the light bulb and the switch.

When the switch is closed and current starts to flow in L1, there will be a voltage induced in L2 and a glow will be seen in the flashlight bulb. However, this glow will last for only

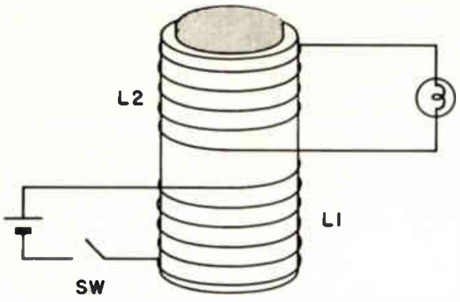

Fig. 20. When the circuit to L1 is opened or closed, a voltage will be induced in L2.

an instant after the switch is closed. When the switch is open and the current flow in L1 is interrupted, the bulb again will glow, indicating that this too induced a voltage in the second winding.

The explanation of this action is the same as for the voltage induced by the magnet moving in and out of the coil in Fig. 19. When the circuit is completed by closing the switch, current starts to flow in the coil. But the magnetic field that accompanies the current flow does not build up instantly; it takes just a short time for this field to build up. When the field is building up, the magnetic lines cutting the turns of L2 are changing just as they cut the coil when the magnet was moved into the coil in Fig. 19. While the magnetic field in L1 is building up, the number of magnetic lines of force is increasing. This change in the number of magnetic lines of force cutting L2 induces a voltage in L2 which causes a current to flow through it and the flashlight bulb. When the circuit is open, the magnetic field must disappear. The number of magnetic lines of force again must change and while this is happening, the change in the number of magnetic lines of force cutting L2 again induces a voltage in L2 which causes the current to flow.

It is important for you to realize that whenever a magnetic field around a coil changes, there will be a voltage induced in the coil. Remember this, it is important; you will be dealing with induced voltages as long as you are in the field of electronics.

SUMMARY

There is a great deal of similarity between magnetism and electricity. Indeed, the basic law of magnetic forces - "like forces repel, and unlike forces attract", is the same as the basic law of electricity, "like charges repel and unlike charges attract". As you go on through your course you will see that electricity and magnetism work together to make the electronic devices that we use today possible.

You are not expected to remember all the details described in this section on magnetism. The information is presented so you will have a complete picture and be able to understand magnetism completely. The important points that you must remember from this section are as follows:

1. A magnet has a north pole and a south pole.
2. Magnetic lines of force travel from the north pole of the magnet around through space to the south pole of the magnet.
3. Like magnetic poles repel; unlike magnetic poles attract.
4. There is a magnetic field around a current-carrying wire.
5. An electromagnet can be made by passing a current through a coil.

6. Inserting an iron core into an electromagnet will result in a stronger magnetic field.
7. If the magnetic lines of force cutting a turn of a coil change, there will be a voltage induced in that turn of the coil.
8. If the magnetic lines of force cutting all the turns of a coil change there will be a voltage induced in each turn of the coil and these voltages will add together. If the coil is connected into a complete circuit, current will flow in the circuit.

SELF-TEST QUESTIONS

(o) State the basic law of magnetism.

(p) If a pole of a magnet attracts the south pole of a compass, is the pole a north or south pole?

(q) In which direction do the magnetic lines of force coming from the poles of a magnet travel?

(r) Where are the magnetic lines of force around a current-carrying wire strongest - close to the wire or at some distance from the wire?

(s) What effect will placing an iron core inside of an electromagnet have on the strength of the magnetic field?

(t) If the ends of a coil are connected to a flashlight bulb, and a very strong permanent magnet is placed inside of the coil, will the flashlight bulb light? How long will the flashlight bulb remain lit?

(u) In the circuit shown in Fig. 20, when the switch is first closed, the flashlight bulb will glow. Why doesn't the flashlight bulb continue to glow as long as the switch is closed?

Electronic Components

The parts used in electronics equipment are often simply called parts, but they are sometimes called components. The two words mean the same thing; we'll use both words so you will get familiar with them.

In the rest of this lesson, you will study a few of the parts found in electronic equipment. We are simply going to introduce these parts; you will study them in detail in later lessons.

You have already seen the schematic symbol for a single-cell battery such as the flashlight cell, for a light bulb and for a switch. You will learn the symbols used for several other parts. It is important that you learn these symbols as you go along. The symbols are used to draw schematic diagrams. Schematic diagrams tell you how the various parts are connected together. You must learn how to read this type of diagram. Manufacturers supply schematic diagrams of electronic equipment, they do not supply picture diagrams. As a matter of fact, picture or pictorial diagrams would be far more complicated and far more difficult to read than schematic diagrams. Once you learn how to read schematic diagrams you will find that they tell you far more about how a circuit is connected than a pictorial diagram could possibly do.

It is quite a job to learn all the schematic symbols at once, but if you take them one at a time, as you come to them in your lessons, and also learn how to read the simple schematic diagrams that will be shown in the early lessons, you will soon find that you know the symbols and that schematic diagrams are really quite easy to follow. If you learn how to read the simple schematic diagrams in the beginning, when you get along further in your course you will find that the large complex diagrams, that you will have to deal with later, are very easy to follow.

CONDUCTORS AND INSULATORS

When we connect parts together in an electronic circuit there will be certain paths through which we want electrons to flow, and other places where we want to avoid a current flow. We use conductors to provide the paths for current flow and insulators where we want to prevent current flow.

There are a number of materials from which one or two electrons in the outer ring of electrons can be displaced. Copper, silver, aluminum, iron and most metals are examples of this type of material. Since electrons can be displaced from these materials it is easy to set them in motion in a wire made of this type of material, and cause a current to flow through the wire. These materials are called conductors. They are so called because they will conduct or transmit an electric current; in other words a current flow can be set up in them. The lines used to connect parts together on schematic diagrams represent the wire conductors used to provide paths for current flow.

There is no such thing as a perfect conductor. All conductors offer some resistance, or opposition, to an electric current. Silver is the best known conductor, but it is used only in special applications because it is too expensive. Copper, which is almost as good a conductor as silver, is used in most wire because it is less expensive than silver. Copper wire is used almost exclusively in connecting electronic components together. It is also used in coils. However, in some special applications where it is essential to keep the resistance as low as possible you will find that silver wire or silver plated copper wire is used. You will learn about these special applications later.

There are other materials which will not readily give up any electrons. A material having its outer ring full of electrons has no place to permit any additional electrons to move into the atom nor will it willingly permit any electrons to move from any of its rings. This type of material is called an insulator. It normally will not pass or conduct an electric current.

There is no such thing as a perfect insulator. Even in materials having all the electron rings filled, an electron will occasionally escape, particularly if enough force is applied to the material. However, the number of electrons that will escape is usually so small, that for all practical purposes we can say that these materials will not conduct current. When an extremely high force is applied to this material, electrons may be forced out and the material will break down, and no longer will be usable as an insulator.

Most copper wire that you will use in electronic equipment to connect the various parts together will be covered with a rubber coating or a plastic coating. The coating is an insulator. Its purpose is to keep the current flowing through the wire to the part it is supposed to reach and prevent its travelling through another circuit. If we did not use an insulator over the wire, and two wires happened to accidentally touch, we might have a short circuit where current would simply flow out one wire and back to the battery and perform no useful service. With an insulating material around the wires, the insulator will prevent this from happening.

BATTERIES

You already know that a flashlight cell is a device that can force electrons through a circuit. You know that the cell has two terminals, a positive terminal and a negative terminal. You know that when the flashlight cell is connected into a circuit, electrons will leave the negative terminal of the cell, flow through the circuit and back to the positive terminal of the cell. You also know that the voltage of a flashlight cell is about 1.5 volts.

Sometimes we need more voltage than can be obtained from a single flashlight cell. For example, you have surely seen a flashlight in which two cells are used. In such a flashlight the cells are arranged as shown in Fig. 21A. The positive terminal of one cell connects to the center terminal on a flashlight bulb. The positive terminal of the second cell is connected to the negative terminal of the first cell. The negative terminal of the second cell connects to a switch and through the switch to the threaded part of the bulb. When the switch is closed current flows

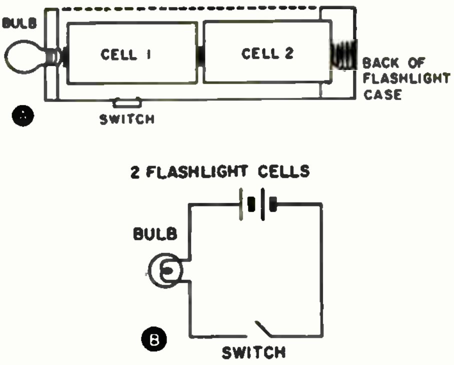

Fig. 21. Two flashlight cells used in series to power a 3-volt flashlight bulb are shown at A. The schematic diagram of this circuit is shown at B.

from the negative terminal of cell 2 through the switch and then through the bulb to the positive terminal of cell 1, through cell 1 to the negative terminal of cell 1 and across to the positive terminal of cell 2 and then through cell 2. Schematically the circuit is shown in Fig. 21B.

In a circuit of this type we say that the two cells are connected in series. Each cell provides a voltage of 1.5 volts so that the total voltage applied to the flashlight bulb is 1.5 + 1.5 or 3 volts.

You can obtain devices in which two cells similar to a flashlight cell are put in a single container to provide a total output voltage of 3 volts. When two cells are put together like this we call it a battery. In other words, a battery is simply a device in which there are several cells. Often we call a flashlight cell a flashlight battery; technically this is not quite correct, but it has come into such wide usage that everybody knows what is meant and as a result the expression is used.

In some applications in electronics you might need a voltage of 4.5 volts. To get this voltage all you need to do is connect three 1.5 volt flashlight cells in series and the voltages will add to give you a voltage of 4.5 volts.

Many of the small portable transistor radios in use today use a small 9-volt battery. Batteries of this type are simply made up of six small cells similar to the flashlight cell. Six times 1.5 gives you a voltage of 9 volts.

In the early days of radio 22.5 volts and 45-volt batteries were widely used. A 22.5 volt battery had fifteen 1.5 volt cells connected in series to give a voltage of 22.5 volts and a 45-volt battery simply had thirty 1.5-volt cells connected in series to give a voltage of 45 volts.

A 3-volt battery is generally indicated schematically by the symbol for two cells arranged such as shown in Figs. 21B and 22A. A 4.5-volt battery usually used three cell symbols as shown in Fig. 22B. However, if we wanted to show a 22.5 or 45-volt battery it would be too tedious to draw the symbol for the required number of cells so the symbol usually shows 5 or 6 cells connected in series such as shown in Fig. 22C and then the voltage is written either above or below the cell as indicated in the figure.

When cells are connected so that

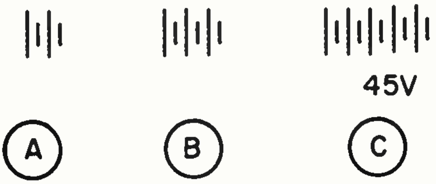

Fig. 22. Schematic symbol for two cells in series is shown at A. Symbol for three cells in series is shown at B. C is symbol for 45V battery.

the negative terminal of one is connected to the positive terminal of another to produce a battery, the total battery voltage is equal to the voltage of the individual cells times the number of cells. However, sometimes a number of cells are connected so that the positive terminals of all the cells are connected together and the negative terminals of the cells are connected together. When cells are connected in this way, we also refer to the device as the battery. However, a battery of this type has an output voltage equal to the voltage of only one cell. We say that the cells are connected in parallel.

You might wonder why we would want to connect cells in parallel. The answer is that in some applications we may need more current than can be supplied by a single cell. In this case by connecting a number of cells in parallel, each cell can supply part of the required current and the total number of cells is connected together to form a battery that is capable of supplying the current required.

This might immediately bring up a question - why not simply make a bigger cell that is capable of supplying the current needed. This can be done, but often manufacturers are making certain size cells in very large quantities and therefore they can make them at a low cost. To make a single cell that could supply two or three times the current capacity of a single cell might cost as much as ten or fifteen times what it would cost to make the smaller cell that they were making in very large quantities. Therefore it is more economical to take three or four of these smaller cells and connect them in parallel for applications where high currents are required than it would be simply to make one special cell that could supply the currents and have to make them only in limited quantities.

When a number of cells are connected in parallel and the output voltage is only 1.5 volts we usually use the same schematic symbol as we use for a flashlight battery. This symbol indicates the voltage, it does not indicate that the cell is capable of a higher current than a flashlight cell. If we want to make it clear that we have several cells connected in parallel, we can use the symbol shown in Fig. 23. This symbol shows four cells connected in parallel.

Other Types of Batteries.

The flashlight cell is only one type of cell. There are many other types of cells. For example, there is the lead cell which is used in storage batteries found in automobiles. Six lead cells are arranged in series in the average automobile battery found in late model cars. In older cars three cells were connected in series. The lead cell has a voltage of about 2 volts so that modern cars have a 12-volt battery in it whereas older cars have 6-volt batteries.

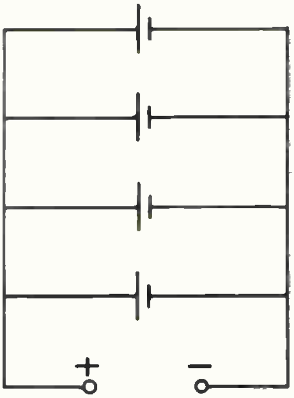

Fig. 23. Four cells connected in parallel.

Other types of cells used today are the mercury cell and the manganese cell. You will study these cells and batteries made up of these cells in later lessons.

COILS AND TRANSFORMERS

You have already been briefly introduced to coils and you know that if the number of magnetic lines of force cutting a coil changes, a voltage will be induced in the coil. In electronics you will run into all kinds of coils. In the tuners of television receivers designed to receive the ultra high frequency channels, you will find coils that have only one or two turns. In other applications you will find coils having many turns. The schematic symbol used to represent a coil is shown in Fig. 24A. This should not be too hard to remember because the symbol itself looks something like a coil.

Fig. 24. Schematic symbols for coils. The lines above the coil at B indicate an iron core.

We mentioned previously that sometimes an iron core is placed inside the coil, and that placing the iron core inside of the coil will greatly increase the magnetic field produced by the coil. Often in electronics there will be iron cores used inside of a coil. When a coil has an iron core, a schematic symbol like that shown in Fig. 24B is usually used. The lines placed beside the coil symbol indicate that the coil has an iron core.

Probably no device has done more for the electronics industry than the transformer. The transformer has made it possible for power companies to supply homes and industry with electric power economically. Without economical power there could be no electronics industry. There is hardly a piece of electronic equipment made that does not use one or more transformers.

In spite of the importance of the transformer, it is basically a simple device. A transformer in its simplest form is nothing more than two coils mounted close together. The two coils we discussed in Fig. 20 actually can be called a transformer. Two typical transformers and the schematic symbols for them are shown in Fig. 25. The transformer shown in Fig. 25A consists of two coils wound on a cardboard frame. This type of coil is called an air-core transformer. The one shown in Fig. 25B is made of two coils wound on iron core. This type is called an iron-core transformer.

Air-core transformers such as shown in Fig. 25A are used in radio frequency applications. By radio frequency we mean radio signals. Iron-core transformers such as shown in Fig. 25B are used in power

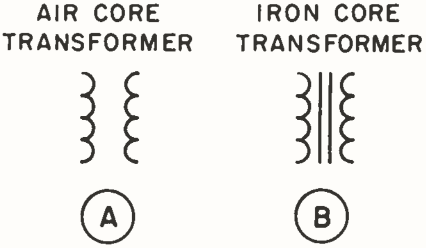

Fig. 25. Schematic symbols for transformers. The transformer at A is an air-core transformer, the one at B, an iron-core transformer.

applications. You will find out what the difference is between radio frequency signals and power frequencies in your next lesson.

We do not expect you to know all there is to know about coils and transformers at this time, the only thing we want you to remember is the schematic symbols used for coils and the schematic symbols used for transformers. You will go into great detail on these important parts in a later lesson.

CAPACITORS

An important electronic part is the capacitor. Basically a capacitor is simply two metal plates that are placed close together. The plates do not touch, they may be separated simply by an air space or some other material may be placed between the two plates of the capacitor.

If a battery is connected to the two plates of the capacitor, the negative charge on the negative terminal of the battery will try to force additional electrons into the one plate of the capacitor. These electrons will repel electrons from the other plate of the capacitor and they in turn will flow towards the positive plate of the battery. As a result, we will build up a charge on the two plates of the capacitor as shown in Fig. 26A. Notice that one plate of the capacitor has a negative charge and the other plate has a positive charge. The schematic symbols used for a capacitor are shown in Fig. 26B. You will find both types of symbols used. As you might expect the two lines represent the two plates of the capacitor. Be sure that you remember the schematic symbols. Capacitors are among the most important parts used in electronics. There are many different sizes and different types; capacitors are so important that we will devote an entire lesson to them and to their uses later.

RESISTORS

Earlier in this lesson we mentioned that conductors were used to carry the electric current from one

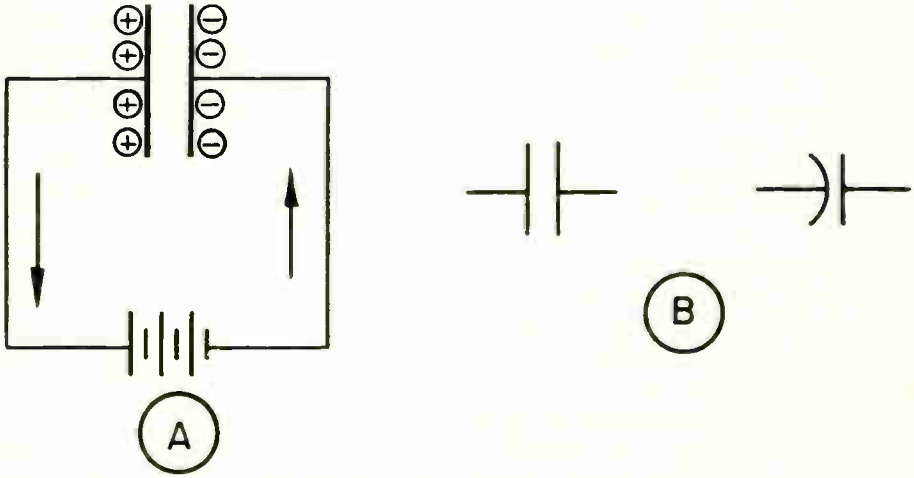

Fig. 26. The circuit at A shows how a capacitor can be charged. The schematic symbols are shown at B.

part of a circuit to another. We pointed out that the materials used in conductors were selected because they had electrons readily available and offered little or no opposition to the flow of electric current through them. In some applications we want to offer opposition to the flow of electric current. In these cases we use a device called a resistor. A resistor may be made of a carbon-type composition or it can be made of a wire that does not have as good conduction capabilities as copper has. In electronics you will run into resistors having a resistance of only a few ohms up to resistors that may have a resistance of well over 1,000,000 ohms.

Fig. 27. The schematic symbol for a resistor.

The schematic symbol for a resistor is shown in Fig. 27. The actual resistance of the resistor is usually written beside the schematic symbol as in Fig. 27. Here we have a resistor that has a resistance of 220 ohms and we have indicated this value above the resistor.

In any piece of electronic equipment you will probably find more resistors, capacitors and coils than any other parts. As a result, their schematic symbols will appear most frequently on schematic diagrams.

Be sure you remember the symbols used for each of these three important parts. Resistors are so important and so widely used that you will go into detailed study of them in a later lesson and you will be dealing with them throughout your entire electronics career.

VACUUM TUBES

Vacuum tubes are so widely used today that almost everyone has seen one. Since tubes are so widely used, it is important for you to learn something about their operation as soon as possible.

The Diode Tube.

The simplest vacuum tube is the diode tube. In the diode tube a filament that can be heated to a red heat by passing a current through it is placed inside of a glass envelope. Around the filament is a metal cylinder called the plate. Leads are brought out of the glass envelope for the two filament leads and for the plate lead. All the air is evacuated from the inside of the glass envelope before the envelope is sealed. The schematic symbol for a diode tube is shown in Fig. 28.

We mentioned earlier that in an atom, the electrons were rotating about the nucleus of the atom. In a diode tube the electrons are rotating about the nucleus of the atom in the material used for the filament. When a battery is connected between the filament terminals as shown in Fig. 29A, the filament is heated to a red heat. This causes the motion of the electrons to speed up and many of

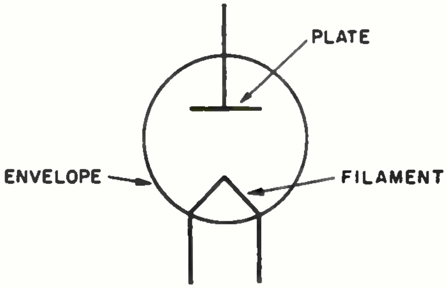

Fig. 28. The schematic symbol of a two-element (diode) tube.

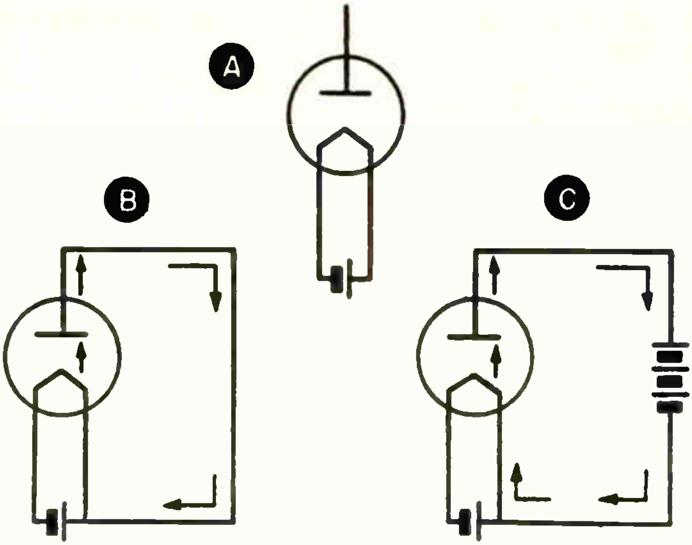

Fig. 29. The filament of a diode is heated as shown at A. When a diode is connected as shown at B, a small current will flow in the direction indicated by the arrows. When a battery is added as in C, a much stronger current will flow.

the electrons to break loose from the atom and fly off into space around the filament of the tube. If we connect the lead from the plate of the tube back to the filament as shown in Fig. 29B, some of the electrons that fly off the filament will travel through the space from the filament of the tube over to the plate and then flow from the plate through the external circuit back to the filament of the tube.

Since electrons have a negative charge they are attracted by a positive charge. Therefore if we connect a battery between the plate and the filament as shown in Fig. 29C, the electrons that fly off the filament of the tube will be attracted by the positive potential on the plate of the tube. As a result, many more of the electrons will travel from the filament over to the plate of the tube to the positive terminal of the battery. Electrons will travel through the battery to the negative terminal and from the negative terminal back to the filament of the tube.

Of course, as with any complete circuit, the current flow around the circuit is instantaneous. The instant the battery is connected to the tube current starts flowing around the circuit, and the amount of current flowing through the circuit is the same at all points in the circuit at all times.

Even though the diode tube is the simplest and the first tube invented, it is still in use today. The high-voltage rectifier used in television receivers today is nothing other than an improved version of this simple diode tube. Be sure that you remember the schematic symbol for the diode tube that is shown in Fig. 28 - this is an important symbol and you must remember it.

The Triode Tube.

While the diode tube is important,

and its discovery was a great milestone in the early days of electronics, it was not until the three-element tube called the triode tube was invented that the electronics industry as we know it today really got started. The schematic symbol of a triode tube is shown in Fig. 30. Notice that the symbol is the same as the symbol for the diode tube except that a third element has been added between the filament and the plate. This third element is called a grid.

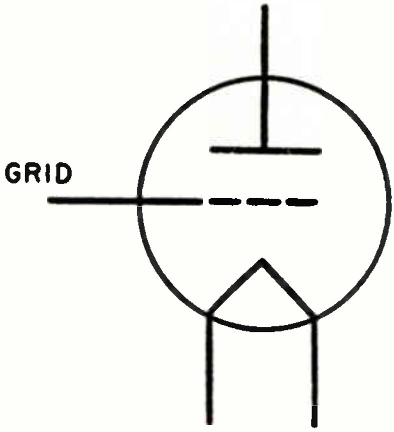

Fig. 30. The schematic symbol for a triode.

In a triode tube the filament is placed in the center of the tube. Around the filament, and close to it is a wire mesh; this is the grid of the tube. Placed some distance from the grid and around it is a round cylinder and this is the plate.

Because the grid is placed so close to the filament, a small voltage applied to the grid will have a large effect on the number of electrons that can flow from the filament to the plate of the tube. If the tube is connected into a circuit as shown in Fig. 31, you can see what will happen.

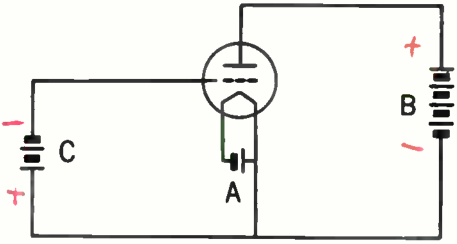

Fig. 31. A triode tube showing how three batteries are used to provide the necessary operating voltages.

The battery marked A is used to heat the filament of the tube. In early days of radio this battery was called the A battery. A small battery having a voltage of 3 or more volts is connected between the filament of the tube and the grid. This battery is labelled C on the diagram, and is called a C battery. Notice that the positive terminal of this battery is connected to the filament, and the negative terminal is connected to the grid. A battery having a somewhat higher voltage is connected between the plate of the tube and the filament. The positive terminal of this battery is connected to the plate and the negative terminal is connected to the filament. This battery is called a B battery.

Now let us see what happens in the tube. The filament of the tube is heated by the current from the A battery. This causes the filament to give off electrons and the electrons fly off into the space between the filament and the grid. However, many of the electrons are repelled by the negative charge on the grid of the tube due to the voltage of the C battery, and travel back to the filament. Some of the electrons manage to get through the grid and they are attracted by the positive potential applied to the plate of the tube by the B battery, and will travel over to the plate. The amount of current flowing from the filament to the plate of the tube can be controlled by the grid voltage. If we increase the negative voltage applied to the grid, the amount of current flowing through the tube will decrease, and if we reduce the negative voltage applied to the grid of the tube, the amount of current flowing from the filament of the tube to the plate will increase.

It is this ability of the grid to control the flow of current from the filament of the tube to the plate that makes the vacuum tube so useful in electronics. You will study vacuum tubes in detail in later lessons. For the present, you should remember how electrons flow from the filament of the tube to the plate of the tube and how the grid can control the flow of electrons through the tube. You should also remember the schematic symbols used to represent a diode (a two-element tube) and a triode (a three-element tube).

The schematic symbol of a triode tube with a cathode instead of a filament is shown in Fig. 32. In the triode tubes we have shown previously, the filament was heated by a battery and the filament gave off the electrons that were used in the tube. More modern tubes have a cathode that is designed to give off the electrons. The cathode is a hollow round tube and it is coated with a special material that readily gives off electrons when it is heated. Inside of the cathode is a heater. The heater is heated by an external voltage applied to it and the heat from the heater radiates to the cathode and heats the cathode to a temperature where it will give off electrons.

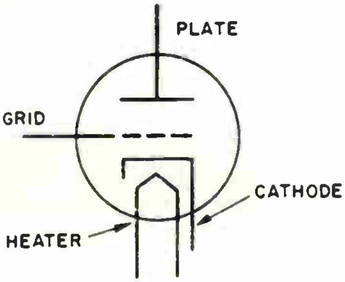

Fig. 32. Schematic symbol of a triode tube with a cathode and a heater.

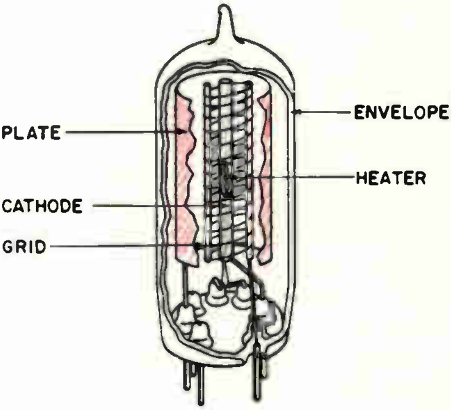

Fig. 33. Cut-away view of a typical vacuum tube showing its elements.

The cathode-type tube has replaced the filament-type tube in modern electronic equipment. The tubes used in modern radio and television receivers are all cathode-type tubes. A cut-away view of a modern tube is shown in Fig. 33. Filament-type tubes were used in portable receivers, but these have been replaced today by transistors.

TRANSISTORS

Transistors are made out of materials called semiconductors. Remember that a conductor is a material that will conduct or pass the flow of electric current. An insulator is a material that will not normally pass an electric current. A semiconductor is a material that falls midway between the two. It is neither a good conductor nor a good insulator.

Two materials, germanium and silicon are widely used in making transistors. Almost all the early transistors were germanium transistors, but now silicon transistors are about as numerous as germanium transistors. In the early days of semiconductors, manufacturing techniques had not been developed for the manufacture of silicon transistors. The few silicon transistors that were available were much more expensive than germanium transistors. However, today both types are widely available and there is very little difference between the price of the two.

A typical transistor is made up of three pieces of germanium or silicon as shown in Fig. 34. These three pieces are arranged as shown. Each piece of the germanium or silicon has been mixed with small quantities of another chemical. The pieces marked 1 and 3 have been mixed with the same chemical and the piece marked 2 has been mixed with small quantities of another chemical.

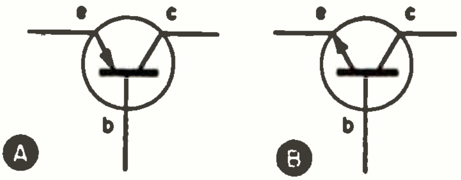

Fig. 35. Schematic symbols for two different types of three-element transistors. The emitter is marked e, the base b, and the collector c.

Since the transistor is made up of three pieces of material, it is often called a triode, just as the vacuum tube with the cathode, a grid and a plate is called a triode. The elements in a transistor are called the emitter, the base and the collector. The schematic symbols for transistors are shown in Fig. 35. The lead with the arrow on it and marked with the letter e, is the emitter, the long straight line marked b is the base and the other lead marked c is the collector. The two different types of symbols are for two different types of transistors. Their operation is somewhat different, but they can be used to accomplish the same thing.

The transistor is a comparatively new device compared to the vacuum tube. However, tremendous pro-

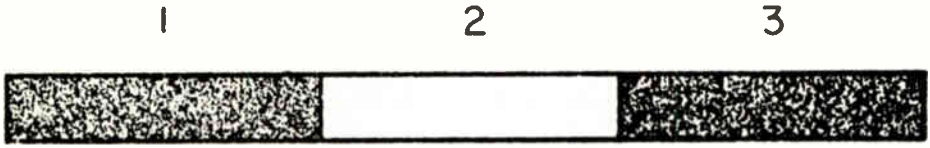

Fig. 34. A triode transistor made of three pieces of germanium. The germanium in the pieces marked 1 and 3 has been mixed with a small amount of one chemical; the germanium in the section marked 2 has been mixed with another.

gress has been made with the transistor in a relatively short space of time. Already, portable radio receivers using vacuum tubes have disappeared. All modern portable radio receivers use transistors. Also automobile radio receivers are now completely transistorized - they all use transistors. The only automobile radio you will find using vacuum tubes will be the automobile receiver designed for a car that is a number of years old.

Since transistors are making such important strides, it is extremely important that you learn all you can about them. For the present, simply remember the symbols used for them, and remember the names of the different elements in a transistor. Later, you will have several lessons devoted exclusively to transistors and you'll study transistor circuits in many of your more advanced lessons.

SUMMARY

In the preceding section you were introduced to many of the parts that you will study in detail in later lessons and will work with in your experimental kits. As we pointed out, it is important that you learn the schematic symbols for these parts as you go along, and also follow the simple circuits as you come to them. If you will do this as you go through your course you will find that schematic diagrams are easy to read, and you will soon be able to read fairly complicated diagrams without too much trouble.

There are a number of important points in this lesson that you should remember:

1. Conductors are used to carry currents from one part to another and insulators are used to keep the current from flowing where it is not wanted.
2. Batteries are made of groups of cells. If the cells in a battery are connected in series, that is the positive terminal of one connected to the negative terminal of the other, the voltages of the cells add so that the total battery voltage will be equal to the voltage of the cell times the number of cells in the battery.
3. When cells are connected so that the positive terminals of the cells are connected together and the negative terminals are connected together we say that the cells are connected in parallel.
4. Coils and transformers are widely used in electronics. A coil is simply made of a number of turns of wire. A transformer consists of two or more coils placed close together so that the magnetic lines of force produced when a current flows through one coil will cut the turns of the other coils. Remember the symbols used for air core coils and transformers and for iron core coils and transformers.
5. A capacitor is a device that can store an electric charge. It is made of two metal plates placed close together. Review the symbol used to represent a capacitor.
6. Resistors oppose the flow of current through them. Resistors having a resistance of only a few ohms up to resistances of over 1,000,000 ohms will be found in electronic equipment.
7. Two important types of vacuum tubes are the diode tube and the triode tube. A diode tube has two

elements, a triode tube has three elements.

8. Transistors are made of materials called semiconductors. Germanium and silicon are used in the manufacture of transistors. A transistor has three elements called an emitter, a base and a collector.

SELF-TEST QUESTIONS

(v) Name three materials that are good conductors.

(w) What metal is most widely used as an electrical conductor?

(x) If four 1-1/2 volt flashlight cells are connected in series to form a battery, what will the battery voltage be?

(y) Draw the schematic symbol of a 90 volt battery.

(z) Draw the schematic symbol for an air core coil.

(aa) Draw the schematic symbol for an iron core transformer.

(ab) What is the name of the device that can store an electric charge?

(ac) Draw the schematic symbol of a capacitor.

(ad) Name the three elements of a triode vacuum tube.

(ae) Name the three elements of a transistor.

Answers to Self-Test Questions

(a) Like charges repel, unlike charges attract.

(b) An atom is the smallest particle of an element that retains the original characteristics of the element. The atom will have a nucleus at its center and a number of electrons revolving around the nucleus.

(c) The nucleus and the electrons.

(d) The nucleus has a positive charge - the electrons have a negative charge.

(e) The copper atom will have a positive charge. If the atom loses one of its electrons, there will not be enough electrons to completely neutralize the positive charge on the nucleus and therefore the atom will have a positive charge.

(f) Electrons in adjacent atoms repel each other because all electrons have a negative charge and like charges repel.

(g) If you draw a diagram of the two atoms, you will soon see the answer to this question. The one atom that has the ten electrons will have two electrons in the first ring and eight electrons in the second ring. This is illustrated in Fig. 4 which shows the maximum number of electrons that can be in each ring. The atom that has eleven electrons will have two electrons in the first ring, eight electrons in the second ring, and the eleventh electron in the third ring. This atom will be quite unstable because the single electron in the third ring will not be held very closely to the nucleus. Indeed, this is the structure of the sodium atom. Sodium is a metal which in its pure state is so unstable that it must be kept submerged in oil. The atom with the ten electrons has the first two rings filled. You will remember that we said that atoms with the outer ring filled are very stable. This atom is indeed stable, it is the neon atom. Neon is called an inert gas by chemists. This means it is chemically inactive and will not combine with other elements.

(h) The negative terminal of a flashlight cell has a surplus of electrons. The positive terminal has a shortage. As a result, when a flashlight cell is connected into a circuit, the electrons leave the negative terminal, flow through the circuit and travel back to the positive terminal of the cell.

(i) When an electric circuit is completed, electrons start in motion instantaneously throughout the entire circuit. In a simple circuit such as shown in Figures 11 and 12, the number of electrons in motion is the same in all parts of the circuit.

(j) We measure electric currents in amperes. We usually abbreviate amperes, amps.

(k) The unit used to measure electromotive force is the volt.

(l) The unit used to measure the opposition to current flow in an electric circuit is the ohm.

(m) Increasing the voltage in an electric circuit will increase the current flowing.

(n) If we reduce the resistance in an electric circuit, the current flowing in the circuit will increase.

(o) The basic law of magnetism is, "like poles repel; unlike poles attract".

(p) The basic law of magnetism will give you the answer to this question. Since the pole of the magnet attracts the south pole of the compass, the pole must be an unlike pole, therefore it is a north pole.

(q) The magnetic lines of force leave the north pole of the magnet and travel through space to the south pole of the magnet.

(r) The magnetic lines of force around a current-carrying wire are strongest close to the wire. The further you get away from the wire, the weaker the magnetic lines of force will be.

(s) Placing an iron core inside of an electromagnet will increase the strength of the magnetic field.

(t) The flashlight bulb will light while the magnet is being placed inside of the coil. Once the magnet is inside of the coil and no longer moving, the flashlight bulb will no longer light.

(u) In the circuit shown in Fig. 20, when the switch is first closed, the magnetic field in L1 builds up slowly. This causes the number of magnetic lines of force to increase and the changing number of magnetic lines of force cutting L2 induces a voltage in L2. Once the magnetic field around L1 is built up to its full strength, the number of magnetic lines of force cutting L2 will no longer change and there will be no voltage induced in L2, therefore the flashlight bulb will no longer light.

(v) Copper, silver, aluminum, iron and most metals are good conductors.

(w) Copper.

(x) When the flashlight cells are connected in series the voltage will be equal to the cell voltage times the number of cells. 1-1/2 times 4 = 6 volts.

(y) See Fig. 22C, use the same symbol but write 90 v instead of 45 v.

(z) See Fig. 24A.

(aa) See Fig. 25B.

(ab) A capacitor.

(ac) See Fig. 26B.

(ad) Plate, grid and filament or cathode.

(ae) Emitter, base and collector.

Answering The Questions

On the last page of this lesson you will find ten questions. These questions are designed to help you learn the important points in this lesson. We do not want you to try to memorize the lesson or answer the questions from memory.

When you are ready to answer the questions, read over the first question carefully, make sure you understand the question and then mentally see if you can answer the question. Next, go to the section of the lesson where the answer is given, and read over that section of the lesson again. Make sure that you completely understand the answer to the question. Then, close the book and write out the answer. Do not copy the answer from the book, but rather try to write the answer in your own words. If you find that you have difficulty and cannot answer the question, it is an indication that you need to study some more.

Many of the questions can be answered by a single word or by one or two words. Make your answers as brief and as direct as possible. Make sure that your answer actually answers the question asked. In some questions you will be asked to draw a schematic diagram or part of a diagram. Be sure you check these diagrams over carefully before you send in your answers for grading, because it is easy to make a mistake in drawing schematics.

Lesson Questions

Be sure to number your Answer Sheet B101.
Place your Student Number on every Answer Sheet.

Most students want to know their grades as soon as possible, so they mail their answers immediately. Others, knowing they will finish the next lesson within a few days, send in two sets of answers at a time. Either practice is acceptable. However, don't hold your answers too long; you may lose them. Don't hold answers to more than two sets of lessons at any time, or you may run out of lessons before new ones can reach you.

1. Two small balls of unknown material that are suspended near each other by threads are charged by being rubbed with a silk cloth. The balls then repel each other. Which one of the following statements will then be incorrect?
   (1) The balls both have a negative charge on them.
   (2) The balls both have a positive charge on them.
   (3) One ball has a positive charge, the other a negative charge.

2. Which does a negatively charged body have, a shortage or a surplus of electrons?

3. Draw a schematic diagram of a wire connected between the two terminals of a flashlight cell. Mark the polarity of the battery terminals and show by means of arrows the direction in which current will flow.

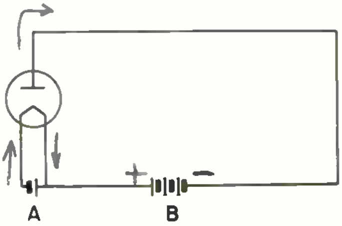
4. If we double the voltage applied to a circuit, what will happen to the current?

5. If you find that when you bring 2 magnetic poles together they attract each other, which one of the following statements is true?
   (1) The two poles must both be north poles.
   (2) The two poles must be south poles.
   (3) One pole must be a north pole and the other a south pole.

6. If a permanent magnet is held motionless inside a coil, will a voltage be induced in the coil?

7. How many flashlight cells would you have to connect in series to get 7.5 volts?

8. Will current flow from the filament to the plate in the circuit shown at right? Explain your answer. (Notice that the negative terminal of battery B is connected to the plate of the diode.)



9. Draw the schematic symbol of a modern triode tube and label the parts.

10. Draw the schematic symbol for a transistor and label each element with its full name.

HOW TO BUILD CONFIDENCE

Self-confidence--an active faith in your own power to accomplish whatever you try to do--is a personal asset which can do big things for you.

One thing which builds self-confidence is a successful experience. Each lesson completed with a passing grade is a successful experience which will build up confidence in you.

Little successes are contagious. Once you get a taste of success, you'll find yourself doing something successful every day. And before you realize it, your little successes will have built up to that big success you've been dreaming of. So--get the habit of success as fast as possible. Resolve to study every day, even if only for a few minutes.

Another confidence builder is a deep, firm faith in yourself--in your ability to get ahead. If you do believe in yourself and you are willing to back up this faith with good hard studying, you can safely leave the final result to itself. With complete confidence, you can look forward to an early success in electronics.

Act as if you could not possibly fail, and you will succeed!

ACHIEVEMENT THROUGH ELECTRONICS

HOW ELECTRICITY IS PRODUCED FOR ELECTRONICS

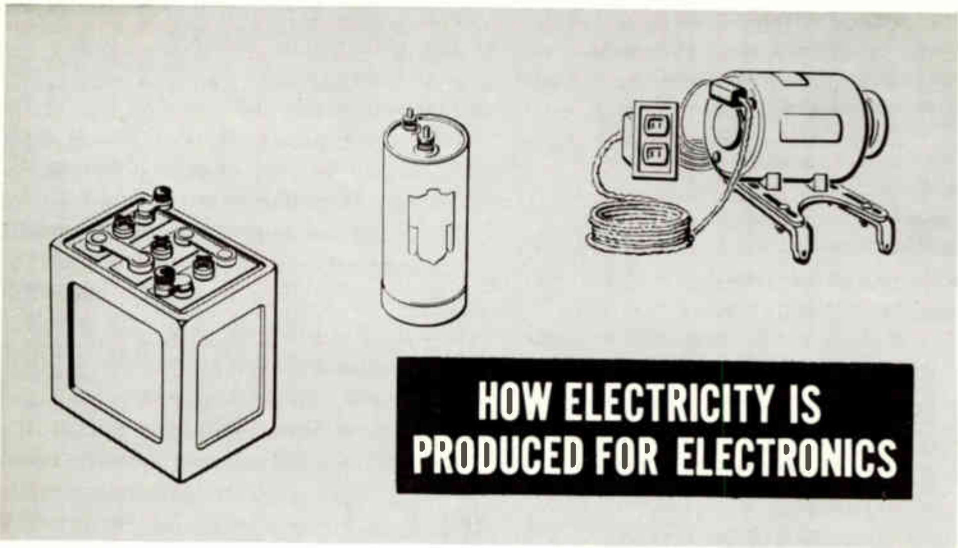
B102

NATIONAL RADIO INSTITUTE • WASHINGTON, D. C.

HOW ELECTRICITY IS PRODUCED FOR ELECTRONICS

B102

HOW ELECTRICITY IS PRODUCED FOR ELECTRONICS



Electronics is a term you will be meeting constantly from now on. Let us take time to see what we mean by the word "electronics." Originally the term electronics was applied only to devices using electronic tubes. However, in recent years the meaning has been broadened to include the whole field of electron behavior. Thus we can consider every application of electricity as part of the general field of electronics.

You have already seen many uses of electronic principles. You see them every day, for example, in your radio and television receivers.

The field of electronics is a growing field. The chances are that at this very minute while you are reading this lesson, engineers are working on new projects that will result in some new use of electronics. They may be working on some method of using electronics to improve on some process we are already using, or they may be working on something that is entirely new, something we have been unable to do before. You can be sure that we are going to see many new developments in electronics in the years to come.

In this lesson you are going to study some of the uses of electronics. We will cover only a few of the details, but you will learn enough to be able to understand these uses of electronics. In addition to learning something about these processes, you will learn more about the behavior of the electron.

The first use of electronics that you will study is in the power industry. Although this is often not considered part of the electronics industry, it is extremely important to electronics, because without economical power there would be very little use of electronics at all. This brief look at the power industry will help you in your study of other pieces of electronic equipment.

You will also learn more about electronics in radio. You will study several new components, and also you will learn how sound is sent through space by means of radio waves. This section on radio is important because the circuits you will study here are similar to ones you will find in radio, in television, and in other industrial applications.

You will also see how electronic principles are used in one branch of industry. Many industrial processes require large amounts of direct current.

It is much more convenient to generate and transmit alternating current than direct current. You will see how alternating current can be changed into direct current by means of electron tubes.

Finally, you will learn about pulse-type signals that are widely used in computers and television. You will learn the basic fundamentals of logic circuits that process these pulse signals in computers.

In studying the following sections of this lesson, it is important for you to understand the basic circuits and ideas presented. However, it is not necessary for you to remember all of the details of the various processes. As you complete a section of the lesson, answer the self-test questions at the end of the section. If you can answer these questions and remember the answers to them, then you should have no difficulty answering the questions at the end of the lesson. Between the self-test questions and the lesson questions, we will cover all of the important points in the lesson. Other details of the lesson will become more familiar to you as you go further in your course; these details will be covered again, and in many cases explained much more thoroughly than in this lesson.

If there are any basic circuits and ideas that you do not understand be sure to go over these points several times. If you need help be sure to take advantage of the NRI consultation service and write in requesting assistance. A thorough understanding of the basic fundamentals is absolutely essential; the more advanced lessons you will study later will be based on the fundamentals you will be learning in this and other basic lessons.

We have already mentioned that without economical electric power, there would be no electronics industry. In addition to economical power, we must have large amounts of power available.

The information on how electric power is generated is important to the radio-TV serviceman, the computer technician, the communications technician, and the industrial electronics technician. All may have occasion to service power-generating equipment. Even the radio-TV serviceman with only a small business may want to fix mobile equipment. There is more and more demand for people who can do repair work of this type, and in order to do such repairs one must be familiar with power-generating equipment.

There are two main sources of power in electronic equipment. One is batteries which you have already studied briefly. You will now look into batteries in more detail, and then go on to the study of generators to see how they operate and how the voltage generated is pictured.

Batteries

Batteries can be divided into two types: those containing primary cells and those containing secondary cells. Primary cells are cells that cannot be recharged. A flashlight cell is an example of this type. A secondary cell is a cell that can be recharged. The storage batteries used in automobiles are made up of secondary cells as are the rechargeable batteries used to operate portable television receivers designed for battery operation.

We mentioned previously that a battery is made up of two or more cells. But the word battery is also used to describe single cells, such as flashlight cells. Consequently, the word battery has come to mean anything from one cell up.

A basic knowledge of batteries is important to the electronics technician today because many of the devices he will encounter operate from batteries. For example, there are millions of portable radio receivers in use; almost all of these operate from batteries made up of cells like the flashlight cell. Portable television receivers which can be operated from either the power line or from a battery pack are becoming increasingly popular. These television receivers operate from small storage batteries that are similar to the storage batteries used in automobiles. Other types of batteries, such as the manganese battery and the mercury battery, are becoming increasingly important. In some ways these cells are similar to the flashlight cell, but they have a longer life. The chances are that they would replace the flashlight cell entirely except for the fact that they are more expensive.

A simple electric cell can be made by inserting two pieces of metal in an acid solution. The voltage produced by the cell will depend upon the metals used. For example, if one metal is zinc and the other copper, the cell voltage will be about 1.1 volts. If the copper electrode is replaced by a silver electrode, a voltage of about 1.5 volts will be produced. On the other hand, if magnesium is used as one electrode and gold as the other, a voltage of about 3.7 volts will be produced. Such a battery, while it has a relatively high voltage, isn't practical because of the cost of the gold and magnesium.

The cells we were speaking of contained acid in a liquid form. This type of cell has the disadvantage that the acid is easily spilled. A much more practical cell is the "dry cell", such as the flashlight cell, which we will now study in detail.

DRY CELLS

Dry cells are not really dry. The chemical mixture in the battery is actually quite moist, and when it becomes dry the battery is no longer usable. The name dry cell was given to these batteries because the chemical mixture was in the form of a paste rather than a liquid. The dry cell uses a carbon rod as the positive electrode and the zinc case as the negative electrode. The voltage of a cell of this type is 1-1/2 volts.

This cell is actually similar to the simple basic cells we mentioned earlier which contain two metals in an acid solution. In this case, one metal is zinc and the other is carbon. We do not often think of carbon as a metal, but actually it is midway between the metals and nonmetals, and in some cases acts like a metal and in other cases acts like a nonmetal. When used in a dry cell it acts like a metal.

The acid is in the form of a paste made up of ammonium chloride, powdered carbon and manganese dioxide. The ammonium chloride is the acid, the other two chemicals are added to improve the performance of the cell.

The construction of one type of dry cell that can supply current for a much longer time than a flashlight cell is shown in Fig. 1. This cell is similar to a flashlight cell except it is larger and has screw-type terminals to which the leads are connected. The metal case and carbon rod are often provided with screw terminals as shown here. Sometimes a plug type of connector is provided instead. A cell of this type can provide a much higher current than a flashlight cell, because it has much larger electrodes. However, the output voltage of the cell is the same as that of the flashlight cell (1-1/2 volts). In the early days of radio, four cells of this type, connected in series, were used to provide 6 volts to operate the filaments of the tubes in many radios.

Fig. 1. Construction of a dry cell.

Fig. 2. A square 1½-volt battery.

In addition to the round cell shown in Fig. 1, 1-1/2-volt cells are often made square. A square cell can often be fitted into a somewhat smaller place than a round cell, and therefore is particularly useful in portable equipment. A square cell is shown in Fig. 2. It would be more correct to call a square cell a battery because it is generally made up of four small round cells instead of one large cell. The negative terminals of all four cells are connected together and brought out to one common terminal which is the negative terminal of the battery. Similarly, the positive terminals of all four cells are connected together and brought to one common positive terminal.

As you learned earlier, this type of

connection is called a parallel connection and though there are four cells used, the output voltage from the battery is only 1-1/2 volts, the same as it would be if only one large cell were used. As we pointed out earlier, the advantage of this type of construction is that the four cells in parallel can supply more current than a single cell could alone. This is because the current the cell can supply depends primarily on the area of the positive and negative electrodes -- the carbon rod and the zinc case. Their area is greater when four cells are used in parallel than it would be if one cell of the same physical size were used. In addition, we pointed out that it is often more economical to use the four cells because the manufacturer may be making them in large quantities for other uses. This will bring the cost down so that it is more economical to use four of the smaller cells than it would be to use one large cell.

You already know that dry cells can be connected in series to provide more than the 1-1/2 volts available from the single cell. An example of this type of battery is shown in Fig. 3. This battery is designed to provide a voltage of 45 volts and is called a "B" battery. This type of battery was widely used in the early days of radio to provide the voltage between the plate and filament of the tubes in radio receivers. Later, smaller versions of the battery were used in portable receivers. Today, the battery itself is not as important as the lesson we can learn from it about the voltages between different points. The following section of this lesson is extremely important, read it several times to be sure you understand it completely.

"B" BATTERY

Fig. 3. A 45-volt battery made of dry cells connected in series.

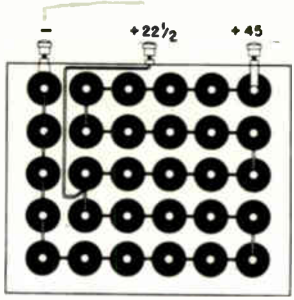


Fig. 4. How the dry cells in Fig. 3 are connected in series.

The battery shown in Fig. 3 is made up of thirty 1-1/2 volt cells connected in series as shown in Fig. 4. Notice that there are three terminals brought out of this battery. It is easy to see that the voltage between the two outside terminals should be 45 volts. There are thirty 1-1/2-volt cells, and 30 X 1-1/2 is 45. Now trace out the circuit between the negative terminal and the terminal marked +22-1/2 and you will see how we get this voltage. You will find that there are fifteen cells connected between these two terminals, and 15 X 1-1/2 is 22-1/2. Thus, if you need only 22-1/2 volts you would connect between the – terminal and the terminal marked +22-1/2.

Now look at the other half of the battery. What is the voltage between the terminals marked +22-1/2 and 45? By inspecting Fig. 4 you can see that there are fifteen cells connected between these two terminals. 15 X 1-1/2 is 22-1/2, and therefore there should be 22-1/2 volts between these two terminals. But which terminal is positive and which is negative? By looking at Fig. 4 again, you can find the answer to this question. Notice that the terminal marked +45 is connected to the positive terminal of one of the cells. The terminal marked +22-1/2 is connected to the negative terminal of the last cell in the group of fifteen cells connected between these two terminals. Therefore, this is the negative terminal and the +45 terminal is the positive terminal.

It may seem somewhat confusing at first that the terminal marked +22-1/2 can be both positive and negative. Let us see how this can be so. Starting with the negative terminal and looking toward the other two, you first see a group of fifteen cells and then a terminal. This terminal is positive compared to the negative terminal. We say it is positive with respect to the negative terminal. Then there is another group of fifteen cells and another terminal. This last terminal is even more positive with respect to the negative terminal. Now, if we started at the positive terminal and looked back through the battery we would see a group of fifteen cells and a terminal. This terminal is negative with respect to the positive terminal. We would then see an additional group of fifteen cells and another terminal, which is even more negative with respect to the positive terminal. We could, if we wished to do so, mark the battery as in Fig. 5. Notice that this is the same battery as the one in Fig. 4; we have simply marked the terminals differently. The voltage between the two outside terminals is still 45 volts, and the voltage between either outside terminal and the center terminal is 22-1/2 volts. In Fig. 4, we have considered the voltage at the negative terminal as zero and marked the other two positive with respect to it. In Fig. 5, we have considered the positive terminal as zero volts and marked the other two negative with respect to it. We could go one step further and mark the center terminal zero and the one outside terminal −22-1/2 volts and the other +22-1/2 volts with respect to the center terminal.

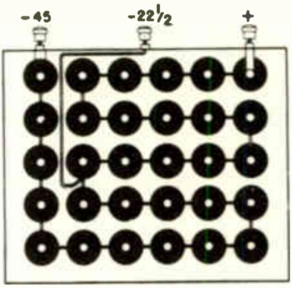

Fig. 5. The terminals of the 45-volt battery which are shown in Fig. 4 can be marked as shown.

You might wonder why there are all these different ways of marking battery terminals. The reason is that in electronic equipment one terminal of a battery is usually connected to a common or ground terminal in the equipment. Sometimes this terminal is the positive terminal of the battery, sometimes it is the negative terminal. It all depends on what the battery is to be used for. Usually the terminal voltages are marked with respect to the terminal that will be grounded in normal operation.

It is important to understand what is meant by a ground terminal or connection. In the early days of radio almost all radios were connected by a wire to a water pipe or to a pipe driven into the ground to improve reception. This was called a "ground" lead. One terminal of the "A" battery, the negative terminal of the "B" battery and the positive terminal of the "C" battery were all connected to the metal chassis on which the receiver was built, and the metal chassis was connected to the ground lead. Now the chassis in electronic equipment is called a chassis ground even though it may not be connected to an external ground connection at all. The negative side or terminal of the B supply is called B– ground or the common ground. In some equipment B– is connected to the chassis, but in other equipment it is not. When B– is connected to the chassis, we refer to both B– and the chassis as ground. When B– is not connected to the chassis, we refer to the chassis as a chassis ground and to B– as a floating ground. You will see these three expressions used frequently.

Remember that one terminal can be both positive and negative at the same time. In other words, one terminal might be positive when it is compared to another terminal, but negative when compared to a third. You will run into this situation over and over again.

Although a B battery is able to supply a much higher voltage than a single cell, the amount of current that can be taken from it is somewhat limited. If a B battery is used to supply a high current, it will soon be exhausted.

When you need a higher current than can be supplied by a single cell or battery, you can obtain it by connecting two or more batteries in parallel. When you connect two batteries in parallel, you connect the two negative terminals together and the two positive terminals together as shown in Fig. 6. This is the same type of connection that is used in the battery shown in Fig. 2, where the 1-1/2-volt battery was made from four cells connected in parallel. Of course, you can only do this if the batteries have the same voltage. When two similar batteries that are connected in parallel are connected to a circuit, each battery will supply approximately one-half of the current used in the circuit. This is more economical than taking the full current from one until it is exhausted and then taking the full current from another, because the batteries connected in parallel will usually last more than twice as long as a single battery.

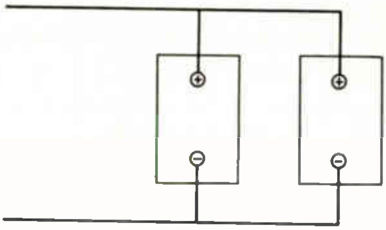

Fig. 6. Two batteries having the same voltage can be connected in parallel if a high current is required.

There are two big disadvantages of the dry cell. It has a fairly short shelf life and a rather large cell is required to supply a moderate current. The shelf life of a cell is the length of time it can be kept after it is made before it deteriorates to such an extent that its life is affected appreciably. When we say a dry cell has a short life we mean that it cannot be kept too long before it is put into service, otherwise it will not last long.

MERCURY CELLS

A cell that overcomes the two main disadvantages of the dry cell is the mercury cell. The voltage supplied by one of these cells is about 1.35 volts or about 1.4 volts depending upon the materials used in the cell.

There are two different types of mercury cells in use. One is a flat cell that looks something like a button, and the other is a cylindrical cell that more closely resembles a standard flashlight cell. The advantage of the button-type cell is that several of them can be stacked inside of one container to form a battery. A typical battery made of three flat cells is shown in Fig. 7. The battery is slightly smaller than a standard flashlight cell, but produces a higher voltage, has a longer life and can supply more current than a flashlight cell.

Fig. 7. The mercury battery shown is slightly smaller than a standard flashlight cell, but produces a higher voltage, and has a longer life than the flashlight cell.

Mercury cells were originally developed for use by the Armed Forces, but are now found in many pieces of portable equipment manufactured for civilian use. Their small size and long life make them ideal for use in transistorized equipment. Since transistors use only a small amount of current, transistorized equipment powered by mercury batteries can be operated for a long time before it is necessary to replace the batteries. When it is necessary to replace a mercury battery, the old batteries must not be disposed of by burning; these batteries will explode if they are thrown into a fire and might cause considerable damage or injury to someone nearby.

One other important point to remember about the mercury cell is that the small terminal on the top of the cell is the negative terminal. The case is the positive terminal. This is the opposite of the standard flashlight cell where the button on the top of the cell is the positive terminal and the case is the negative terminal.

MANGANESE BATTERIES

The big disadvantage of the mercury battery is that it is quite expensive. This has limited its use somewhat in entertainment type equipment, such as portable radios, etc. A battery that is not as expensive, but has many of the desirable characteristics of the mercury cell, such as long life, is the manganese cell. This cell is also often called the alkaline-manganese-zinc cell.

The manganese cell looks very much like a flashlight cell and is generally made in the same physical sizes as the small dry cells used for flashlights and portable radios. The voltage of a cell of this type is 1.5 volts so it can be readily substituted for a dry cell. A manganese cell can supply a certain value of current for much longer than the same size dry cell. Manganese cells are particularly useful in applications where the equipment is to be left on for a long time. Here their life will greatly exceed the life of a dry cell. However, in applications where equipment is operated intermittently for short periods, the manganese cell will outlast the dry cell, but the increase in performance may not be justified by the increased expense of the manganese cell.

LEAD-ACID BATTERIES

The storage battery used in automobiles is the best known example of a secondary cell. This type of cell has two groups of plates: one attached to the positive terminal and the other to the negative terminal. The plates are made of lead and fit together as shown in Fig. 8A. Between the plates are sheets of insulating material called separators, made either of porous wood or perforated wood or fiber glass. The separators prevent the plates from touching each other and destroying the cell. One of the sets of the plates is treated chemically to form an oxide of lead (a combination of lead and oxygen), and the two sets of plates with the separators between them are then placed in a container filled with a solution of sulphuric acid in water. The term "lead-acid battery" came about as a result of the use of lead plates in a solution of sulphuric acid.

The voltage in this type of cell is approximately 2 volts. Storage batteries used in modern automobiles are usually made of six cells connected in series so that the output voltage from the battery is 12 volts. Older automobiles used batteries in which three cells were connected in series to give an output voltage of 6 volts. A three-cell battery is shown in Fig. 8B.

To charge this type of battery, the battery is connected to a battery charger which simply applies a voltage slightly

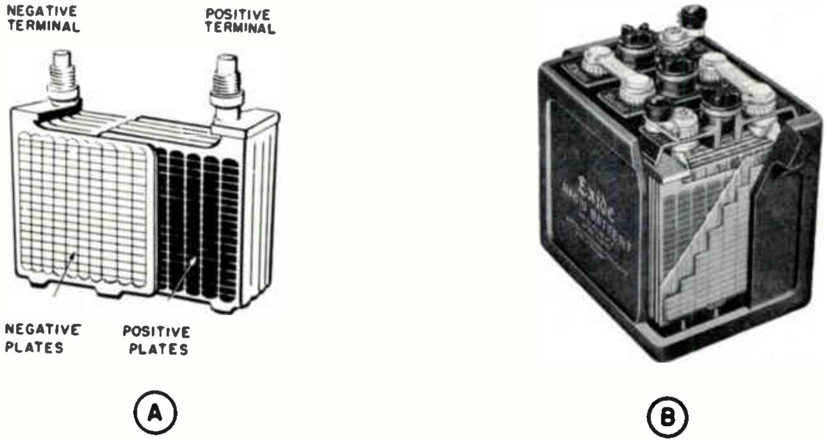

Fig. 8. (A) shows the construction of a storage battery; (B) shows a three-cell battery.

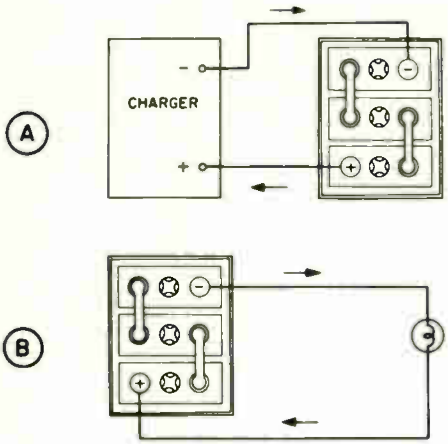

Fig. 9. (A) shows the direction current will flow when a storage battery is being charged; (B) shows the direction current will flow when the battery is supplying current.

higher than the battery voltage. The charger forces current through the battery as shown in Fig. 9A. This current causes a chemical change in the battery, and the electrical energy put in the battery is stored in it in the form of chemical energy. When the battery is connected to a circuit, the energy stored in the battery is released by the chemical action of the battery and current will flow in the circuit as shown in Fig. 9B.

Notice the direction of current in Figs. 9A and 9B. When the battery is being charged, the current is forced through the battery in the opposite direction to which it flows when the battery is supplying current. The storage battery can supply current for a much longer time than the average dry cell. When the storage battery is discharged and is no longer able to supply the current required by the circuit, the battery can be removed from the circuit and recharged by passing current through it in the opposite direction. Once the battery has been recharged, it can again be connected to the circuit and will supply current to the circuit.

In an automobile, the battery is usually connected to a generator. As long as the car is running at a reasonable speed, the generator is both charging the battery and supplying the current needed to operate the car. However, when the car is operating at a slow speed or when it is stopped, the generator is not turning fast enough to provide the electricity needed by the car and the battery supplies this energy. In the next section of this lesson you will study generators and you will see how they produce an electric current.

NICKEL-CADMIUM BATTERIES

There are two main disadvantages of the lead-acid storage battery. One disadvantage is that it has a somewhat limited life and the other is that it gives off hydrogen and oxygen when it is charged, and therefore the cell must be vented to allow these gases to escape. The hydrogen and oxygen given off from the battery come from the water in the cell and this water must be replaced periodically. As a result, the cell requires considerable maintenance.

A cell that overcomes this disadvantage is the nickel-cadmium cell. While the cell does give off gases when it is being charged, methods have been developed to take care of these gases so that the cell may be sealed. As a result, you do not have to add water or acid to the cell; the cell requires no maintenance other than to charge it when it becomes discharged.

The nickel-cadmium cell has an operating voltage of about 1.2 volts. While the cell cannot supply quite as much current as the same size lead-acid cell can supply, the fact that it will last almost indefinitely if it is cared for and that it can be sealed and requires no maintenance has made it ideally suited for use in operating portable electronic equipment. As more portable transistorized equipment is developed, it is likely that this type of cell will become more important to the electronics technician.

In charging both the lead-acid and the nickel-cadmium storage batteries or cells, the technician should follow the manufacturer's recommendations and avoid charging either type of cell at a higher rate. This is likely to cause excessive heat which can cause the plates in the cell to warp and touch. Once this happens, the cell is shorted and it is no longer usable.

SUMMARY

In this section of the lesson we have covered three important primary cells and two important secondary cells. We do not expect you to remember how these cells are made, but you should remember the voltage of each cell and remember their important characteristics. There may be occasions when you will want to substitute one type of cell for the other to obtain improved performance. In order to do this you must know the voltage supplied by each type of cell so that you can be sure that you will have the proper operating voltage for the equipment. You must also know something about their characteristics so that you will be able to select a suitable replacement that will result in improved performance.

The most important characteristic of the dry cell is its economy. Its disadvantages are its limited shelf life and its limited current capabilities.

The mercury cell has a much longer shelf life than a dry cell, and a given size mercury cell is capable of supplying a much higher current than a dry cell. That is to say, it can supply the same current as a dry cell for a much longer time. Mercury cells have a voltage of about 1.35 or 1.4 volts, depending upon the materials used in them. The disadvantage of the mercury cell is its cost.

The manganese cell can provide a given current for a much longer time than a dry cell can. Its shelf life is better than a dry cell, but not as good as a mercury cell. The output voltage of a manganese cell is about 1.5 volts.

The storage cell has the advantage that it can be recharged and used again. There are two important types of storage cells, the lead-acid cell and the nickel-cadmium cell. The lead-acid cell has a voltage of about 2 volts and the nickel-cadmium cell has a voltage of about 1.2 volts.

The advantage of the nickel-cadmium cell over the lead-acid cell is that it can be sealed and does not require the periodic maintenance that the lead-acid cell requires.

SELF-TEST QUESTIONS

(a) What is the output voltage of a dry cell?

(b) If fifteen dry cells are connected in series to form a battery, what would the output voltage be?

(c) If eight dry cells are connected in parallel to form a battery, what would the output voltage be?

(d) If six dry cells are connected in series to form a 9-volt battery and the negative terminal is marked with a minus sign and the positive terminal marked +9V, how would you expect a center tap terminal connected between the third and fourth cells to be marked?

(This is a difficult question - look at Figs. 4 and 5 before you make up your mind as to what the answer should be.)

(e) What are the two main advantages of the mercury cell over the dry cell?

(f) What is the output voltage of a mercury cell?

(g) What is the output voltage of a manganese cell?

(h) Since the manganese cell is a better cell than the dry cell, why hasn't it completely replaced the dry cell?

(i) Name two types of secondary cells.

(j) Which type of secondary cell provides the longest life, and the most maintenance-free performance?

Generators

Although batteries are very useful, their ability to supply large amounts of power is limited. If a battery, even a lead-acid storage battery, is called upon to supply large amounts of current, it will soon be exhausted and must be removed from the circuit and recharged. Even if storage batteries could supply the large amounts of electricity consumed daily by the average large city, we would still have to have some way of recharging the batteries. Thus, we would have a need for a device other than a battery that is capable of supplying large amounts of electricity.

You already know that if the magnetic field cutting through a coil is varied, a voltage will be induced in the coil. If the magnetic field is made to vary rapidly enough, the voltage will be induced continuously in the coil; this voltage can be connected to an outside circuit and current will flow through the circuit. This is the principle that is used in electric power generators.

Before studying generators, let us learn about two important kinds of current you will have to deal with: direct current and alternating current.

DIRECT CURRENT AND ALTERNATING CURRENT

The current supplied by a battery always flows from the negative terminal of the battery through the external circuit and back to the positive terminal of the battery. The current always flows in one direction. We call this kind of current ***direct current.*** We usually abbreviate this ***dc.***

The voltage supplied by a battery that causes a direct current to flow is referred to as a ***dc voltage.*** The expression dc voltage means that the voltage causes a direct current to flow. This means that the polarity does not change. In other words, on a battery, one terminal is always the negative terminal and the other terminal is always the positive terminal. We say that the terminals always have the same polarity -- the polarity of the terminals does not change.

A dc generator is a device that generates a direct current. In other words, the current coming from the generator always flows in the same direction. This means that the terminals of the generator must always have the same polarity; one terminal will always be the negative terminal and the other terminal will always be the positive terminal.

Besides direct current, there is another important type of current with which you must be familiar. This type of current is called ***alternating current*** or simply ***ac.*** Alternating current differs from direct current in that its direction is continually changing. The current flows first in one direction and then in the opposite direction. This reversal of current occurs many times a second. The current supplied to your home is alternating current. The voltage that produces an alternating current is called an ***ac voltage.*** In order to produce a flow of alternating current the polarity of the terminals of the device causing the current flow must be continually reversing. In other words, when the current is flowing in one direction, one terminal must be negative and the other positive. When the current flows in the opposite direction, the polarity of the terminals must reverse so that the terminal that was the negative terminal must become the positive terminal and the terminal that was the positive terminal must become the negative terminal.

While alternating current cannot be used to operate such electronic devices as tubes and transistors, it has many useful applications; indeed our modern industries depend upon large amounts of alternating current being readily available.

Now we will go ahead and learn how a simple generator operates and at the same time learn more about alternating current and ac voltage.

A SIMPLE GENERATOR

A simple generator capable of generating electric power can be built as shown in Fig. 10. This generator consists of a single-turn coil placed between the poles of a magnet. As the coil is rotated, it will cut through the magnetic lines of force flowing from the north pole to the south pole of the magnet and a voltage will be induced in the coil. The amount of voltage will depend upon the number of magnetic lines being cut by the coil as it rotates. This in turn will depend upon the strength of the magnetic field and upon the speed at which the coil is rotated.

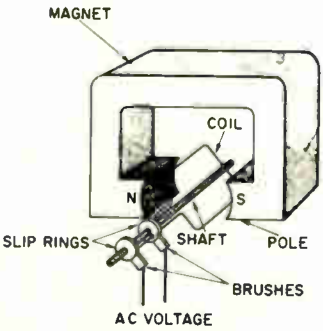

Fig. 10. A simple ac generator.

First, let us consider the voltage that will be produced by a generator of this type. When the coil is in the position shown in Fig. 11A, the movement of the coil is parallel to the lines of force flowing from the north pole to the south pole of the magnet. They are moving along the lines of force and are not cutting through any of the lines of force. You will remember that in order to induce a voltage in a coil, the turns of the coil must be cut by magnetic lines of force. In Fig. 11A, the coil is moving along the lines of force and not cutting through them. There will be no voltage induced in the coil when the coil is in this position.

When the coil moves counterclockwise to the position shown in Fig. 11B, it will still be moving almost parallel to the lines of force. However, it is moving at a small angle to these lines of force and therefore it will cut through some of them and there will be some voltage induced in the coil. When the coil moves down to the position shown in Fig. 11C, it will be cutting more lines of force because it is moving at a sharper angle to them and a somewhat higher voltage will be induced in the coil. Finally when it reaches the position shown in Fig. 11D, it will be moving directly perpendicular to the lines of force and will be cutting through them at maximum speed, and the voltage induced in the coil will reach its highest

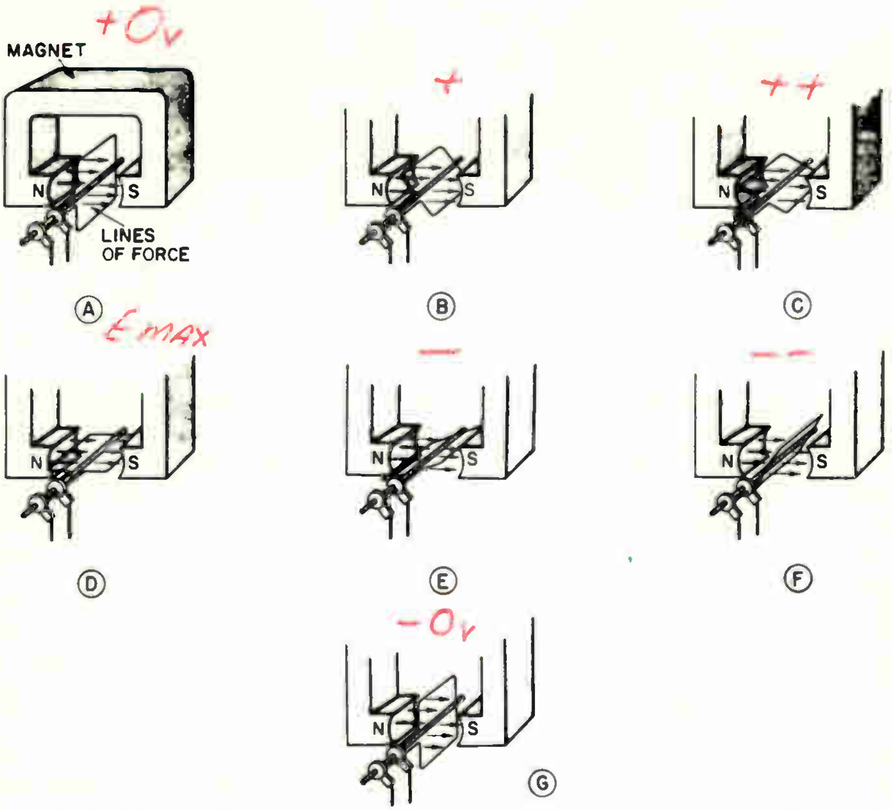

Fig. 11. In the illustration, the coil is rotating counterclockwise. The voltage produced by this generator depends upon the movement of the coil in relation to the magnetic lines of force.

value. As the coil moves down to the positions shown in Figs. 11E and 11F, it will be cutting fewer and fewer lines of force until it finally reaches the position shown in Fig. 11G. Once again the coil will be running parallel to the lines of force and no voltage will be induced in the coil.

HOW VOLTAGES ARE PICTURED

You will remember that when we discussed the batteries shown in Figs. 4 and 5 we said that one terminal of the battery could be considered as zero voltage and the voltage at the other terminals marked in reference to this terminal. You can do the same thing with a generator. You can use one lead as the ground or common lead and measure the voltage at the other lead as either positive or negative with respect to the common lead.

If we assume that one lead is a common or ground lead, we can conveniently represent the voltage at the other lead by a graph. A graph is merely a simple way of presenting information in the form of a picture. In Fig. 12A, you will notice a

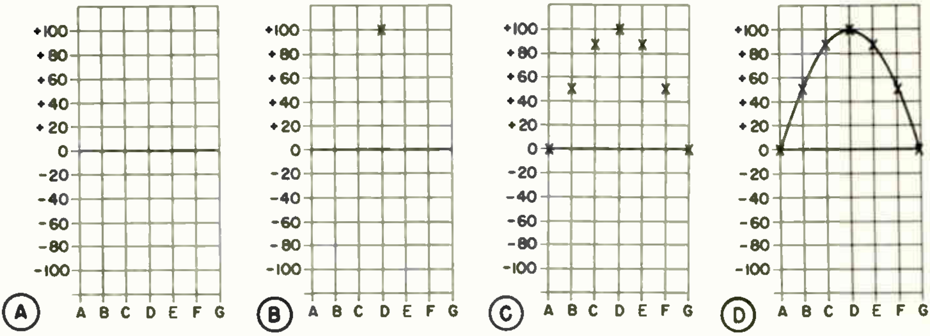

Fig. 12. Construction of a graph of the voltage produced by the generator in Fig. 11.

horizontal line which is marked zero running through the center of the graph. This is the zero voltage line which represents the voltage of the ground or common lead. The horizontal lines above this line represent positive voltages, and the lines below the zero line represent negative voltages. The vertical lines represent the positions .of the coil shown in Fig. 11.

Let us assume that at the instant the coil is in the position shown in Fig. 11D, the voltage generated is 100 volts. If the voltage is 100 volts positive with respect to the common terminal, we would place a mark (X) on the graph at the point where the +100 volt line crosses the vertical line running through D, as shown in Fig. 12B. Similarly the voltages that are present at the remaining points would be marked on the graph. This would look like Fig. 12C. The only step left is to draw a smooth curve joining all these points as shown in Fig. 12D. This curve represents the voltage generated by the generator through one half turn.

When the coil is rotated through the remaining half turn, the polarity of the voltage produced will be reversed. In other words, the voltage will now be negative with respect to the ground terminal because the coil will now be cutting through the magnetic lines of force in the opposite direction. If we complete the

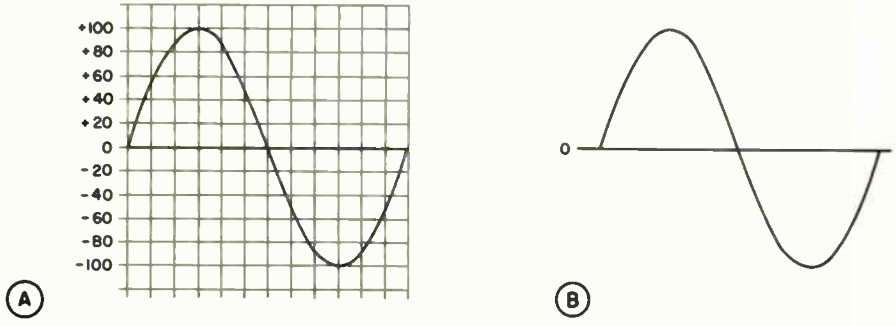

Fig. 13. The appearance of the output voltage produced by the generator as it travels through one complete turn.

drawing to show what the voltage will look like during the other half turn, the picture would look like Fig. 13A. For convenience, if we leave the horizontal and vertical lines of the graph off, we can get a better look at the shape or appearance of the output voltage as in Fig. 13B. This is called a waveform.

This is how the ac voltage supplied by the power company may be represented. It is called a sine (pronounced sign) wave.

The voltage represented by one complete turn of the coil in the magnetic field is called a cycle. The power supplied by most power companies in this country is 60-cycle power. When we say 60-cycle, we mean 60 cycles per second. In other words, the voltage goes through 60 cycles each second, like the one shown in Fig. 13. This is called the "frequency" of the ac voltage. To make the generator produce this type of voltage, it would have to be turned at a speed of 60 revolutions per second, which is 3600 revolutions per minute. The part of the cycle above the line is called a half cycle, and it is referred to as the positive half cycle. The part of the cycle below the line is also called a half cycle, and it is referred to as the negative half cycle.

You will also see the term Hertz, abbreviated Hz, used to designate the frequency of an ac signal. Hertz and cycles per second mean exactly the same thing and you will see these expressions used interchangeably. Hertz is the preferred term, but you will see cycles per second used almost as often. Just remember when you see the expression 60 Hz signal, we are referring to an alternating voltage or current that completes 60 cycles per second.

The voltage generated by this generator with only a single-turn coil would be extremely low, even with a very strong magnetic field. However, we can obtain a higher voltage simply by putting more turns of wire on the coil. Ten times as much voltage would be induced in a ten-turn coil as in a single-turn coil. If one-tenth of a volt is induced in a single-turn coil, one-tenth of a volt will be induced in each turn of the ten-turn coil. These voltages will be induced in series with each other so that the total voltage available at the output terminals of the coil will be 1 volt. By putting 100 turns on the coil, we could get 10 volts; by putting 1000 turns on the coil, we could get 100 volts.

Thus, by putting the proper number of turns on the coils of a generator we can generate any required voltage.

DC GENERATORS

Instead of using a permanent magnet such as the one shown in Fig. 10, a practical generator would use an electromagnet to supply the magnetic field. The current required to operate this electromagnet can be obtained either from the generator itself or from another generator. However, it must be dc. The voltage generated by the generator we have discussed is ac. Now let us look into the generator further and see how we can obtain dc instead of ac.

In an ac generator such as the one described, the ends of the coils are connected to slip-rings. By means of contacts riding on the slip-rings (which are called brushes), we could take the ac voltage off the generator. However, if, instead of using two slip-rings, we use a

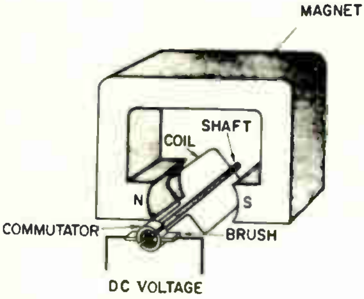

Fig. 14. A simple dc generator.

commutator, as shown in Fig. 14, we can obtain dc. A commutator is similar to a slip-ring except that it is split in half and the two halves are insulated from each other. The brushes are placed so that when the coil is going through the first half revolution, one brush will be connected to one section of the commutator and the other brush will be connected to the other section. When a coil starts to go through the second half revolution, the brushes will be connected to the opposite section; the one that was connected to the first section will then be connected to the second section, and the one that was connected to the second section will then be connected to the first section and current will always flow through the external circuit in the same direction, as shown in Fig. 15. As a result, at the output we will have a voltage like that shown in Fig. 16.

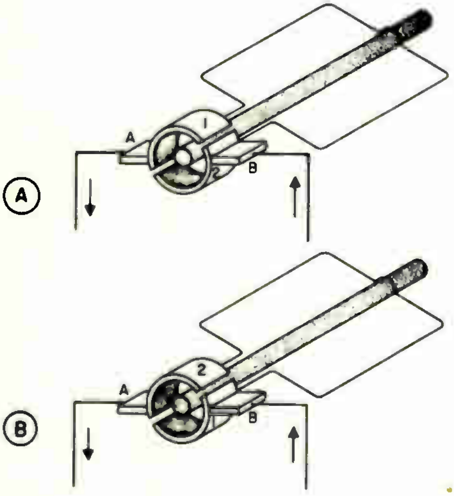

Fig. 15. In (A), section 1 of the commutator is negative, and section 2 is positive. In (B), section 1 is positive, and section 2 is negative. This means that brush A is always connected to the negative section of the commutator and brush B to the positive section, and current flows in only one direction.

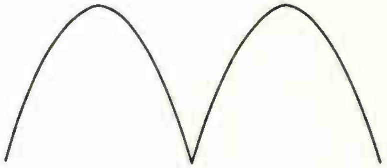

Fig. 16. Output of a simple dc generator.

Here we have essentially the same wave shape as we had in Fig. 13, except that the half of the cycle that was previously negative and drawn below the line has now been reversed by the automatic reversing of the connections to the coil performed by the commutator and brushes.

A voltage like that shown in Fig. 16 is called pulsating dc. It is dc inasmuch as the current that flows as a result of this voltage will always flow in one direction. However, since the voltage varies, the current varies; it will flow in pulses and actually drop to zero twice through each revolution of the coil. This can be used in some applications but it is not what we call pure dc, like the dc supplied by a battery.

As in the case of the ac generator, the output voltage from a dc generator with only a single turn would be extremely

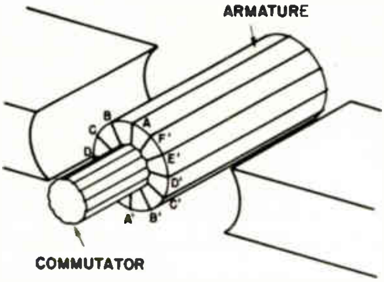

Fig. 17. The armature of a dc generator with 6 series-connected coils.

low – too low to be usable. However, by winding several turns on the coil, a higher voltage can be obtained. This will still provide a pulsating type of dc like that shown in Fig. 16.

A better arrangement is shown in Fig. 17. Here, there are a number of coils on an iron form called an "armature." The coils are in different positions around the armature. In the position shown, coil A-A′ will not cut any lines of force and therefore there will be no voltage induced in it. The coil B-B′, however, is cutting a few lines of force and some voltage will be induced in it. Coil C-C′ is cutting still more lines of force and a somewhat higher voltage will be induced, and coil D-D′ is cutting directly across the lines of force and the maximum voltage will be induced in it. These coils are all connected in series and brought out to connections on the commutator. Two brushes are used on the generator, and the output voltage from this type of machine will be nearly constant. This is because there will always be one coil either in or close to each position shown in Fig. 17. The voltage produced by the generator will be the voltage of all the coils in series. While some of the coils are producing very little voltage, the coils near the position D-D′ will produce considerable voltage. The commutator used with this type of generator would have twelve sections instead of two, as is the case in the generator with only one coil. There will be some fluctuation in the voltage so that the output voltage will look like Fig. 18 as the generator goes through one revolution. Notice that with this type of generator, instead of two big half cycles, an almost constant value of dc is obtained.

Fig. 18. Only a small ripple will be noticeable in the output of a dc generator having 6 coils and 12 commutator sections.

AC VALUES

Now look back at the ac cycle shown in Fig. 13. Notice that at the start of the cycle the voltage is 0. When the coil has rotated through one quarter of a turn, the voltage has built up to a maximum value; when the coil has gone through one-half a turn, the voltage is back to zero again. At three-quarters of a turn, the voltage has reached a maximum value with the opposite polarity and finally at the end of the cycle, the voltage is back to zero. The end of this cycle is actually the start of the next cycle. The voltage reaches a maximum value twice in each cycle, and it drops to zero twice in each cycle.

Let us see how we measure ac. When we talk about a dc current and we say that the current flowing in the circuit is 1 amp, we mean that a certain number of electrons are flowing past a given point in the circuit. This same number of electrons continues to flow as long as the current in the circuit is 1 amp. However, what happens when we're dealing with ac? Since the voltage reaches a maximum twice each cycle and falls to zero twice each cycle, the current must also have two maximums in each cycle and fall to zero twice each cycle. Therefore, the number of electrons flowing in the circuit is not constant; in fact it is continually changing as the ac voltage goes through its cycle.

To overcome this difficulty, we measure ac in terms of equivalent dc. When we say that the ac current flowing in the circuit is 1 amp, we mean that the current is the equivalent of 1 amp of dc. In other words, if a dc current of 1 amp flows through a heating element such as found in an electric iron or toaster, a certain amount of heat will be produced. When the ac current flowing through the same heating element produces the same amount of heat, we say that the ac current is 1 amp.

The same system is used to measure ac voltage. If a dc voltage of 100 volts is required to force the current of 1 ampere through a circuit made up of a resistance, the ac voltage that will force an ac current of 1 amp through the same resistance is said to be 100 volts. This is called the ***effective*** or ***rms voltage*** and it will cause an ac current to flow that will produce the same heating effect as the equivalent amount of direct current.

From looking at an ac voltage cycle, it is quite obvious that the voltage must be greater than the effective value during part of the cycle and less than the effective value during the remainder of the cycle. The maximum value that the ac voltage reaches during a half cycle is called the ***peak voltage***. The peak voltage is approximately 1.4 times the effective voltage. Each peak is 1.4 times the effective voltage, and the voltage between the two peaks will be 2.8 times the effective voltage. This voltage is called the ***peak-to-peak voltage***. Fig. 19 shows an ac voltage of 100 volts. The peak value is 140 volts, and the peak-to-peak value 280 volts. Study this figure to be sure you understand what the terms mean.

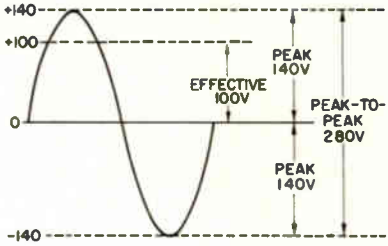

Fig. 19. AC waveform showing effective (rms), peak and peak-to-peak voltages.

It's important to remember when we are talking about ac voltages that unless we specifically refer to the peak or peak-to-peak voltages, we are talking about effective voltages; in other words, the ac voltages that will produce the same effect as the equivalent dc voltage. Also remember that the peak or greatest voltage reached during a half cycle will be 1.4 times as great as the effective voltage, and that the peak-to-peak voltage will be 2.8 times the effective voltage. You will run into the terms "peak voltage" and "peak-to-peak voltage" as well as the expression "effective voltage" many times during your career in electronics. Knowing the peak value of an ac voltage is often very important.

A good example of how high the peak voltage in a circuit may be is the voltage supplied in most homes in this country. The average power company supplies a voltage somewhere between 115 and 120 volts, 60 Hertz ac for lighting and general domestic uses. This is the effective value of the voltage. Let us assume that the voltage supplied to your home is exactly 120 volts. What is the peak voltage reached during each half cycle? It will be 1.4 X 120, which is 168 volts. In other words, twice during each cycle the actual voltage between the two power leads connected to each electric light and appliance in your home reaches a value of 168 volts. Twice during each cycle the voltage also drops to zero.

The net effect of this ac voltage is the same as supplying a dc voltage of 120 volts to the electric lights. The peak-to-peak voltage supplied to your home will be 2.8 X 120 volts or 336 volts!

THE IMPORTANCE OF AC

You may wonder why we have gone into so much detail in describing alternating current. Alternating current is important not only because it is the type of power supplied by the power companies, but also because ac signals are used throughout the whole electronics industry. The sound that comes from the loudspeaker in your radio or your television receiver and the sound from your telephone are produced by ac signals having a frequency not too much higher than the power line frequency. The radio waves that travel through space are actually ac signals of a much higher frequency. Signals used in many industrial applications are ac signals.

SUMMARY

We have covered a great deal of material in the preceding sections. There are several important things that you should remember. First, remember what an ac cycle looks like. Also remember that this ac voltage is called a sine wave.

Remember that when we speak of ac voltage and current we are speaking of the voltage and current that will produce the same effect as the equivalent values of dc. Remember that the peak value of the ac cycle is 1.4 times the effective value, and the peak-to-peak value is 2.8 times the effective value.

SELF-TEST QUESTIONS

(k) What are the two kinds of current that the electronic technician must know about?

(l) What do we call the voltage that produces a current that flows in only one direction?

(m) What is the name given to a voltage that causes current to flow first in one direction and then in the other direction many times in a second?

(n) What is the name given to the ac voltage wave supplied by the power company?

(o) What is a cycle?

(p) What do we mean by 60 cycles per second (60 Hertz)?

(q) What is the name given to the device on a dc generator that is used to reverse the connections of the coil to produce dc instead of ac?

(r) What type of current is produced by a simple dc generator such as the one shown in Fig. 14?

(s) What do we mean when we say that the ac current is 1 amp?

(t) If we say the ac voltage is 100 volts, do we mean the effective or the peak value of the ac voltage is 100 volts?

(u) If the rms voltage is 200 volts, what is the peak value of the voltage?

Electronics in Communications

Radio waves are sine waves like the one shown in Fig. 13. They are similar to the 60 Hertz ac power waves. The only difference is in the frequency of radio waves. The lowest frequency radio waves have a frequency of about 15,000 Hertz. We usually use kilohertz instead of Hertz when speaking of radio waves around this frequency. -- one kilohertz equals one thousand Hertz. Therefore, 15,000 Hertz is equal to 15 kilohertz (kHz). This is a very low frequency radio signal; there are only a few very high-powered stations operating on such low frequencies. They are used mostly by government services for world-wide communications.

The standard radio broadcast stations operate on frequencies between 550 kHz (550,000 Hertz) and approximately 1,700 kHz (1,700,000 Hertz). This group of frequencies is called a band; in this case, the broadcast band. The word band when it is used this way means nothing other than a group of frequencies.

Needless to say, ac signals of such high frequencies cannot be generated by means of mechanical generators such as those used to produce 60-cycle power voltages and current. These ac signals must be generated by electronic devices such as vacuum tubes and transistors.

We mentioned that the frequency of radio signals is often expressed in kilohertz rather than in Hertz. A kilohertz is equal to 1,000 Hertz. However, many broadcast services operate on such high frequencies that even the kilohertz is not large enough to provide a convenient method of expressing their frequency; so in addition to the kilohertz we use the megahertz. The megahertz is 1,000,000 Hertz and it is abbreviated MHz. There are 1,000 kilohertz in a megahertz. The standard broadcast band is 550 kHz to 1700 kHz. This can also be expressed as .55 MHz and 1.7 MHz. TV stations operate up in the megahertz region. Channel 2, the lowest TV channel, occupies the band of frequencies from 54 MHz to 60 MHz. Channel 13 occupies the band of frequencies from 210 MHz to 216 MHz. These channels are referred to as the vhf (very high frequency) TV channels. The FM broadcast band, which is located between channels 6 and 7, occupies the band of frequencies from 88 to 108 MHz.

TV channels 14 through 83 are referred as the uhf (ultra high frequency) channels. Channel 14 occupies the band of frequencies from 470 MHz to 476 MHz and Channel 83 occupies the band of frequencies from 884 MHz to 890 MHz.

Now let us look at some parts of a radio system. We will briefly describe a radio transmitter and a receiver. Let us look at the transmitter first.

THE RADIO TRANSMITTER

Radio transmitters are actually made up of a number of sections, each designed to do a specific job. Let's discuss some of the more important sections of a typical transmitter.

The sound signal to be transmitted starts in the microphone. There are a number of different types of microphones in use. We will look at one of the simpler types. Before we discuss the microphone, let's learn a little about sound.

Sound is a vibration set up in air or some other medium. The key you strike on a piano is connected to a hammer, which strikes a string that is tightly stretched on a frame. The string begins to vibrate and sets the air surrounding it into vibration. The frequency at which the string vibrates will determine the tone that you hear. Similarly, when we speak, the speech muscles in our throat set the air in our throat into vibration. This vibration is projected from our mouth and nose, and the vibration travels through the air. However, instead of producing a single frequency, our voices are actually quite complex and may produce vibrations of many frequencies, causing the different tones by which we can distinguish the voice of one person from that of another.

Microphones. A simple microphone is shown in Fig. 20. This microphone consists of a coil and a magnet and a flat metal disc which is called a diaphragm. Fastened to the diaphragm is a small light coil form on which a coil is wound. The coil is placed between the poles of a permanent magnet. When you speak in front of the microphone, your voice sets the air into vibration. The vibrating air will cause the diaphragm to vibrate. Since the diaphragm is connected to the coil, the coil will vibrate between the poles of the magnet. You already know what will happen when a coil is moved in a magnetic field; the turns of wire on the coil will cut through the magnetic lines of force, and voltage will be induced in the coil. If this coil is connected to an external circuit, there will be a current flow through the circuit. The frequency of the current will depend upon the frequency at which the diaphragm and coil vibrate. This in turn will depend upon the frequency at which the air is vibrating, which in turn depends upon the vibrations set up by the vocal muscles in the throat of the person speaking in front of the microphone.

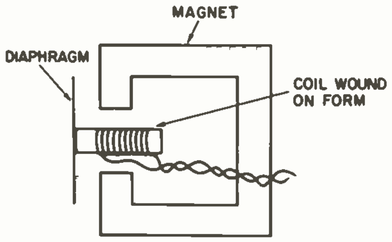

Fig. 20. A simple dynamic microphone.

This electrical signal produced by the microphone is called an audio signal or audio voltage. The word audio is used to designate electrical signals in the frequency range of sound. An audio voltage or signal is the electrical equivalent of sound.

An Audio Amplifier. In a typical transmitter the output of the microphone is fed to an audio amplifier. The audio voltage is fed to a vacuum tube or a transistor that will amplify the signal so that a much stronger signal will appear in the output circuit of the tube or transistor. The amplified signal will be just like the signal generated by the microphone, but it will be stronger. A tube or transistor along with its associated parts is called a stage. A stage used to amplify an audio signal is called an audio stage.

In a typical transmitter, the audio signal produced by the microphone will be amplified by a number of stages in order to build up the strength of the signal until it is hundreds of times stronger than the original signal produced by the microphone. The signal is first fed to one stage where it is amplified and then on to a second stage where it is amplified still further and on to a following stage and so on until its strength has been built up to the desired level. The amplified signal, however, will have exactly the same frequency and characteristics as the original signal produced by the microphone.

The microphone and the audio amplifiers in a transmitter are called the audio section. This is often abbreviated af (audio frequency) section. Another important section of the transmitter is the radio frequency section -- this is abbreviated rf section.

The RF Section. The rf section of a transmitter is made up of a number of separate stages. The first stage is the stage that actually generates the radio frequency signal. This stage is called the oscillator stage. The oscillator stage is carefully designed to produce a signal of the desired frequency. The signal from the oscillator stage is then amplified by additional stages which are called rf power amplifier stages. These stages build up the strength of the radio frequency signals generated by the oscillator so that the signals will be strong enough to travel through space from the transmitter to the receiver.

In one of the radio frequency stages of the transmitter, the audio signal is superimposed on the radio frequency signal. This is called modulation. The audio signal is the modulation signal and the rf signal is the modulated signal.

In a radio system of this type, the modulation signal varies the amplitude or strength of the rf signal. This type of modulation is called amplitude modulation and is abbreviated AM. In some transmitters the modulated signal is then fed directly to the antenna, but in others it is amplified further and then fed to the antenna.

The modulated rf signal from the transmitter is fed through a cable or wire, called a transmission line, to the antenna. The transmission line is something like the power lines that are used to bring the power from the power-generating station to your home. They simply carry the power from the transmitter to the antenna.

The antenna at a radio station is simply a length of wire or a tower to which the transmission line is connected. When the radio frequency signal is fed to the

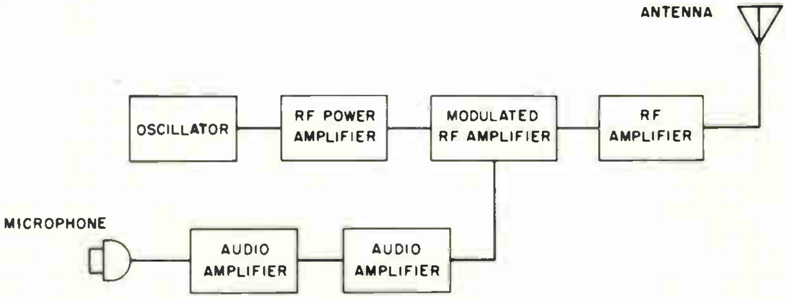

Fig. 21. A block diagram of a simple transmitter.

antenna, the rf signal sets up a current in the antenna which produces a magnetic field and an electric field surrounding the antenna. These fields travel out in space from the antenna and carry the signal from the transmitting antenna to the receiving antenna.

A simplified diagram of a radio transmitting system is shown in Fig. 21. This type of diagram is called a block diagram. It is a simpler way of representing the various stages or sections of a piece of electronic equipment than showing the complete schematic diagram. We will use this type of diagram frequently because it enables us to give an overall picture of the various stages of a piece of electronic equipment without going into all the details of the circuitry. You will find later that the circuits used in the various stages follow certain basic patterns. In other words, there is little difference in the circuits used in the individual stages; the difference is the manner in which the stages are used.

Notice that the sound signal is generated by a microphone and fed to the audio amplifier stages. At this same time the rf signal is generated by an oscillator and amplified by rf power amplifier stages. In the third rf stage, the rf signal is modulated by the audio signal and the modulated signal is then amplified by the last stage in the transmitter. This stage is called the final amplifier or simply the final because it is the last rf amplifier stage in the transmitter. The signal from the final is then fed through a transmission line to the transmitting antenna.

This brief description of Fig. 21 is all you need to know about radio transmitters at this time. However, you should understand in general terms what is done in a transmitter; it will be helpful to you, even though you may never work on a radio transmitter. Notice the symbols used in Fig. 21 for the microphone and the antenna. Remember these symbols; you will see them frequently in future lessons.

THE RECEIVER

The job that the receiver has to perform is exactly the opposite of the job the transmitter has to perform. The transmitter must take the sound and convert it to an electrical signal, which is the audio signal, and then superimpose the audio signal on an rf carrier signal. The receiver must take the rf carrier and remove the audio signal from it and then convert the audio signal back into sound.

In spite of the fact that the receiver must perform the opposite tasks from those performed by the transmitter, there are many similarities between a transmitter and a receiver. A transmitter has rf amplifiers, so do many receivers. The transmitter has audio amplifiers, so do receivers. The transmitter has a stage in which modulation occurs -- the receiver has a stage in which demodulation occurs. Demodulation is sometimes called detection; it is the recovery of the audio signal from the modulated signal. You will see later that there is a great deal of similarity between the operation of the stage in which modulation occurs and the stage in which demodulation occurs. The transmitter has a microphone which converts the sound into an electrical signal; the receiver has a speaker which converts the electrical signal to a sound signal. Even though the microphone and speaker perform opposite tasks, there is a great deal of similarity between the two.

Now let's look at a simple receiver system. Modern receivers are somewhat more complicated than the one we will describe, but nevertheless millions of receivers like this one have been made.

The Antenna. The radio receiving antenna is a much simpler device than the transmitting antenna. The signals transmitted by modern broadcast transmitters are so strong that only simple receiving antennas are needed. A simple outside antenna may be made from a wire 25 to 50 feet long mounted between two poles. Most modern radio receivers do not need any outside antenna at all. An indoor antenna made of a coil wound on a powdered iron core is called a ***loopstick***. It is mounted in the rear of the receiver, inside of the receiver cabinet. This is all the antenna that is needed to provide satisfactory reception on local broadcast stations. A loopstick mounted in the rear of a receiver is shown in Fig. 22.

The RF Amplifier. The signal picked up by the receiving antenna is quite weak even if the station being received is a fairly strong local station. Before the signal can be used it must be amplified. This amplification is usually carried out in a stage called an rf amplifier. It is quite similar to the rf amplifier in a transmitter, except it is called an rf voltage amplifier (in a transmitter it is called an rf power amplifier). The rf amplifier in the receiver is designed to increase the strength of the signal voltage picked up by the antenna.

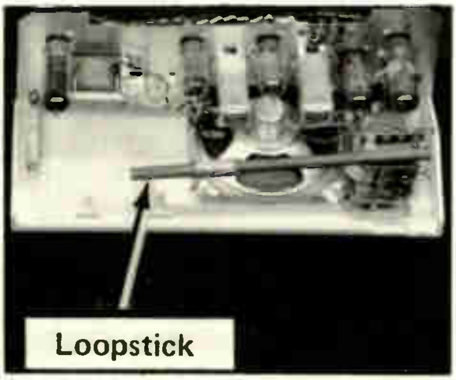

Fig. 22. Loopstick mounted in the rear of a receiver.

The Demodulator. The amplified signal from the rf amplifier is fed to a stage called the demodulator or detector. This stage separates the audio signal from the rf signal. The rf signal is called the carrier; it carries the audio signal from the transmitter to the receiver. However, it serves little or no useful purpose in the receiver. In the detector stage, the rf signal is separated from the audio signal. The rf signal is discarded so that the signal at the output of the detector is an audio signal. This audio signal is exactly like the audio signal that was originally produced by the microphone in the transmitter.

The Audio Amplifier. The signal at the output of the detector is still a weak signal. Before it can be used to operate a loudspeaker, the strength of this signal must be increased. It is increased by feeding the signal to an audio amplifier, which is similar to the audio amplifier in a radio transmitter. The signal at the output of the audio amplifier is identical to the signal at the input, but much stronger.

The Speaker. A speaker is not very different from a microphone. In fact, sometimes speakers are used as microphones in intercommunications units such as between two offices.

A sketch of a simple speaker is shown in Fig. 23. Notice that the speaker has a magnet like the microphone. Between the poles of the magnet is a coil, and the coil

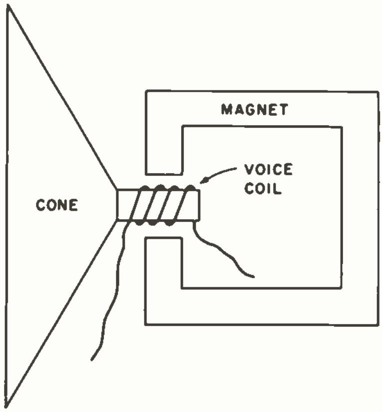

Fig. 23. A simple pm dynamic speaker.

is connected to a diaphragm. However, instead of having a flat diaphragm as in the microphone, the diaphragm is cone-shaped and in a speaker it is called the cone. The cone is fastened to the coil.

When the varying current from the audio amplifier is fed to the coil in the speaker, a varying magnetic field is produced. Depending on the polarity of the field produced by the current flowing in the coil, the field may either aid or oppose the magnetic field produced by the permanent magnet. Since the audio signal is being fed to the speaker, it is actually an ac signal. The polarity of the magnetic field produced by the coil will sometimes aid and sometimes oppose the permanent magnet field. This varying effect will cause the coil to vibrate in and out. Since the coil is fastened to the cone, the cone will vibrate in and out with the coil. The rate of vibration will depend upon the frequency of the audio signal.

The vibrating cone will set the air in front and in back of the cone in motion. The air will vibrate at the same frequency as the cone vibrates. Since the cone is vibrating at the frequency of the original sound signal produced by the microphone, the air around the speaker will be set into vibration at the same frequency. The effect of setting this air into vibration is exactly the same as setting the air into vibration with your vocal chords by speaking. The vibration will be heard as sound, and the sound will be at the same frequency and tone as the original sound that was first uttered in front of the microphone.

The operation of modern speakers is similar to that of the speaker shown in Fig. 23. This type of speaker with a moving coil is called a dynamic speaker. Modern dynamic speakers have a permanent magnet like the one we have shown, and this type is called a permanent magnet dynamic speaker and is usually abbreviated simply a pm speaker. Another type of dynamic speaker uses an electromagnet instead of a permanent magnet. This small coil placed between the poles of the magnet is called the voice coil. Usually the voice coil is wound on a small lightweight form.

The magnets used in pm speakers are strong permanent magnets made of alnico. You will remember that alnico is an alloy of aluminum, nickel, and cobalt which can be used to make extremely strong permanent magnets.

TELEVISION

The transmission and reception of a television signal is not very different from that of a radio signal. However, in television there are two signals to be taken care of, the sound signal and the picture signal. To transmit these two signals through the air, two rf carriers are needed, a picture carrier and a sound carrier. The sound signal in television is called the audio signal as it is in radio and the picture signal is called the video signal.

The sound signal is picked up by a microphone, fed to audio amplifiers and then used to modulate the sound carrier. However, in television, instead of varying the amplitude of the carrier, the frequency of the carrier is varied. This is called frequency modulation and is abbreviated FM. Some radio stations also use this type of modulation. They are called FM stations.

The picture is picked up by a camera that contains a set of lenses similar to the lenses used in a camera that takes photographs. The lenses project the picture on the face of a special tube called a camera pickup tube. This tube has a specially treated face plate on it and the light striking it produces a small voltage. The brighter the light, the more voltage produced. The pickup tube produces a video signal that varies in amplitude with the brightness of the different parts of the picture. The video signal is something like an audio signal; however, it is the electrical equivalent of the picture.

In a color television system, in addition to the signal that contains the brightness information, a color signal is developed, and this signal contains the color information. In other words, the video signal contains the information that tells how bright different parts of the picture are, and the color signal tells what color they are.

The video signal at the output of the pickup tube is fed to a stage called the video amplifier stage where the signal is amplified. In a transmitter, the video signal will be amplified by several video amplifiers. Similarly, in a color TV system, the color signal is amplified by color amplifiers. The color signal is then used to modulate an oscillator which is called a subcarrier oscillator, and this signal is combined with the video signal. The video signal and the color subcarrier signal are then used to amplitude-modulate an rf carrier. Amplitude modulation is used; this is the same type of modulation that is used in the standard radio broadcasting band.

Thus the TV transmitter, instead of transmitting only one rf signal, must actually transmit two rf signals, one to carry the sound signal and the other to carry the video signal along with the color signal if the broadcast is in color. The two signals from the transmitter are fed to a single antenna.

At the receiving installation, the two signals are picked up by one antenna, amplified by rf amplifiers and then separated from the rf carriers by separate detectors, one for the video and the other for the sound. In the case of a color television receiver, the video signal and the color subcarrier are separated from the video carrier and the color signal is then separated from the color subcarrier by a color detector.

The sound signal from the detector is amplified and fed to a speaker. The video signal is amplified and fed to the picture tube. In a black and white TV receiver the picture tube brightness is controlled by the video signal. In a color television receiver the brightness is controlled by the video signal which is mixed with the color signal to produce the original colors picked up by the camera.

This is only a brief run through of a

television transmitter and receiver. There are many details that have been simplified, many more that have been omitted, but you need not be concerned about them at this time. Keep in mind that the operation of the video portion of a TV transmitter is not very different from that of the audio portion of the transmitter. There are many differences in details, but the basic principles are the same.

SUMMARY

This brief description of a broadcasting system gives you a birdseye picture of what happens in a radio transmitter and a radio receiver. We do not expect you to remember the details at this time, but having a general idea of what takes place will help you with later lessons. Remember that an rf stage amplifies a radio frequency signal and that an audio stage amplifies an audio signal. Remember what an rf signal is, what an audio signal is and what a video signal is. You should also remember that the stage that separates the audio signal from the rf carrier and the stage that separates the video signal from the rf carrier are both called detector stages. You should remember the basic principles of the operation of a microphone and a speaker and also the schematic symbols for a microphone and an antenna.

SELF-TEST QUESTIONS

(v) How many kilohertz are there in a megahertz?

(w) Write 1900 kHz in megahertz.

(x) What is the name given to the electrical signal produced by sound striking a microphone?

(y) What is an audio stage?

(z) What is the name given to the stage in a transmitter that actually generates the radio frequency signal?

(aa) What is the name of the device used to feed an rf signal from the transmitter to the antenna?

(ab) What is the name given to the stage that separates the audio signal from the rf carrier?

(ac) What is the name of the small coil placed between the poles of the magnet in a speaker?

(ad) What are the names of the two signals that must be transmitted in a black and white television system?

(ae) What type of modulation is used in the sound section of a TV transmitter?

(af) What type of modulation is used in the video section of a TV transmitter?

Electronics in Industry

We have already mentioned that there are many uses for electronics in industry and that the number of applications is growing daily. Electronics is used in oil refineries to control the various steps in the refinement of crude oil. It is used in the livestock feed industry to control the mixing of grains and the preparation of feed for farm animals. It is used in the factories to control the operation of precision machines, to inspect the finished product coming off the assembly lines and to count the output of high-speed automatic machines. It is used by railroads to automatically guide loaded and/or empty cars in switching operations and to control the speed of the car so that it hits the cars already standing on the track at just the right speed to couple to the car without damaging the cars or their contents. We have all been thrilled in the past few years by the amazing feats performed by space ships sent to the moon to take television pictures of the moon, by the launching and orbiting of the ships and recovery of the astronauts. All these phenomenal feats have been possible due to many electronic devices at the control stations and aboard the space ships. In spite of all the advances we have made, the chances are that in the next ten years we will see even greater advances and even more opportunities in the field of electronics.

CHANGING AC TO DC

One of the important uses of electronics in industry is converting ac to dc. This can be accomplished by large electronic tubes designed for this type of service and by solid-state devices.

It is much more convenient to generate and transmit ac than it is dc. The reason for this is that ac can be transmitted at very high voltages. The higher the voltage is for a given amount of power to be transmitted, the lower the losses in the transmission lines will be. AC voltages can be conveniently increased or decreased by means of a transformer, whereas dc voltages cannot be changed from one value to another conveniently.

The Transformer. You have already briefly studied a simple transformer. A transformer consists of two coils wound on a common core. In the preceding lesson you learned that if a battery was connected to one winding and a switch inserted into the circuit and the switch opened and closed rapidly, the changing magnetic field set up in the one winding would induce a voltage in the second winding.

We call the winding to which the battery is connected the primary winding and we call the other winding the secondary winding. These names are easy to remember; remember that primary is first, and secondary is second.

If instead of a battery and switch, we connected ac voltage to the primary winding on the transformer, the ac voltage will cause an alternating current to flow in the primary winding. When the alternating current flows in one direction it will build up a magnetic field and the changing lines of force, as the field is built up, will cut the turns of the secondary winding and induce a voltage in these turns. As the ac current collapses and then begins to flow in the opposite direction, the magnetic field being produced will be continually changing. As the field builds up in the opposite direction, a voltage of the opposite polarity will be induced in the secondary winding.

The voltage that will be induced in the secondary winding will depend upon how many turns there are on the secondary winding. If the secondary winding has the same number of turns as the primary winding, the voltage induced in the secondary will be equal to the voltage applied to the primary. If the secondary winding has twice as many turns as the primary winding, the voltage induced in the secondary will be twice the voltage induced in the primary. A transformer of this type is called a step-up transformer because it steps the voltage up to a higher value. On the other hand, if the secondary winding has only half as many turns as the primary, the voltage induced in the secondary will be only half the voltage applied to the primary. This type of voltage is called a step-down transformer because it steps down the voltage.

Thus by means of a step-up transformer an ac voltage generated by a generator can be stepped up to a very high value. It can then be transmitted to a distant point by means of high-voltage transmission lines and at that point stepped down by means of a step-down transformer. This is why it is more convenient to transmit alternating current than direct current.

Alternating current is changed to direct current by means of rectifiers. A rectifier is a device that will let current flow through it in one direction, but will not let it flow through it in the opposite direction. You will learn about tube rectifiers now and about other types later.

Half-Wave Rectifiers. A half-wave rectifier is a device that will allow current to flow during only one half of each cycle. Remember that the ac cycle we looked at before in Fig. 13 had a positive half and a negative half. A half-wave rectifier can be connected to allow current to flow either during the positive half or during the negative half of the cycle, but it will not let current flow during both halves of the cycle.

A schematic diagram of a half-wave rectifier circuit is shown in Fig. 24. You are already familiar with the schematic symbols used on this diagram. T_1 and T_2 are iron-core transformers, and V_1 is a tube with a filament and a plate. Notice that the tube is drawn upside down. You will find them drawn in any position on schematic diagrams, but the pointed symbol is always the filament and the straight line is the plate. On the schematic diagrams the dots where several connecting lines meet indicate a connection. The crossovers without a dot indicate that there is no connection.

Now let us study Fig. 24. The ac power from the power line is fed to the primary

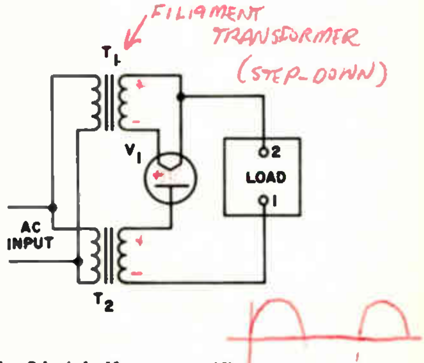

Fig. 24. A half-wave rectifier circuit.

winding of the transformers marked T_1 and T_2. T_1 is a step-down transformer. The winding on this transformer provides the voltage necessary to heat the filament of the diode tube. This transformer is often called a filament transformer because it supplies the power required to heat the tube and serves no other useful purpose in the circuit.

Transformer T_2 may be either a step-up or step-down transformer depending upon the dc voltage required by the load. If the dc voltage needed is higher than the power line voltage, a step-up transformer is used, whereas if it is lower, a step-down transformer is used. The block marked "load" on the diagram represents whatever is going to use the dc power produced. This might be a number of storage batteries we are charging, or it could be a bath which is being used to refine copper or aluminum in a refinery. You will see the word load used frequently in this way.

Now let us see how the half-wave rectifier works. Refer to Fig. 25 as you read the explanation. We have simplified the figure by leaving out the filament transformer T_1 and the primary winding of T_2. The filament transformer T_1 heats the tube filament, but does not enter into the operation of the rectifier in any other way.

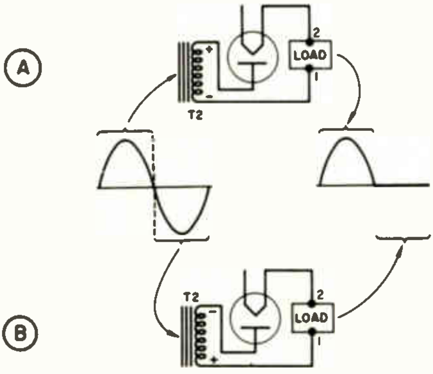

Fig. 25. How a half-wave rectifier works.

Looking at Fig. 25A we see the first half cycle which is the positive half cycle. At the left of the drawing we see the ac voltage across the secondary of T_2. In the center we see the polarity of the voltage across the secondary of T_2 and at the right we see the voltage that will appear across the load. The voltage will cause a current flow through the load. During this half cycle, the end of the secondary winding of T_2 which is connected to the plate of the diode tube is positive and the other end is negative. When this happens, current will flow from the lower end of the transformer winding to terminal 1 of the load, through the load to terminal 2 and to the filament of the tube. You know that the red-hot filament will emit or give off electrons. These electrons will be attracted to the plate of the tube by the positive voltage on the plate. Therefore, the electrons will flow from the filament to the plate of the tube to the positive end of the transformer. Since this is a complete circuit, current can flow.

However, when the polarity of the voltage across the secondary of T_2 reverses, we will have the negative half cycle shown in Fig. 25B. The polarity of the secondary of T_2 is shown. Notice that the end of the secondary winding connected to the plate of the tube will be negative and the other end will be positive. Now let us see how current will have to flow during this part of the cycle.

You will remember that current flows from the negative terminal of the voltage source through the external circuit and back to the positive terminal of the source. This means the electrons will have to flow from the negative end of the secondary winding of the transformer to the plate of the tube. They could do this, but then they would have to flow from the plate of the tube to the filament. However, there is no way the plate can give off electrons. Furthermore, electrons will not flow from the filament of the tube to the plate because they will be repelled by the negative voltage on the plate. The plate will be negative because the side of the transformer it is connected to is negative during this half cycle. Since electrons cannot get across the tube there is no complete circuit and, therefore, there will be no current in the circuit.

The current in a half-wave rectifier of this type will look like the drawing in Fig. 25. Notice that during the first half of the cycle when the plate is positive there will be current through the circuit. During the next half cycle when the plate is negative there is no current. This chain of events will continue so that during the third half cycle when the plate becomes positive again, current will flow and then during the fourth half cycle again there will be no current. The current will flow in pulses, with one pulse for each cycle. Again, this type of dc is called a pulsating dc and the rectifier is called a half-wave rectifier because it rectifies only one half of each cycle.

In a practical circuit the need for two transformers can be avoided by putting two secondary windings on one transformer. One winding as a step-down winding provides the voltage needed to operate the filament of the rectifier tube. The other winding may be either a step-up or a step-down winding depending upon the dc voltage required by the load.

SILICON RECTIFIERS

In many applications silicon rectifiers have replaced diode tubes. The advantage of a silicon rectifier is that it does not have a filament and hence does not use any power to heat the filament such as a tube does. In addition, silicon rectifiers are quite small and can pass rather large currents for their size. They have an additional advantage in that there is very little voltage lost across the rectifier, whereas in a tube there will be some voltage lost across the tube. A silicon rectifier is made of two different types of silicon placed together to form a junction. This junction will permit current to cross it in one direction, but will not permit it to cross in the other. In the forward direction there is practically no resistance in the junction and therefore the current flows freely in that direction. In the reverse direction, the junction offers such a very high resistance that practically no current crosses it.

A schematic diagram of a half-wave rectifier using a silicon rectifier is shown in Fig. 26. The arrows indicate the

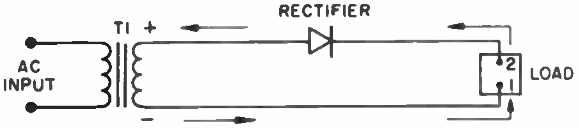

Fig. 26. A half-wave rectifier using a silicon rectifier.

direction in which current will flow during the half cycle the rectifier passes current.

Notice that the arrows indicating the direction of current flow point in the opposite direction to the arrow used as part of the symbol in the silicon rectifier. The reason for this is that the symbol dates back to the early days of electricity when engineers and scientists thought that current flowed from the positive terminal of a battery or generator through the load and back to the negative terminal. Hence the symbol was drawn with the arrow indicating this direction of current. Now we know that current flows in the opposite direction, but the symbol has been carried over to indicate a solid-state rectifier such as a silicon rectifier and the arrow points in the wrong direction. Remember this symbol, it is used to represent all types of solid-state devices that will permit current flow in only one direction. It is used to represent detectors made out of germanium which can be used in radio and television receivers; it is used to represent selenium rectifiers which are another type of solid-state rectifier; and it is used to represent copper-oxide rectifiers which are used in meters. You will learn more about these devices later. They are often called diodes because there are two types of material used in them.

SUMMARY

At this time you need not remember all the details of how a rectifier operates. However, you should remember that a rectifier is a device that will permit current to flow through it in only one direction. By using a rectifier, alternating current can be changed to pulsating direct current. Remember that a half-wave rectifier rectifies only half of each cycle so that you'll get a pulse during one half cycle and no current during the next half cycle.

SELF-TEST QUESTIONS

(ag) What is the name given to a transformer where the secondary voltage is higher than the primary voltage?

(ah) If a transformer has fewer turns on the secondary winding than it has on the primary winding, will the secondary voltage be equal to, greater than or less than the primary voltage? What is the name given to this kind of transformer?

(ai) In a half-wave rectifier circuit, in which direction will current flow through a diode tube?

(aj) What must the polarity of the voltage on the plate of a diode rectifier tube be in order for current to flow in a half-wave rectifier circuit?

(ak) Draw the schematic symbol for a silicon rectifier and by means of an arrow above it indicate in which direction the current will flow through the rectifier.

(al) When two connecting lines cross and there is a dot placed on the junction, what does this indicate?

Electronics for Computers

Almost all of the electronic circuits used in communications equipment, industrial applications and in computers operate from direct current. While this dc could be obtained from a set of batteries, most often it is obtained from a power supply that consists of a power transformer and rectifier similar to that discussed in the previous section. The transformer takes the ac line voltage and steps it up or down to the required voltage level. The rectifier then converts this ac into a pulsating dc. This pulsating dc is then fed through a filter circuit to smooth it into a clean pure dc signal very similar to that obtained from a battery. The resulting dc voltage is then used to power the various electronic circuits used in communications, industrial and computer equipment.

The sine wave is the basic electrical signal used in communications and industrial electronic equipment. In communications equipment, oscillator circuits are used to generate a sine wave signal and produce a carrier signal that is radiated by the transmitter and detected by the receiver. In computer circuits, however, the sine wave is not the basic electrical signal. Computers use another class of signals known as pulse signals. Let's take a look at some of these interesting signals and see how they are produced and used in computers.

PULSE SIGNALS

A pulse signal is an electrical voltage or current that switches rapidly from one voltage level to another and back again. A simple pulse signal is shown in Fig. 27. Notice that this signal switches rapidly from a zero volt level to a 10 volt level and then back again to zero, repeating itself periodically. The resulting wave shape of this signal is approximately square and, therefore, this pulse signal is often referred to as a square wave or more generally as a rectangular wave. This signal is basically a pulsating dc signal similar to the output of the half-wave rectifier you studied in the previous section. The difference between this signal and the rectifier output is the wave shape.

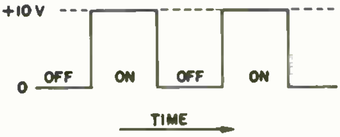

Fig. 27. A simple pulse signal.

A pulse signal like this is relatively easy to generate. In fact, we could generate it very simply with the battery and switch circuit shown in Fig. 28. When the switch is open, or off, no voltage appears between points A and B. However, when we close the switch or turn on the circuit, the battery voltage appears between points A and B. If we turn the switch off

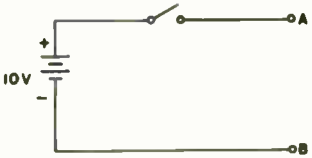

Fig. 28. One means of generating a square wave.

and on at a rapid rate, it will produce a square wave similar to that shown in Fig. 27.

While pulse signals are sometimes produced with a circuit as simple as that shown in Fig. 28, they are usually produced by electronic circuits known as multivibrators. A multivibrator generates a very fast high frequency square wave whose frequency, amplitude and pulse width can be varied over wide ranges.

Any pulse signal is usually specified by these three characteristics: frequency, amplitude and pulse width. Frequency is the rate at which the pulses occur. The amplitude of the pulse is the amount of voltage or current that it represents when it is "on". Pulse width designates the amount of time that the pulse is "on".

There are a wide variety of different pulse signals that you may encounter in computers and in other electronic equipment. The signal in Fig. 29A is a rectangular wave that switches from 0 to +5 volts. This signal is similar to that shown in Fig. 27 with the exception that the amplitude of the voltage is less and the off and on times are unequal. It is quite common to have unequal off and on periods in a pulse signal. Here we show the on period being longer than the off period. However, just the opposite could be true in another waveform.

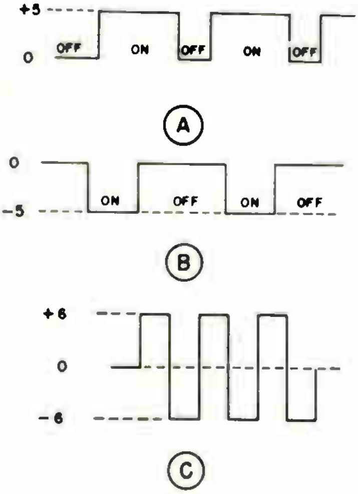

Fig. 29. Some different types of rectangular pulses. (A) unequal on-off times; (B) negative going pulses; (C) an ac square wave.

Fig. 29B shows another rectangular waveform where the voltage switches from 0 volts to –5 volts. It is easy to generate either positive or negative voltage signals with pulse circuits.

In Fig. 29C we show yet another type of pulse circuit that switches between two voltage levels, +6 volts and –6 volts. This type of pulse signal is really an ac signal since it produces an alternating current. When the pulse is positive, the voltage will cause electrons through a circuit to flow in one direction. When the voltage is negative, electrons will flow through the circuit in the opposite direction.

The pulse waveforms we have shown here are typical of what you might encounter in computer equipment but other variations are possible. Pulse signals like these are also used in television, telemetry and communications equipment. Just keep in mind the basic fact that a pulse signal usually switches rapidly between two voltage or current levels rather than varying smoothly and continuously like a sine wave does.

LOGIC CIRCUITS

There is a special class of electronic circuits known as logic circuits that are used to process or manipulate the pulse signals you have just studied. Such cir-

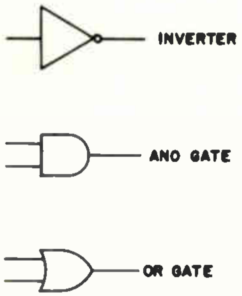

Fig. 30. The three basic digital logic circuits.

cuits are also referred to as digital circuits. The three basic logic circuits are the inverter, the AND gate, and the OR gate. The symbols representing these three basic digital circuits are shown in Fig. 30. Let's see how these circuits work. All of these circuits operate on pulse signals similar to those shown in Fig. 27 and 29.

An inverter circuit does exactly what it says, it inverts a pulse signal so that the inputs and outputs are going in opposite directions. We say that the signals are complements of one another. For example, if a pulse switching from +5 volts to 0 volts is applied to the input of an inverter as shown in Fig. 31A, the resulting output will be a signal that switches from 0 to +5 volts at the output. A positive-going pulse at the input to an inverter produces the negative-going pulse on the output.

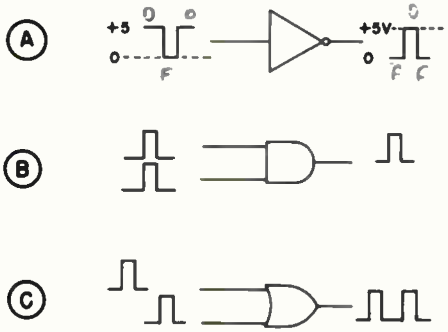

Fig. 31. (A) inverter operation; (B) AND gate operation; (C) OR gate operation.

An AND gate is a logic circuit that produces an output pulse if two or more pulses are applied to its inputs simultaneously. See Fig. 31B. An AND gate can have two or more inputs and a single output. The gate does not produce an output signal unless input signals are applied to all of its inputs simultaneously. If an input signal occurs on only one of the input lines, no output pulse will be produced. The AND gate is commonly referred to as a coincidence gate since it produces an output only when the two inputs are coincident in time.

Fig. 31C shows how the OR gate works. The OR gate also has one output and can have two or more inputs. It produces an output any time a pulse occurs on any of its inputs. In Fig. 31C we show two pulses occurring at different times at the two inputs. An output pulse is produced for each of the input pulses.

Any digital logic function can be performed by just these simple circuits. More complex operations than those described here are performed by combining these three circuits. Any digital computer is made up of nothing but a large quantity of these three basic types of circuits. A digital computer or other large digital system may be very complex. However, if you understand the operation of the three simple circuits discussed here, you can easily learn how the more complex systems work. This is true, of course, of any piece of electronic equipment. If you learn how the basic simple circuits such as oscillators, amplifiers and power supplies work, you will then be able to understand more complex pieces of equipment. In your NRI lessons to come, you will study these important fundamental circuits to prepare you for more complex equipment.

Now answer the self-test questions on this section and then do the lesson questions. Remember that if you have difficulty with the self-test questions it is an indication you need to go over the section again. Do not hesitate to spend any time you need to review. Learning the basic fundamentals you are studying now is the most important part of your course. If you understand these fundamentals, you will be able to build on them in later lessons and you will find that as you go on your course becomes easier and easier. On the other hand, if you do not master the fundamentals covered in the early lessons you will find it difficult to grasp some of the ideas presented in later lessons.

SELF-TEST QUESTIONS

(am) What is the main difference between a pulse signal and a sine wave signal?

(an) Name three characteristics by which a rectangular pulse signal is usually specified.

(ao) Which type of logic circuit produces an output pulse if input pulses occur on either of its two inputs?

(ap) True or False? A pulse signal can be either ac or pulsating dc.

Answers to Self-Test Questions

(a) 1-1/2 volts.

(b) 22-1/2 volts. Each cell has a voltage of 1-1/2 volts and since there are fifteen cells, the voltage will be 1-1/2 × 15 = 22-1/2 volts.

(c) 1-1/2 volts. When cells are connected in parallel the voltage of all the cells must be equal and the total voltage of the cell will be equal to the voltage of one cell. Connecting cells in parallel does not increase the voltage -- it increases the current capabilities of the battery.

(d) +4-1/2 volts. The battery will be marked essentially the same as the battery in Fig. 4. Since one terminal is marked with a – sign, we consider this terminal as the reference point. The center tap has three cells between it and the reference point and therefore the voltage will be 4-1/2 volts. It will be marked + to indicate that this terminal is positive with respect to the negative terminal.

(e) A longer shelf life and a higher current capacity.

(f) 1.35 volts or 1.4 volts, depending upon the materials used in the mercury cell.

(g) 1.5 volts. The output voltage of a manganese cell is approximately the same as the output voltage of a dry cell.

(h) The manganese cell has not replaced the dry cell because it is more expensive than the dry cell, so in many cases the economy of the dry cell overrules the advantages of the manganese cell.

(i) The lead-acid cell and the nickel-cadmium cell.

(j) The nickel-cadmium cell provides longer life and more maintenance-free performance than the lead-acid cell because it can be sealed and hence water does not escape from it when it is charged.

(k) Direct current and alternating current.

(l) DC voltage.

(m) AC voltage.

(n) The voltage wave supplied by the power company is called a sine wave.

(o) The waveform shown in Fig. 13B represents one cycle. In a cycle of alternating current, the voltage between the two terminals of the generator starts at zero and then builds up to a maximum value with one polarity and then drops back to zero; it then builds up to a maximum value with the other polarity and then drops back to zero. During the next cycle it will simply repeat the first cycle.

(p) 60 cycles per second means that we have 60 complete cycles in a second. This means that the voltage starts at zero, builds up to a maximum with one polarity, drops back to zero, builds up to a maximum value at the opposite polarity and drops back to zero a total of sixty times in a second.

(q) A commutator.

(r) A simple dc generator such as shown in Fig. 14 would produce a pulsating dc such as shown by the waveform in Fig. 16. A pulsating dc of this type is normally not desired and the excessive pulsating can be eliminated by means of an armature such as shown in Fig. 17. In this armature a number of series-connected coils are used and a more even dc is produced.

(s) When we say that the ac current is 1 amp we mean that the ac current is the equivalent of 1 amp of direct current. In other words, if an ac current of 1 amp is flowing through the coils of a heater, it will produce the same amount of heat as a dc current of 1 amp flowing through the same coils would produce.

(t) When we give an ac voltage and do not specifically mention that it is the peak value, we always assume that the value is meant to be the effective or rms value of the voltage. If we want to give the peak value of an ac voltage, we should specifically state that it is the peak value, otherwise it would be assumed to be the effective or rms value.

(u) 280 volts. The peak value of an ac voltage is 1.4 times the rms value. Thus if the rms value is 200 volts, the peak value will be: 200 X 1.4 = 280 volts.

(v) There are 1,000 kilohertz in one megahertz.

(w) 1900 kHz = 1.9 MHz.

(x) An audio signal.

(y) An audio stage is a stage designed to amplify an audio signal. The stage may consist of a tube and a number of components or it may consist of a transistor and a number of components.

(z) The oscillator stage.

(aa) The transmission line.

(ab) A detector stage or a demodulator stage. Both names are used.

(ac) A voice coil.

(ad) The audio signal which carries the sound information and the video signal which carries the picture information.

(ae) Frequency modulation (FM) is used in the sound section of a TV transmitter.

(af) Amplitude modulation (AM) is used in the video section of a TV transmitter.

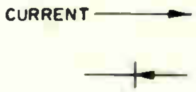
(ag) A step-up transformer.

(ah) Less than; a step-down transformer.

(ai) Current flows from the filament or cathode to the plate.

(aj) The plate must be positive.

(ak)



(al) It indicates a connection between the two circuits.

(am) A pulse signal switches abruptly from one voltage level to another while a sine wave varies smoothly or continuously between its two peak levels.

(an) Frequency, amplitude and pulse width.

(ao) An OR gate.

(ap) True.

YOU'VE GOT COURAGE

An eight year old boy was discussing arithmetic with a friend. Said Johnny: "Teacher's gonna start us on subtraction tomorrow; wish I could stay home." But Harry laughed outright at Johnny's fears, and said; "Aw, I've had that and it's easy once you get started; what I'm worrying about is multiplication!"

It is natural even for grown men to feel like these boys – to fear most the things about which they know the least.

Did you know that some of the world's best speakers are always afraid when they get up to make a speech before a strange audience? Their courage gets them started, and in no time at all their fear changes to a confident enthusiasm which makes their talk a big success.

You've got courage! Use your courage to overcome normal fears, to carry you into each new subject and carry you over each difficulty. In no time at all, you will be looking forward to new subjects with intense interest – you will be eager to tackle new problems. Remember that each conquered difficulty brings you one step closer to your goal of SUCCESS IN ELECTRONICS!

CURRENT, VOLTAGE AND RESISTANCE

B103

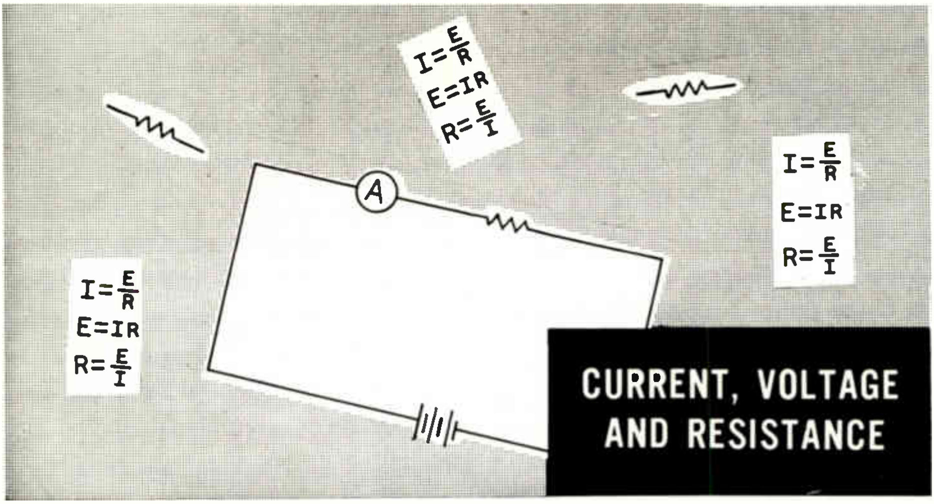
STUDY SCHEDULE

By dividing your study into the steps given below, you can get the most out of this part of your NRI Course in the shortest possible time. Check off each step when you finish it.

☐ 7. Answer the Lesson Questions.

☐ 8. Start Studying the Next Lesson.

PII3M1174 1974 EDITION Litho in U.S.A.



CURRENT, VOLTAGE AND RESISTANCE

Have you ever looked into the back of a color television receiver? If you have, you probably wondered how it would be possible to identify the parts in the set and to trace out the circuits. You may have wondered how an experienced technician can find a defective part among the maze of parts and circuits in the receiver. The technique that he uses is the same as the technique that you are going to learn now. Most of the circuits in a color television receiver or in any other piece of electronic equipment are basically rather simple circuits. The difficulty comes from the fact that so many of them are used together. However, once you learn how to trace simple circuits and understand what is happening in the circuit you will find that you will be able to apply that knowledge to more complex circuits, and also to larger groups of simple circuits when they are used together.

Your first two lessons introduced you to a number of important things in the field of electronics. You learned the important laws of electric and magnetic charges: like charges repel, unlike charges attract. In magnets like fields repel and unlike fields attract. You also learned that an electric current was a movement of electrons. You already know that an electron has a negative charge and that it will be attracted by a positive charge and repel other negative charges.

You learned about direct and alternating currents and studied batteries and generators. You also took a quick look at a broadcast system and learned what is meant by an audio signal and a radio frequency signal.

We will go into more detail later on the various things covered in your first two lessons. These lessons were primarily introductory lessons to get you started. In this lesson we will start going into considerable detail. You will learn that the units of electrical measurement - the volt, the ampere, and the ohm - are in some cases too small and in other cases too large. You'll learn how to convert them into practical sizes when necessary.

You will study simple circuits and learn how voltage, current and resistance are related in these circuits. You will study Ohm's Law; this is a very simple law, but it is probably the most important rule or law in electronics. You will use Ohm's Law over and over again as long as you are in the electronics field.

As you study this lesson, keep in mind that it is perhaps the most important lesson in your entire course. You must understand basic simple circuits thoroughly. If there is anything you do not understand, be sure to go over that section of the lesson several times. If you can't work it out for yourself be sure to write to NRI and ask for help. Our instructors will be glad to help you; they all agree that this is a very important lesson and will do everything they can to be sure that you understand the entire lesson.

Pay particular attention to the self-test questions. These questions will tell you whether or not you have learned all you should have about each section of the lesson as you go along. If you find there is a self-test question you cannot answer, this means you need to restudy that section of the lesson. Don't be afraid to go back and spend whatever extra time may be necessary. A little extra time on this lesson will pay great dividends in later lessons not only in helping you understand these lessons better, but it will also make it easier for you and save time in the long run.

Now let us go ahead and learn more about current, voltage and resistance. We will study current first, then voltage, and finally resistance. In each case, we will review the important points that you already know, and then go ahead and expand that knowledge.

Current

You have already learned that an electron is part of an atom. An electron has a negative electrical charge. All electrons have exactly the same negative electric charge. Electrons repel each other because like charges repel. Electrons are repelled by all negative charges and attracted by all positive charges.

An electric current is the movement of electrons in the circuit. There are two kinds of electric current, direct current and alternating current. Let us discuss direct current first.

DIRECT CURRENT

When a battery is connected to an electric circuit, electrons are repelled from the negative terminal of the battery and attracted by the positive terminal of the battery. Electrons move in one direction through the circuit. This type of current flow is called direct current. We usually refer to it simply as dc.

In a simple circuit such as shown in Fig. 1, it is important for you to remember that the current flow is the same in all parts of the circuit at all times. The number of electrons leaving the negative terminal of the battery is exactly the same as the number of electrons passing point A on the wire connecting the battery to the lamp. The number of electrons flowing through the lamp is the same as the number of electrons passing point B on the other wire, and the same number of electrons are moving into the positive terminal of the battery.

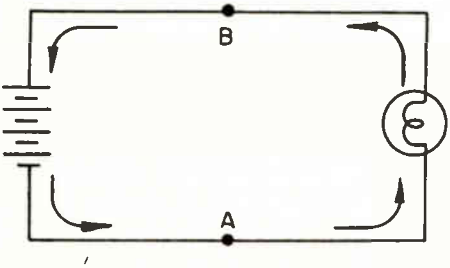


Fig. 1. A simple dc circuit.

Another important point that you must remember about an electric current is that the instant the circuit is closed, the electrons start moving in all parts of the circuit. One electron does NOT leave the negative terminal of the battery, hit another, and so forth, and thus start movement in the circuit after a certain period of time; each electron starts movement immediately the moment the circuit is completed.

The unit of current flow is the ampere which we usually abbreviate amp. A current of 1 ampere represents a certain number of electrons moving past a point in the circuit in a second. If twice as many electrons are moving past that point in the circuit, the current flow is 2 amperes, and if ten times the number of electrons are moving past the point in the circuit, the current flow is 10 amperes.

Direct current is widely used in electronic equipment. Current will flow through a vacuum tube or a transistor in only one direction and therefore the current used to operate these devices is direct current. There are other applications of direct current in industry. Direct current is used in purifying metals, in plating operations and in running some motors that require precise controls. Direct current motors can be more closely controlled than alternating current motors.

ALTERNATING CURRENT

The electric current supplied to homes for lighting, for cooking and operation of small appliances is alternating current. An alternating current flows first in one direction and then in the other direction. The current starts at zero amplitude and builds up to a maximum value which we call the peak value, then drops back to zero, then builds up to a peak value flowing in the opposite direction, and then drops to zero again. This action of flowing first in one direction and dropping back to zero value, then building up to a maximum value in the opposite direction and then once again dropping back to zero is called a cycle. The current supplied by most power companies is 60-cycle current. This means that it goes through 60 cycles per second.

Alternating current is also measured in amperes. However, since the number of electrons flowing past a point in the circuit is continually changing when we have alternating current, we use a somewhat different method of expressing the value of the current. The alternating current is compared to direct current. If the alternating current flowing through a heat-producing device produces the same amount of heat as a direct current of 1 ampere produces, we say that the ac current is 1 ampere. We call this the effective value or the rms value.

The change in amplitude of an alternating current follows a pattern or waveshape which is known as a sine wave. A typical sine wave showing one complete cycle is shown in Fig. 2. In this figure the rms value of the alternating current is 1 amp. As you can see, for part of the cycle the actual current flowing will be less than 1 amp and during part of the cycle it will be greater than 1 amp. The actual peak or highest value that the current reaches is 1.4 × the rms value. In the example shown, where the rms value is 1 amp, the peak value will be 1.4 amps.

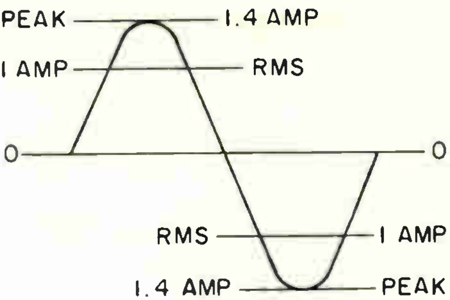

Fig. 2. A sine wave showing rms and peak values.

In the first half cycle, we have drawn the waveshape above the horizontal line representing zero current. This half of the cycle is referred to as the positive half cycle. The other half cycle is referred to as the negative half cycle. Notice, the negative half is exactly the same as the positive half. The current reaches the same rms and the same peak values. We simply call one a positive half cycle and the other a negative half cycle to indicate that the current is flowing in opposite directions during the two half cycles.

To convert rms values of current to peak values you multiply the rms value by 1.4. If you have the peak value of the current and want to convert it to the rms value, you simply divide by 1.4.

THE MILLIAMPERE

While the unit of current measurement is the ampere, in electronics this unit is often so large that it is cumbersome. For example, in an audio amplifier stage using either a tube or a transistor, the current flow may be only a few thousandths of an ampere. In a case where the current flow was three thousandths of an ampere we could write this as 3/1000 or we could write this value as a decimal, in which case it would be .003.

However, rather than do this it is much more convenient to express the current flow in milliamperes. A milliampere is one thousandth of an ampere. Thus a current flow of three thousandths of an ampere will be 3 milliamperes.

There are one thousand milliamperes in an ampere. Therefore to convert amperes to milliamperes you simply multiply by one thousand. You do this by moving the decimal point three places to the right. For example, suppose you have a current of 5 amperes. We would normally simply write this as 5 amps. However, we can also write it as 5. amps. Now to move the decimal point three places to the right we simply add three zeros to the right of the decimal point, and then move the decimal point to the right of the three zeros. Thus 5.000 amps becomes 5,000. milliamps.

We seldom use milliamperes to express currents that are over 1 ampere, but when the current is some fraction of an ampere the milliampere becomes particularly useful. For example, suppose the current flow in a circuit is .05 amperes. To change this to milliamperes we move the decimal point three places to the right. To do this, write .05 amps as .050 amps and then move the decimal point three places to the right. Thus .05 amps = .050 amps = 50 milliamperes.

If you have a current in milliamperes and want to convert it to amperes you move the decimal point three places to the left, adding zeros as necessary. For example, to convert 47 milliamperes to amps we first write 47 milliamperes as 47. milliamperes. Now we move the decimal point three places to the left by moving it past the 7 and past the 4. Now we add a 0 so we can move the decimal point three places and get .047 amps. Another example, suppose the current is 7 milliamperes and we want to convert this to amperes. We write 7 milliamperes as 7. milliamperes. Next, we move the decimal point three places to the left; we move it past the 7 and then add two zeros to the left of the 7 and get .007 amps.

You will deal with milliamperes a great deal in electronics, and often you will have to convert them to amperes. Remember the rules for converting back and forth. To convert milliamperes to amperes you move the decimal point three places to the left. To convert amperes to milliamperes you move the decimal point three places to the right. In effect, when you convert from milliamperes to amperes by moving the decimal point three places to the left, you are dividing by 1000. When you convert amperes to milliamperes by moving the decimal point three places to the right, you are multiplying by 1000.

Since we use milliamperes so often in electronics it is convenient to have an abbreviation for this rather long word. We often abbreviate milliampere milliamp and to make it plural we simply add an s. An even more convenient abbreviation is ma. Thus 27 milliamperes can be abbreviated 27 milliamps or 27 ma.

You might think that converting from amperes to milliamperes and from milliamperes back to amperes is difficult and something that you are not used to doing. This is not true. Whether you realize it or not you are doing conversions of this type all the time. For example, suppose somebody gave you four hundred cents. It is not too likely that you would say that you had four hundred cents. Chances are that you would convert cents to dollars by moving the decimal point two places to the left and say you had $4.00. However, if you did have $4.00 and wanted to change it to cents you would move the decimal point two places to the right and know that you should have four hundred cents. The conversion back and forth between amps and milliamps is exactly the same except that we have one additional place. To convert from the larger unit, dollars in one case and amperes in the other, to the smaller unit, cents in one case and milliamperes in the other, we move the decimal point to the right. To convert from the smaller unit (cents in the one case and milliamperes in the other) to the larger unit (dollars in the one case and amps in the other case) we move the decimal point to the left. Remember the dollars and cents conversion and remember that you have one extra place and you will have no difficulty changing back and forth between amps and milliamps; it is that easy.

THE MICROAMPERE

In some circuits, even the milliampere is too large a unit to conveniently express current flow. Thus we have an even smaller unit, the microampere, which we abbreviate microamp. The microamp is one millionth of an ampere. It is one thousandth of a milliamp.

To convert amps to microamps you move the decimal point six places to the right. Remember it is the same as converting amps to milliamps except that you move the decimal point six places instead of three places. To convert microamps to amps you move the decimal point six places to the left. This is the same as converting milliamps to amps, or cents to dollars except that you move the decimal point six places to the left.

Even the abbreviation microamp is somewhat long and inconvenient, and since we have already used the letter ma for milliamps, we use the Greek μ which looks something like our u to abbreviate microamps. We write it μa.

Sometimes you will want to convert microamperes to milliamperes and vice versa. To do this, you move the decimal point three places. To go from the larger unit, milliamperes, to the smaller unit, microamperes, move the decimal point to the right, and to go from the smaller unit to the larger unit move it to the left.

In Fig. 3 we have shown a number of examples of conversions from one unit to another. Before going ahead study this figure and the conversions and then try to do them yourself. This is the best way to learn how to convert from one unit to another. Once you learn how to do this you

LARGE TO SMALL	SMALL TO LARGE
Dollars To Cents $1 = 100 cents We moved the decimal point 2 places to the right. $1 = $1.00 $1.00 = 100 cents	**Cents To Dollars** 1000 cents = $10.00 = $10. We moved the decimal point 2 places to the left. 1000. ¢ = $10.00
Amps To Milliamps 1 amp = 1000 milliamps We moved the decimal point 3 places to the right. 1 amp = 1.000 amp 1.000 amp = 1000 milliamps	**Milliamps To Amps** 10 milliamp = .010 amp We moved the decimal point 3 places to the left. 10. milliamp = .010 amp = .01 amp
Amps To Microamps 1 amp = 1000000 µamp We moved the decimal point 6 places to the right. 1 amp = 1.000000 amp 1.000000 amp = 1000000 µamp	**Microamps To Amps** 100000 µamps = .100000 amp We moved the decimal point 6 places to the left. 100000. µamp = .100000 amp = .1 amp

Fig. 3. Examples of conversion from one unit to another.

will find it is really quite simple and in a very short while you will find that you are converting from one unit to another mentally just as easily as you convert dollars and cents.

SUMMARY

In this section of the lesson you have reviewed many of the things you learned earlier about current flow. The important thing to remember about current flow is that it is a movement of electrons, and that in a series circuit the current flowing is the same at all parts of the circuit. Also remember that once the circuit is completed, current starts to flow in all parts of the circuit at the same instant.

You learned that to convert from rms values to peak values of ac current you multiply the rms value by 1.4 and to convert from peak values to rms values you divide by 1.4. The milliampere is one thousandth of an ampere. The microampere is one millionth of an ampere. To convert from the larger units to the smaller units you move the decimal point to the right and to convert from the smaller units to the larger units you move it to the left. In converting amperes to milliamperes and vice versa you move the decimal point three places, and in converting amperes and microamperes you move it six places. In converting microamperes and milliamperes you move the decimal point three places. These conversions are the same as converting dollars and cents and it is something that you will learn to do almost automatically.

Fig. 3 shows a number of examples of how to convert the different units. Be sure to study this figure carefully and then do the self-test questions. When you are doing these questions, if there is a conversion you do not know how to do, look at Fig. 3 and try to work it out yourself. If you can't, go to the back of the book and see how the conversion is made. Just look at the one you can't do and then go back to the self-test questions. There are several examples of each type of conversion. They are put in deliberately so that if you have trouble with the first one you can look at Fig. 3 to get help. Then look at the answer for additional help if necessary, and have another crack at doing it yourself. Changing back and forth becomes almost automatic - you simply move the decimal point the correct number of places.

SELF-TEST QUESTIONS

(a) If the current flowing past a point in the circuit is 1 ampere and it is increased so that four times the number of electrons pass the point in a second, what will the new current flow be?
(b) If the rms value of current is 3 amps, what will the peak value be?
(c) Change 7 amps rms to its peak value.
(d) If the peak value of current in a circuit is 7 amps, what is the rms value?
(e) In a circuit, the peak value of current is 21 amps; find the rms value.
(f) Convert $6.00 to cents.
(g) Convert 350 cents to dollars.
(h) Change 2 amps to milliamps.
(i) Convert 6 amps to milliamps.
(j) Convert 3.5 amps to milliamps.
(k) Convert .42 amps to milliamps.
(l) Convert .037 amps to milliamps.
(m) Convert .002 amps to milliamps.
(n) Convert 46 ma to amps.
(o) Convert 822 ma to amps.
(p) Convert 1327 ma to amps.
(q) Convert 2 amps to μa.
(r) Convert .0017 amps to μa.
(s) Convert 20 μa to amps.
(t) Convert 147 μa to amps.
(u) Convert .26 ma to μa.
(v) Convert .031 ma to μa.
(w) Convert 6100 μa to ma.
(x) Convert 927 μa to ma.
(y) Convert 327,000 μa to ma, and then to amps.

.026 600

Voltage

You have already learned that voltage is the electrical pressure or force that can set electrons into motion. You know that two voltage sources are the battery and the generator. You also know that the unit in which voltage is measured is the volt.

Now let us review some of the important things you learned about voltage, and then expand that knowledge.

DC VOLTAGE

You know that dc is the abbreviation for direct current. A dc voltage is a voltage that will cause a direct current to flow. We refer to this voltage as dc voltage, not direct current voltage.

A battery is an excellent source of a dc voltage. The battery will supply a potential that will cause a constant current to flow in one direction. A dc voltage will cause a current flow from the negative terminal of the voltage source, through the circuit to the positive terminal of the source.

In the early days of radio, radios were built on a metal chassis and one side of the voltage source used to operate the radio was connected to this chassis. The chassis in turn was usually connected to a ground, such as a water pipe or a metal pipe driven into the ground. As a result, the connection to the chassis became known as the ground connection.

Today, you should not connect the chassis of a radio or television receiver to a ground connection because you might place a short across the power line if you do this. However, if the chassis is still connected to one side of the voltage source operating the radio or television set we still refer to it as a ground connection. Sometimes instead of using the chassis as a common connection for the various circuits in the receiver, we run a series of connections from one common point in the receiver to another and back to one side of the voltage source. We call this type of connection a "floating ground" to distinguish it from a ground that is actually connected to the chassis.

With one side of the voltage source connected to the ground, we make dc voltage measurements between the ground and various other points in the circuit. We then have a convenient method of indicating the voltage that should be found in various parts of the circuit.

An example of what this can lead to is shown in Fig. 4. Here we have shown a 15 volt battery connected to a small lamp. The positive terminal of the battery in Fig. 4A is numbered 1 and the negative terminal is numbered 2. Notice that connected to the negative terminal we have a lead going to a symbol that is marked ground. This is another new schematic symbol for you to remember.

We are going to start using an expression which may be new to you. It is "with respect to". It means simply "compared to" and is always used by electronics technicians. You will have no trouble if you know that "compared to" and "with respect to" mean the same thing.

In Fig. 4A the negative terminal of the battery is connected to ground. Using ground as a reference

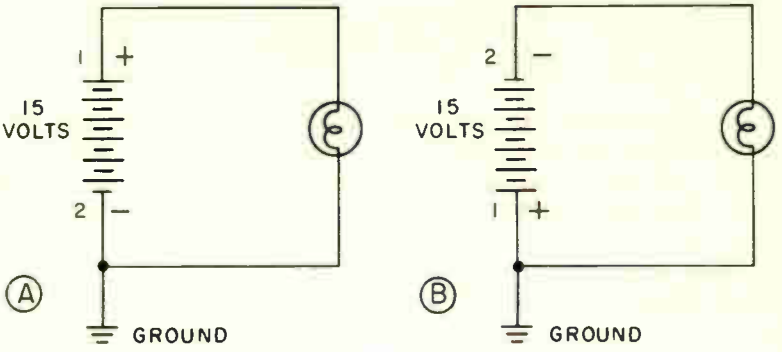

Fig. 4. Simple circuits with ground connections.

point we say that terminal 1 is +15 volts with respect to ground.

Now look at Fig. 4B. Here terminal 1 of the same battery, which is the positive terminal, is connected to ground. In this case using ground as a reference point we say that terminal 2 is -15 volts with respect to ground.

The important thing for you to understand in these two examples is that the voltage is the same in both cases. However, the polarity of the different points in the circuit will be positive or negative depending upon how the voltage source is connected to the circuit.

A 15 volt battery made up of 1-1/2 volt cells will have a total of ten cells. If the battery has a center connection, as shown in Fig. 5, and the center connection is connected to ground, we have a situation where we have both negative and positive polarities with respect to ground. Terminal 1 is + 7-1/2 volts with respect to ground and terminal 2 is - 7-1/2 volts with respect to ground. However, the total voltage is still 15 volts, as it was in both examples in Fig. 4, and the current flow through the bulbs would be the same in all three cases.

In your studies of electronic equipment you will run into equipment where the negative terminal of the voltage source is grounded as in Fig. 4A; you will run into equipment where the positive terminal is grounded as in Fig. 4B, and you will also encounter equipment where you have voltage both negative and positive with respect to ground as in Fig. 5.

AC VOLTAGE

You will remember that an ac voltage is one that causes an alternating current to flow. We refer to it as ac voltage instead of alternating current voltage. As in the case of dc voltage, we always use the abbreviation.

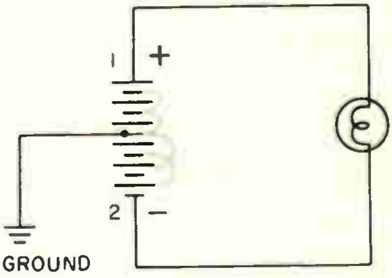

Fig. 5. A simple circuit where a voltage positive with respect to ground and a voltage negative with respect to ground are present.

Ac voltages are produced by generators or alternators. An alternator is a type of generator similar to the generator you studied earlier.

A schematic diagram of a simple ac circuit (similar to the dc circuit shown in Fig. 4) is shown in Fig. 6. Notice the symbol we have used to represent an ac generator. This is another important schematic symbol for you to remember.

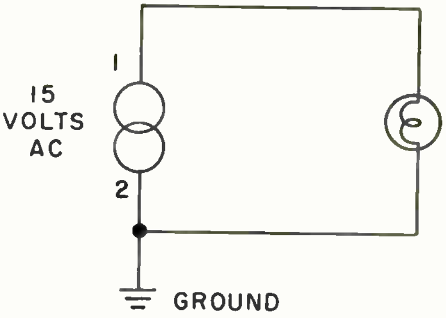

Fig. 6. A simple ac circuit with one side grounded.

In Fig. 6, terminal 2 of the generator is grounded. If we measure the voltage on terminal 1 with respect to ground or to terminal 2, we will get a voltage reading of 15 volts. The generator will produce an ac current flow that will have the same heating effect in the bulb as the 15 volt batteries did. However, you will remember that the voltage is continually varying. During one cycle, the voltage at terminal 1 starts at 0 as represented by point a in Fig. 7. The voltage begins to increase until it reaches its peak value at point b. If the rms or effective voltage is 15 volts then we know that the value of b will be 1.4 × 15 = 21 volts. Then the voltage between ground and terminal 1 begins to decrease until a half cycle after point a when we reach point c, where the voltage once again is 0. The voltage immediately begins to build up with the opposite polarity until we reach point d where once again the voltage between ground and terminal 1 is 1.4 × 15 = 21 volts. The voltage then begins to drop back until it reaches 0 again at point e.

The waveform between points a and e represents one complete cycle. The same cycle is completed again between points e and i, and then again between points i and m. In an ac circuit this cycle goes on indefinitely as long as the generator is operating.

During the first half cycle the voltage is positive at terminal 1 with respect to ground. During the next

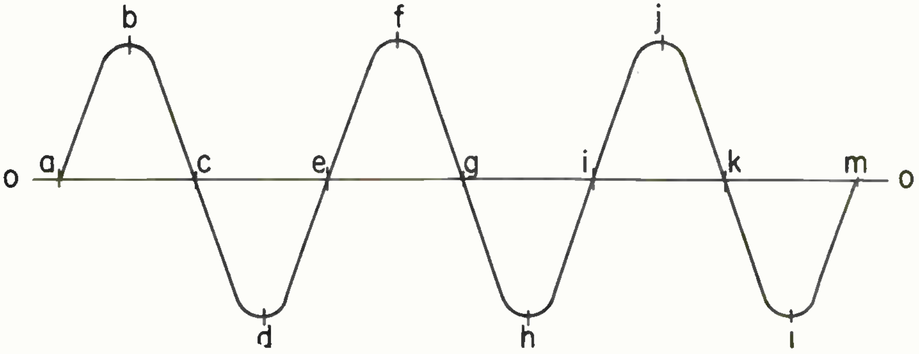

Fig. 7. Three cycles of an ac sinewave.

half cycle the voltage is negative with respect to ground. We draw the waveform above the line to represent a positive voltage and below the line to represent a negative voltage. We call the waveform between points a and b a quarter of a cycle; between b and c is also a quarter of a cycle as it is between c and d and d and e. The waveform between points a and c, points c and e, points e and g, etc., is referred to as a half cycle.

We said that we have a complete cycle between points a and e. By a complete cycle we mean the ac voltage starts at one point and goes through a complete cycle back to the equivalent point on the next cycle. We also have a complete cycle between points b and f because the waveform has gone through a full cycle between these two points. Between points c and g is also a full cycle as it is between points d and h. In speaking of a complete cycle we can start at any point on the cycle and continue on to the equivalent point on the next cycle. However, it is usually more convenient to start at a 0 point such as either point a or c when referring to a complete cycle. In fact, in most cases when speaking of an ac cycle we will start at point a and refer to the positive half of the cycle first and then the negative half. There is no reason why we have to do this; it is just something that is done by custom.

Notice the difference between the polarity at terminal 1 with respect to ground in Fig. 6 and the polarity of the ungrounded terminal in Figs. 4A and 4B. In Fig. 4A terminal 1 is the ungrounded terminal and it is always positive because the battery polarity does not change. In Fig. 4B, terminal 2 is the ungrounded terminal and it is always negative, again because the battery polarity does not change. In Fig. 6, terminal 1 is positive for one half cycle and negative for the next half cycle. Its polarity changes every half cycle because the voltage generated is an ac voltage. It is important for you to understand this difference between ac voltages and dc voltages.

VOLTAGES IN SERIES

Voltage sources can be connected in series. Whether they add together or subtract from each other depends upon the way in which they are connected.

In Fig. 8A we have shown two 4.5 volt batteries connected in series aiding. By this we mean that the two voltages add together. Notice that the batteries are connected together in the same way as the cells forming the battery are connected together. The positive terminal of the lower battery is connected to the negative terminal of the upper battery. With the arrangement shown in Fig. 8A the negative terminal of the lower battery is at ground potential. The voltage between terminal 1 and ground will be equal to the sum of the voltages of the two batteries, which in this case will be 9 volts.

In Fig. 8B, we have shown batteries with different voltages connected in series aiding. Notice that the positive terminal of the one battery is connected to the negative terminal of the other. The voltage between terminal 1 and ground will be the sum of the two battery voltages which is 7.5 volts. The position of the two batteries could be reversed; the voltage between terminal 1 and ground or terminal 2 would be the same in either case.

In Fig. 9, we have shown three examples of batteries connected in

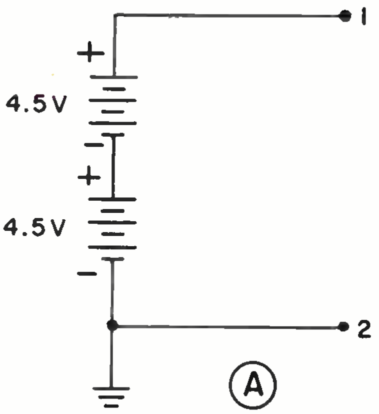

Fig. 8. Batteries connected in series so their voltages add.

series opposing. These batteries are connected so that their voltages oppose, and to find the total voltage we must subtract the battery voltages.

In Fig. 9A, each battery is a 4.5 volt battery. When you subtract 4.5 from 4.5 the result is 0 and therefore the potential between terminals 1 and 2 or between terminal 1 and ground is 0. The two batteries have equal voltages and therefore their voltages cancel.

In Fig. 9B, we have batteries of unequal voltages connected to oppose each other. The lower battery has a voltage of 3 volts, and the upper battery a voltage of 4.5 volts. Subtracting 3 from 4.5 gives us 1.5 volts. Since the upper battery has the higher potential, the voltage at terminal 1 will be positive with respect to ground or terminal 2. In other words, this voltage is able to overcome the voltage of the 3 volt battery and cause terminal 1 to be +1.5 volts with respect to ground.

In Fig. 9C, we have the opposite situation. Here the two batteries again subtract to give us a voltage

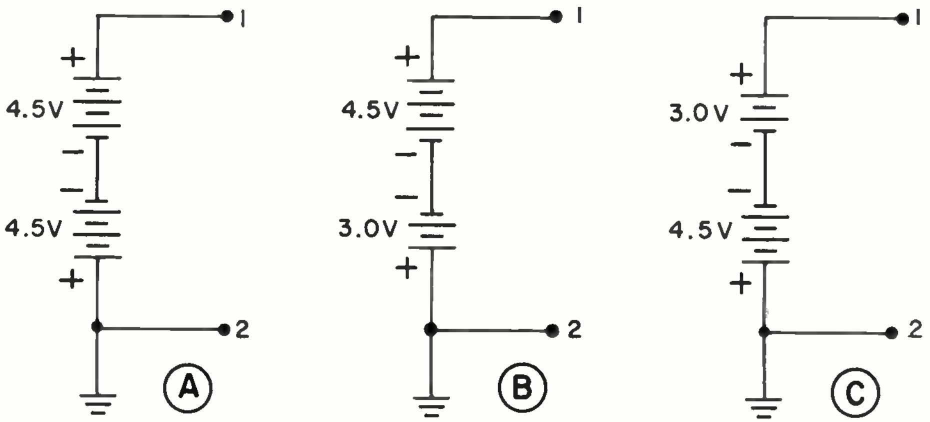

Fig. 9. Batteries connected in series so their voltages subtract.

of 1.5 volts. However, in this case, the polarity of the 4.5 volt and 3 volt batteries is reversed, so that now terminal 1 becomes -1.5 volts with respect to ground.

From the preceding examples you can see that batteries connected in series can either aid or oppose each other depending upon how they are connected. You will also see that when one side of the circuit is grounded, the other side can be either positive or negative depending upon the battery voltages and how they are connected. When unequal batteries are connected in series opposing, the polarity of the circuit will be the polarity of the battery with a higher voltage. When batteries are connected in series aiding, the polarity will be the same as the polarity of both batteries, since they must be connected in the same way in order to aid.

We can connect dc generators in series in exactly the same way as the batteries shown in Figs. 8 and 9 are connected. If they are connected in series aiding so that the negative terminal of one generator is connected to the positive terminal of the other, the total voltage available from the series combination will be the sum of the two voltages. If they are connected in series opposing so that the negative terminals of the generators or the positive terminals of the two generators are connected together, the voltage available will be the difference in voltage between the two generators, and the polarity of the circuit will be the polarity of the generator producing the higher voltage.

It is also possible to connect a battery in series with an ac generator such as shown in Fig. 10. Here, since the polarity of the voltage produced by the ac generator reverses every cycle we have a situation where during one half cycle the voltage produced by the generator will aid the battery voltage, and during the next half cycle the voltage will oppose the battery voltage.

In Fig. 11A, we have shown a graph of what the voltage will look like between terminals 1 and 2 of Fig. 10A when the peak voltage generated by the generator is exactly equal to the battery voltage. Terminal 2 is grounded and therefore is shown as zero voltage. The voltage at terminal 1 with respect to terminal 2 is shown

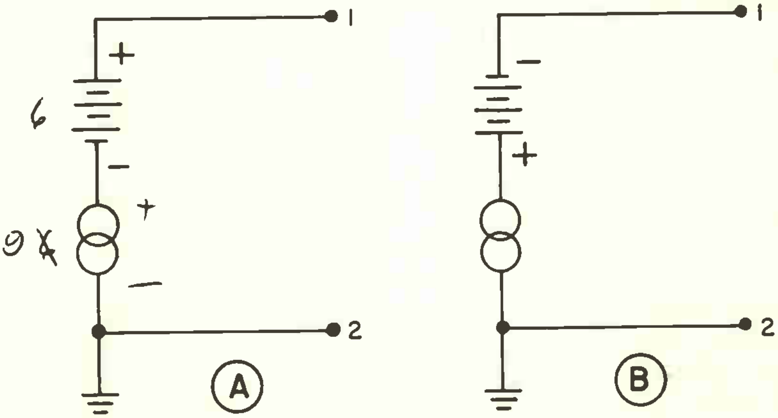

Fig. 10. Battery connected in series with ac generator.

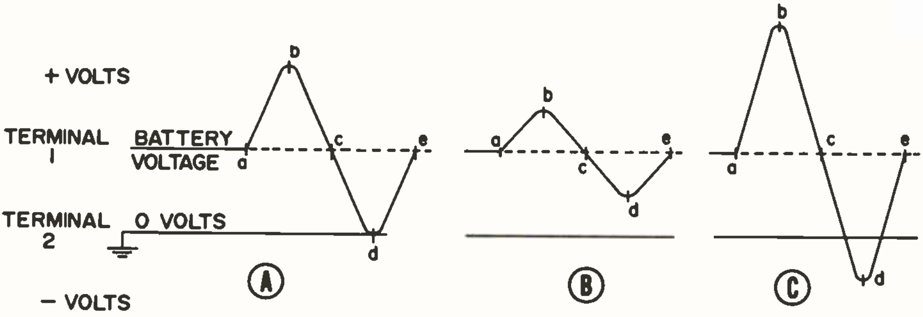

Fig. 11. Waveform showing how battery and generator voltages add in Fig. 10A. Voltage between terminal 1 and ground is shown.

by the graph. In electronics, as we have already pointed out, the expression "with respect to" means "compared to".

At the left of the graph in Fig. 11A, before the generator begins to turn, the voltage between terminals 1 and 2 will be the battery voltage. Terminal 1 is positive with respect to terminal 2 because the positive terminal of the battery is connected to terminal 1. When the generator begins to turn at point a in Fig. 11A, the generator voltage begins to build up during the first quarter cycle and adds to the battery voltage. When the generator voltage reaches its peak value at point b, the voltage between terminals 1 and 2 will be twice what it was at point a. This is because the peak generator voltage is adding to the battery voltage.

During the next quarter cycle, the generator voltage is falling from point b to point c. At the end of the first half cycle, the generator voltage will be zero as shown at point c, so the voltage between terminals 1 and 2 will be the battery voltage alone.

During the next quarter cycle, as shown between points c and d in Fig. 11A, the generator voltage begins to build up again, but this time the polarity of the generator voltage is reversed so it opposes the battery voltage. At point d, at the end of the third quarter cycle, the generator voltage will be exactly equal to the battery voltage but will have the opposite polarity. As a result, the two voltages will subtract, so at point d the voltage between terminals 1 and 2 will be zero. The actual voltage on terminal 1 at point d will be zero.

During the next quarter cycle, from point d to point e, the generator voltage decreases (becomes less negative) so that at the end of the cycle, at point e, the generator voltage is back to zero, and the voltage at terminal 1 is once again equal to the battery voltage.

In Fig. 11B, we have shown a situation in which the peak generator voltage is only half the battery voltage. Under these circumstances, the voltage builds up during the first quarter cycle. At point b, the total voltage between terminal 1 and terminal 2 will be 1-1/2 times the battery voltage. At point c on the curve, at the end of a half cycle, the generator voltage will be back to zero so the voltage between terminal 1 and ground (or terminal 2) will be equal to the battery voltage.

During the next half cycle, when the generator voltage begins to oppose the battery voltage, the voltage between terminals 1 and 2 drops until at the peak of the negative half cycle the voltage between terminals 1 and 2 is half the battery voltage. This is illustrated at point d in Fig. 11B.

As the ac voltage drops back to zero during the final quarter cycle, the voltage at terminal 1 increases back to the battery voltage as shown at point e.

In Fig. 11C, the peak generator voltage is 1-1/2 times the battery voltage. At the end of the first quarter cycle (at point b) the voltage between terminals 1 and 2 will be 2-1/2 times the battery voltage consisting of the generator voltage, which is 1-1/2 times the battery voltage, plus the battery voltage. At the end of the first half cycle (at point c) the generator voltage will be back to zero and the voltage between terminals 1 and 2 drops back to the battery voltage.

The peak generator voltage overcomes the battery voltage during the next half cycle because it is greater than the battery voltage and has the opposite polarity. As a result, at point d on the graph, terminal 1 is negative with respect to ground and terminal 2. Since the peak generator voltage is 1-1/2 times the battery voltage, it will cancel the battery voltage and then swing terminal 1 negative to a value equal to half the battery voltage.

You can see from Fig. 11 that when an ac voltage and a dc voltage are connected in series, they aid during one half cycle and oppose during the other half cycle. If the peak generator voltage is equal to the battery voltage, the total voltage will drop to zero volts once each cycle and will swing up to a value which is twice the battery voltage once each cycle. If the generator voltage is less than the battery voltage, the total voltage increases above the battery voltage and drops to less than the battery voltage once each cycle. On the other hand, if the generator voltage is greater than the battery voltage, the total voltage will reach a value which is more than double the battery voltage during one half cycle. When the generator voltage opposes the battery voltage during the other half cycle, the polarity of the output voltage will reverse when the generator voltage exceeds the battery voltage.

In Fig. 12, we have shown the voltage between terminal 1 and terminal 2, which is connected to ground, with the generator and battery connected as in Fig. 10B. The peak generator

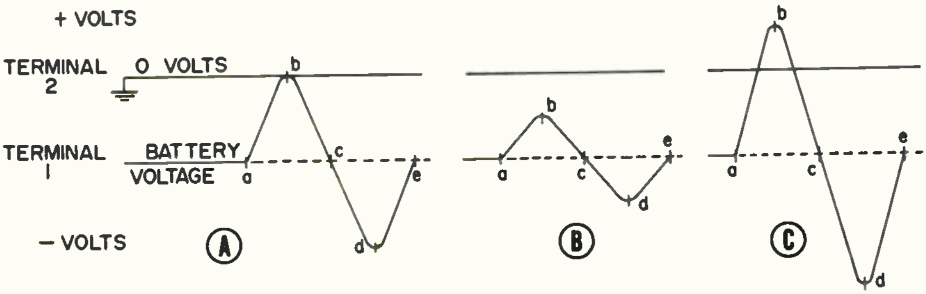

Fig. 12. Waveform showing how battery and generator voltages add in Fig. 10B. Voltage between terminal 1 and ground is shown.

voltage is exactly equal to the battery voltage in Fig. 12A, less than the battery voltage in Fig. 12B, and greater than the battery voltage in Fig. 12C.

When the peak generator voltage is exactly equal to the battery voltage, terminal 1 remains negative with respect to ground (terminal 2) at all times except when it drops to zero at the peak of the positive half cycle of the generator. When the peak generator voltage is less than the battery voltage as in Fig. 12B, terminal 1 remains negative with respect to ground (terminal 2) at all times. When the generator voltage is greater than the battery voltage as in Fig. 12C, terminal 1 becomes positive during a portion of the positive half cycle of the generator. For the remainder of the time, terminal 1 remains negative with respect to ground (terminal 2).

Having a battery and an ac generator connected in series is not much different from having two batteries connected in series except that in the case of the generator the polarity is changing each half cycle so that during one half cycle the two voltages aid and during the next half cycle the two voltages oppose. You can find the peak value that the two reach when they aid simply by adding the peak generator voltage to the battery voltage, and you can find the peak value that they reach when they oppose by subtracting the two. If the generator voltage is less than the battery voltage, then the voltage polarity in the circuit does not change. But if the generator voltage is greater than the battery voltage, the polarity of the voltage will change during the half cycle when the two voltages are opposing.

Why have we spent so much time explaining how voltages add or subtract? Do we ever make such connections in practical electronic circuits? This explanation was given to prepare you for actual circuits which will be described later. For example, in a tube or transistor we will have a fixed dc voltage so the part works properly. Then to this fixed dc voltage we will add a signal voltage, which is ac. The resulting combined voltage then becomes more negative or less negative (Fig. 12B) or more positive or less positive (Fig. 11B) and the tube or transistor can amplify the ac portion. This will be explained in greater detail later on. For the present, we just want you to know that there is a very practical reason for what you have just studied.

MILLIVOLTS

Just as the ampere is too large a current unit and we had to use milliamperes in some instances, so also is the volt sometimes too large a unit and we use the millivolt. A millivolt, abbreviated mv, is one thousandth of a volt. The prefix milli means the same when used with volts as it does with amperes - it means one thousandth. Therefore, to convert from volts to millivolts, you do the same thing as you did in converting from amps to milliamps. You multiply by 1000 - to do this you simply add zeros and move the decimal point three places to the right. To convert from millivolts to volts, you do the opposite; you divide by 1000 and to do this move the decimal point three places to the left. Remember, it is exactly the same as going back and forth between amps and milliamps. Thus, 2.5 volts = 2.5 × 1000 = 2500 millivolts; 49 millivolts = .049 volts.

MICROVOLTS

Sometimes even the millivolt is too large a unit and we use the microvolt, which is one millionth of a volt, just as the microampere is one millionth of an ampere.

To convert from volts to microvolts multiply by 1,000,000. You do this by moving the decimal point six places to the right. To convert from microvolts to volts you move the decimal point six places to the left, just as you did in converting microamps to amps.

You might wonder where such a small unit as the microvolt is used. It is sometimes used in measuring the strength of a radio or TV signal at a certain point. Also, in testing radio and television receivers, signals from a few microvolts are fed into the receiver and then measured at various points in the receiver to see how much the various stages are amplifying the signal. You might find that the signal at the input of one stage is 10 microvolts and at the output was 100 microvolts; this means that the stage amplified the signal voltage ten times. Technicians seldom have to convert back and forth between volts, millivolts and microvolts, as often as they do in the case of amps, milliamps and microamps. However, since the procedures for converting from one to the other are the same, if you know one, you know the other.

You will remember that to convert from milliamps to microamps you moved the decimal point three places to the right, and to convert from millivolts to microvolts you do the same thing. Similarly, to convert from microvolts to millivolts you move the decimal point three places to the left.

THE KILOVOLT

A unit that you will encounter in voltage measurements is the kilovolt. The kilovolt is one thousand volts. Thus 25 kilovolts, which is often abbreviated 25 kv, is equal to 25,000 volts. You will run into high voltages of this type in television receivers. Black and white television receivers often use voltages of 15 kv or more (15,000 volts) to operate the picture tube. In color television receivers some will have voltages as high as 25 kv. Just remember that a kilovolt is equal to 1000 volts, so to convert kilovolts to volts, you simply multiply by 1000.

SUMMARY

You should remember the important differences between ac and dc voltages. A dc voltage, which is produced by a battery or a dc generator, will have a polarity that does not change. Connected to a circuit, a dc voltage source produces a current which flows in one direction. An ac voltage changes potential (having one polarity during one half cycle and the opposite polarity during the next) and produces a current which flows in one direction during one half cycle and in the opposite direction during the next.

Voltages are often connected to common connections called grounds, and may be either positive or negative with respect to ground depending upon how they are connected to it.

Batteries and/or generators can be connected in series aiding so that their voltages add, or in series opposing so that they subtract. When connected in series between ground and another point, the polarity of the point may be positive or negative when the batteries oppose, depending on the polarity of the larger voltage source.

A dc voltage source such as a battery can be connected in series with an ac generator, and the two voltages will add during one half cycle and oppose during the next. The highest voltage produced is equal to the battery voltage plus the peak generator voltage. If one side of the circuit is connected to a common ground, the polarity in the circuit will not change unless the generator voltage is greater than the battery voltage. In this case, the polarity will change during the portion of the cycle when the voltages are opposing.

Some circuits you will encounter will have very small voltages; others will have very high voltages. Remember that the millivolt (abbreviated mv) is one thousandth of a volt, the microvolt (abbreviated µv) is one millionth of a volt, and the kilovolt (abbreviated kv) is one thousand volts.

SELF-TEST QUESTIONS

(z) If in the circuit shown in Fig. 4B, the battery is a 45 volt battery, what voltage is present at terminal 2 with respect to ground?

(aa) If in the circuit shown in Fig. 5, the battery is a 90 volt battery, and the ground terminal is a center tap, what is the voltage at terminal 1 with respect to ground? What is the voltage at terminal 2 with respect to ground?

(ab) In the circuit shown in Fig. 6, if the rms value of the voltage is 20 volts, what will the peak voltage be between terminal 1 and ground? Will it be positive or negative?

(ac) If a 15 volt battery and a 45 volt battery are connected in series as in Fig. 8B, what will the voltage be at terminal 1?

(ad) If two 22-1/2 volt batteries are connected in series as shown in Fig. 9A, what is the voltage at terminal 1 with respect to ground?

(ae) If two batteries are connected as shown in Fig. 9B, and one is a 45 volt battery and its positive terminal is connected to terminal 1, and the other is a 22-1/2 volt battery and its positive terminal is grounded, what will the voltage at terminal 1 be?

+
45v
−
−
22.5v
+

(af) If in Fig. 9C the positions of the two batteries are reversed so that the negative terminal of the 4.5 volt battery is connected to terminal 1, and the negative terminal of the 3 volt battery connects to ground, what will the voltage be at terminal 1?

(ag) If a generator that has a peak voltage of 15 volts is connected in series with a battery that has a voltage of 15 volts, what is the maximum voltage produced during the half cycle when the two aid, and what will be the minimum voltage produced when the two oppose?

(ah) If in the circuit shown in Fig. 10A the battery voltage is 15 volts and the peak generator voltage is 20 volts, what will the voltage be between terminal 1 and ground when they are aiding and when they are opposing?

(ai) If a generator and battery are connected as in Fig. 10B, and the battery voltage is 30 volts and the generator peak voltage is 45 volts, what will the voltage be between terminal 1 and ground when the two are aiding and when the two are opposing?

(aj) If a battery and generator are connected as shown in Fig. 10A and the battery voltage is 20 volts and the peak generator voltage is 10 volts what will the voltage be between terminal 1 and ground when they are aiding? When they are opposing?

(ak) If a battery and generator are connected in series as shown in Fig. 10B, and the battery voltage is 45 volts and the peak generator voltage is 30 volts, what will the voltage be between terminal 1 and ground when the generator reaches its peak value aiding the battery and when it reaches its peak value opposing the battery?

Resistance

One of the most important values you will work with in your electronic career is resistance. All wires and parts in electronic equipment have a certain amount of resistance. In some cases, such as in a short piece of copper wire, the resistance may be so low that it has no effect on the performance of the circuit. However, in every circuit there will be some part that has enough resistance to affect the operation of the circuit.

You know that when a voltage is applied to an electrical circuit a current will flow in the circuit. In a dc circuit, the thing that limits the amount of current that will flow for a given voltage is the resistance of the circuit. In an ac circuit, resistance also limits the current flow, but there may also be some other parts that will affect the current flow.

THE OHM

The unit of resistance is the ohm. It is named after the scientist George Simon Ohm who did a great deal of work in the early days when scientists first began studying electricity. If a voltage of 1 volt is applied to a circuit and a current of 1 amp flows in the circuit, the resistance of the circuit is 1 ohm. If a voltage of 2 volts is applied to a circuit, and a current of 1 amp flows, the resistance in the circuit is 2 ohms. Here we have twice the voltage applied to the circuit and, therefore, twice the force to force a current flow in the circuit. However, since the current flow is 1 amp in both cases, the circuit in the second case must offer twice the opposition to current flow. This is why the resistance of the circuit is 2 ohms.

In electronic equipment, the wires used to connect parts together have a very low resistance, usually only a fraction of an ohm. However, several of the parts that you have studied do have a much higher resistance. For example, a transformer has two or more windings on a common core. In the case of a transformer used to operate on a 60-cycle power line, there will be many turns on the primary winding of the transformer. The resistance will depend upon the size of the wire used on the primary winding of the transformer, but a resistance of about 100 ohms is typical of what you might find if you measured the resistance of the primary winding of the transformer used in a large radio or a small television receiver.

DC Resistance.

Dc resistance is the opposition offered to the flow of direct current in a circuit. If a dc voltage is applied to an electrical circuit, the dc resistance of the circuit will limit the current that will flow in the circuit. When we speak of dc resistance, we simply refer to it as resistance rather than by its entire name "dc resistance".

AC Resistance.

The ac resistance of a part may not be the same as the dc resistance. For example, at high radio frequencies, which are simply very high ac frequencies, the current flowing in a circuit has a tendency to flow on the outside of the conductor. This often causes the ac resistance to be somewhat higher than the dc resistance. In some coils used in very high frequency equipment you will find that the coils are silver plated. The purpose of the silver plating is to keep the resistance on the outside of the conductor as low as possible.

At power line frequencies and audio frequencies as well as low radio frequencies, the ac resistance of most parts is almost the same as the dc resistance and so we generally consider them as being the same. You will see later that it is comparatively easy to measure the dc resistance of a part, but it is much more difficult to measure the ac resistance.

Resistors.

While copper wire is used to connect electronic parts together to keep the resistance in the circuit low, there are some instances where we want resistance in the circuit. Parts made to put resistance in the circuit are called resistors. There are many different values and sizes of resistors used in electronic equipment, and several different types, but the most commonly used type is the "carbon resistor". This type of resistor is made of a mixture of powdered carbon and a cement-like material that is used to hold the carbon together. By varying the composition of the mixture, different values of resistance from a few ohms up to several million ohms can be obtained.

Carbon resistors come in several different sizes and in many different resistance values. The size of the resistor tells you how much power the resistor can handle. Three different sizes of carbon resistors are shown in Fig. 13. Each resistor has a resistance of 1000 ohms. The resistor in the middle can handle twice the power that the resistor on the top can handle. The resistor on the bottom can handle twice the power the resistor in the middle can, or four times the power the resistor

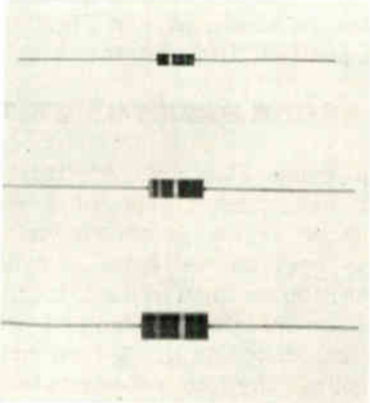

Fig. 13. Three 1000-ohm carbon resistors. The resistor at the top is a ½ watt size, the middle resistor, a 1 watt size and the bottom one, a 2 watt resistor.

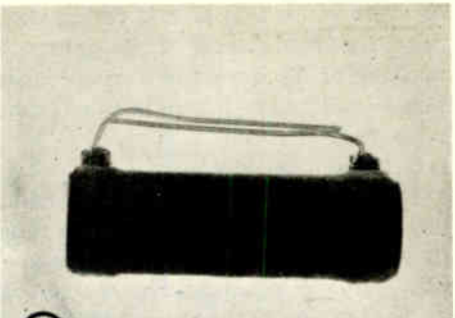
on the top can handle. The resistor on the top is called a half-watt resistor, the one in the middle a one-watt resistor and the one on the bottom a two-watt resistor. The watt is a unit of electrical power, which you will learn about later.

Another type of resistor that you will encounter is the "wire-wound resistor". It is made of wire wound on a form, which is usually some type of ceramic form. The wire used to wind the resistor is called resistance wire; it gets its name because it has a much higher resistance than copper wire. Wire-wound resistors are used in places where they must handle a higher current than could be handled by a carbon resistor.

Another type of resistor that you will encounter is the deposited film resistor. This type of resistor has a metal oxide (a combination of a metal and oxygen) film deposited on a ceramic form. The advantage of this type of resistor is that it can be made to handle higher currents than a carbon resistor and at the same time can be made in larger resistance values than the wire-wound resistor. A wire-wound resistor is shown at A in Fig. 14 and a deposited film resistor at B.



Ⓐ WIRE-WOUND RESISTOR

Ⓑ DEPOSITED-FILM RESISTOR

Fig. 14. A wire-wound resistor is shown at A; a deposited film resistor at B.

LARGER RESISTOR UNITS

In many electronic circuits you will have resistances of several thousand ohms; in others you will have resistances over a million ohms. Rather than indicate the value of these resistors in ohms it is more convenient to use the K-ohm and the megohm. The letter K stands for one thousand so the K-ohm is one thousand ohms. Meg stands for one million so one megohm is one million ohms. Thus, rather than mark the value of a resistance as 2,200 ohms we would indicate the value as 2.2K. A resistor having a resistance of 100,000 ohms would be labelled 100K. A resistor with a resistance of 470,000 ohms would be marked 470K.

We use the unit megohms for resistors larger than one million ohms. A resistor whose value is 2,200,000 ohms would be labelled 2.2 megs or 2.2M; both abbreviations are used. Sometimes a resistor that is somewhat less than a megohm in resistance is also expressed in megohms. For example, a 470,000 ohm resistor could be labelled 470K, and it can also be labelled .47 megs or .47M. Any one of the three labellings could be used since they all mean the same thing.

Converting back and forth between ohms, K-ohms and megohms is essentially the same as converting between amps, milliamps and microamps. However, in this case remember that the ohm is the small unit, the K-ohm is one thousand ohms and the megohm is one million ohms. To convert from the small unit to the larger unit you simply move the decimal point to the left, either three places or six places, depending on whether you are converting to K-ohms or to megohms. To convert from the large unit to the small unit you move the decimal point in the opposite direction. As a technician you will have to convert values back and forth. The values of carbon resistors are identified by means of a color code. The color code will give the resistance in ohms, but the value may be given on a circuit diagram in K-ohms or megohms to save space. Thus you have to know what the different units mean so you will be able to identify them on circuit diagrams.

SUMMARY

Much of the material covered in this section of the lesson will be a review for you. However, resistance is a very important subject, and you should make sure you understand everything in this section before going on to the next. In the next section of the lesson you are going to study Ohm's Law.

The important points to remember in this section are that in a dc circuit the current flow in the circuit will be limited by the resistance in the circuit. In an ac circuit the resistance will also limit the current, but there may be some other factors that also aid in limiting the current.

The unit of resistance is the ohm. If a current of 1 ampere flows in a circuit when a voltage of 1 volt is applied to the circuit, the resistance in the circuit is 1 ohm.

Three important types of resistors that you will encounter in electronic equipment are the carbon resistor, the wire-wound resistor, and the metal oxide film resistor. These resistors are made in many different resistance values and in different sizes to handle different values of current.

In many electronic circuits the resistance is so high that we use the K-ohm, which is equal to one thousand ohms and the megohm which is equal to one million ohms. You should be able to convert from one unit to another so you will be familiar with all three units.

SELF-TEST QUESTIONS

(al) If the current flowing in a circuit is 1 amp, and we double the resistance in the circuit, will the current increase, decrease, or remain the same?
(am) Name the three types of resissistors that are used in electronic equipment.
(an) Convert 4,700 ohms to K-ohms.
(ao) Convert 5,600,000 to megohms.
(ap) Convert .330 megs to K-ohms.
(aq) Convert 2.2 megs to ohms.
(ar) Convert 8.2 K-ohms to ohms.
(as) Convert 680 K-ohms to megohms.
(at) Draw the symbol used to represent a resistance. You should remember this from an earlier lesson.

Ohm's Law

Ohm's Law is one of the most important laws or rules in electronics. It tells you how the voltage, current and resistance are related in an electrical circuit. Ohm's Law states that the current flowing in the circuit is equal to the voltage divided by the resistance. Rather than use words every time to express this law, we use symbols. We use the letter I for current, E for voltage and R for resistance. Using these symbols we can express Ohm's Law as:

$$I = E \div R$$

This is more often written in the form:

$$I = \frac{E}{R}$$

By using this expression, or by rearranging it mathematically, if we know any two of the three values, resistance, current or voltage, we can determine the other. As a radio television serviceman you will be concerned with replacing parts and will not have many occasions to work out the value of a part using Ohm's Law. However, an understanding of it will help you understand what is going on in the circuits you will study in this and in following lessons. A technician who wants to get his FCC license to work at a broadcasting or television station, or a technician who wants to work in industry or as an engineering aid will have to be able to work out problems involving Ohm's Law. We are going to use Ohm's Law to learn more about how voltage and resistance affect the current in a circuit. We will do some simple problems involving Ohm's Law. Be sure to follow these through carefully so you will understand what is happening in the circuits we discuss. We will work out each step in detail even though some of the steps may seem comparatively simple.

HOW VOLTAGE AFFECTS CURRENT

In Fig. 15 we have shown a simple circuit consisting of a voltage source and a resistor. The battery voltage, E = 20 volts; the resistance of the resistor, R = 2 ohms. Notice the symbol we have used to indicate ohms. This is the Greek letter omega and it is often used on diagrams as an abbreviation for ohms.

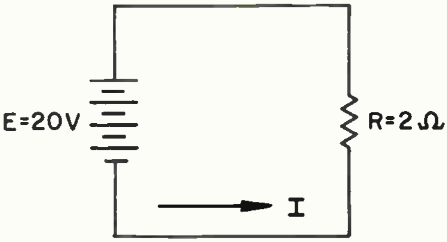


Fig. 15. A simple circuit consisting of a voltage source and a resistor.

We can determine the current that will flow in this circuit by using Ohm's Law. We simply take the formula and then substitute the values of E and R which we have and this will give us the value of I.

$$I = \frac{E}{R}$$

$$I = \frac{20}{2} = 10 \text{ amps}$$

Thus in the circuit shown in Fig. 15 the current flowing will be equal to 10 amps. If we increase the voltage to 40 volts, the new current flowing will be:

$$I = \frac{40}{2} = 20 \text{ amps}$$

and if we reduce the voltage to 10 volts, the current flowing in the circuit will be:

$$I = \frac{10}{2} = 5 \text{ amps.}$$

The important thing to see from the preceding is how the current flowing in the circuit with a given resistance in the circuit is tied directly to the voltage. Increasing the voltage increased the current, and reducing the voltage reduced the current. In the example where we doubled the voltage, the current doubled, and where we cut the voltage in half, the current was cut in half. This relationship will always hold true. If we increase the voltage to three times its original value, then the current will increase to three times the original value, and if we reduce the voltage to one third of its original value, then the current will be reduced to one third of its original value. We can say that in a given circuit the current will vary directly with the voltage. Any change in the voltage will result in a corresponding change in the current.

Notice that in the example given, the voltage was given in volts, the resistance was given in ohms and the current we calculated was in amps. In using Ohm's Law we must always use these basic units. Often this leads to a somewhat more difficult problem than shown in Fig. 15. Look at the example in Fig. 16.

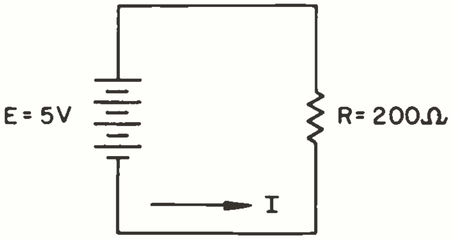

Fig. 16. A simple circuit where E = 5V and R = 200Ω.

In Fig. 16, the voltage is 5 volts and the resistance in the circuit is 200 ohms. Using Ohm's Law to determine the current we have:

$$I = \frac{5}{200}$$

Here the division is not quite as simple as it was in the preceding example because we have to resort to a decimal division. The division is not particularly difficult; it is shown in Fig. 17. We see that we get a current of .025 amps. We could leave our answer like this, or we can convert it to milliamperes by multiplying by 1000. To do this we simply move the decimal point three places to the right and get the answer, I = 25 ma.

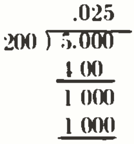

Fig. 17. Solution for I in Fig. 16.

Since our answer is in milliamperes, and we multiplied the current in amperes by 1000 to get our answer into milliamperes, if we want to avoid the decimal division we can multiply by 1000 before performing the division and get the answer directly in milliamperes. When we do this the problem becomes:

$$I = \frac{5}{200} \times 1000$$

$$I = \frac{5000}{200}$$

Now we can cancel two zeros above the division line and two below the line so we have:

$$I = \frac{50\cancel{0}\cancel{0}}{2\cancel{0}\cancel{0}} = \frac{50}{2}$$

$$I = 25 \text{ ma}$$

You can use whichever method you want in determining the current in a circuit of this type. If you multiply by 1000 before performing the Ohm's Law division, be sure to remember that your answer will be in milliamperes. Incidentally, sometimes we use mils as well as ma for an abbreviation of milliamperes. In the preceding problem we can say our answer is 25 mils.

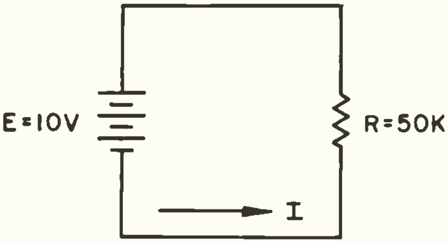

Fig. 18. A simple circuit where E = 10V and R = 50 K-ohms.

Another example is shown in Fig. 18. Notice that here we have an even larger resistor and also notice that the resistance is given in K-ohms. Let us see how we go about tackling a problem of this type.

You will remember we said that in using Ohm's Law the units must be in volts, amps and ohms. Therefore, the first thing we must do is to convert 50K-ohms to ohms. We do this simply by multiplying by 1000 and get a resistance of 50,000 ohms. Now using 50,000 ohms and 10 volts we can find the current using Ohm's Law.

$$\begin{array}{r} .0002 \\ 50000\,\overline{)\,10.0000} \\ \underline{10\ 0000} \end{array} \qquad \begin{array}{r} .2 \\ 50000\,\overline{)\,10000.0} \\ \underline{10000\ 0} \end{array}$$

Ⓐ Ⓑ

Fig. 19. Solution for I in Fig. 18.

$$I = \frac{E}{R}$$

$$I = \frac{10}{50{,}000}$$

Here again we have a decimal division. We can go ahead and perform this division as shown in Fig. 19A. We get as an answer .0002 amps. We can convert this to milliamperes by multiplying by 1000. To do this, we move the decimal point three places to the right and get .2 milliamps as the current. However, we still have a decimal so instead of converting to milliamps it would be more logical to convert to microamps. We do this by multiplying by 1,000,000 and this involves moving the decimal point six places to the right. We get as the current 200 μa.

If we want to avoid the decimal

division we can again convert before we perform the division. If we try converting to milliamps first by multiplying by 1000 we would have 50,000 divided into 10,000. This can be worked out as shown in Fig. 19B and we get our answer, .2 ma. However, since 50,000 is larger than 10,000 it is obvious that we have another decimal division and so to avoid this why not simply multiply the voltage, 10 volts by 1,000,000, and then get our answer directly in microamps. When we do this the formula becomes

$$I = \frac{10}{50{,}000} \times 1{,}000{,}000$$

$$= \frac{10{,}000{,}000}{50{,}000}$$

Notice that in 50,000 there are four zeros so we can mark these four zeros off and mark four zeros off from the ten million so that we will have

$$I = \frac{10{,}00\cancel{0}{,}\cancel{0}\cancel{0}\cancel{0}}{5\cancel{0}{,}\cancel{0}\cancel{0}\cancel{0}}$$

$$= \frac{1{,}000}{5}$$

$$= 200 \text{ microamps}$$

In electronic circuits you will frequently run into comparatively small voltages and very large resistances. This means that if you want to find the current flowing in the circuit and you divide directly, you will run into a decimal division. Therefore the easy way is to multiply by 1,000 or 1,000,000 first to convert the answer directly to milliamps or microamps. If you are doubtful about whether you should multiply by 1000 or 1,000,000, multiply by 1,000,000 and then perform the division. If your answer, which will be in microamperes, is over 1,000 microamperes you can convert this to milliamps if you want to by simply moving the decimal point three places to the left. However, it really doesn't matter whether you say that the current is 4,700 microamps or 4.7 milliamps, it means the same thing. For that matter, if you don't mind doing decimal divisions you don't have to convert at all. You can simply give the answer in amperes as .0047 amps. All three mean the same thing. If you like doing mathematics then the chances are that the decimal divisions won't bother you, but on the other hand if you are like most people and steer away from math, then multiplying either by 1,000 or a 1,000,000 first to convert the answer directly to milliamperes or microamperes is probably the easiest way to tackle problems of this type.

In examples shown in Figs. 15, 16 and 18, the voltage source was a battery and therefore the problems all involved dc voltage and current. If the voltage source had been an ac generator instead, we would have found the current in exactly the same way. In a circuit containing only resistance, Ohm's Law is used in exactly the same way in an ac circuit as it is in a dc circuit. Where the value of E is the rms value of the voltage, then the current will be found in its rms value. If the value of E given is the peak value of the voltage, and we use this value in Ohm's Law, then we will get the peak value of the ac current. If we want the rms value we can get it either by converting the peak value of the current to its rms value after we perform the calculation or we can convert the peak voltage to an rms value first.

HOW RESISTANCE AFFECTS CURRENT

In the simple circuit shown in Fig. 15 where the voltage is 20 volts and the resistance 2 ohms, we found by using Ohm's Law that the current flowing in the circuit is 10 amps. The same circuit is repeated in Fig. 20 except that we have replaced the 2 ohm resistor with a 4 ohm resistor. How will this affect the value of I? Using Ohm's Law we can find the current.

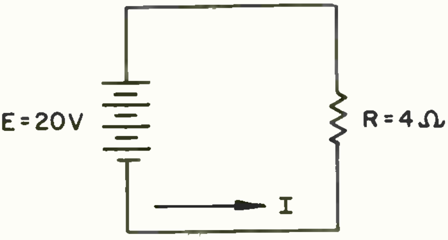

Fig. 20. The 2Ω resistor in the circuit of Fig. 15 is replaced by a 4Ω resistor.

$$I = \frac{E}{R}$$

$$I = \frac{20}{4} = 5 \text{ amps}$$

Here the current is 5 amps, half of what it was before. In other words, doubling the resistance cut the current in half. If instead of doubling the resistance, we had cut it in half so that R is equal to 1 ohm, then using Ohm's Law again we find that the current is equal to 20 amps. In other words, cutting the resistance in half has doubled the current. We will find that this relationship between current and resistance holds true regardless of how we change the resistance. If we increase the resistance to 3 times its original value, the current will be reduced to one third and if we cut the resistance to one third its original value the current will increase to three times its original value. We say that the current varies inversely to the resistance.

As a matter of fact, this relationship between current and resistance is obvious if we examine Ohm's Law. If we look at the expression for current

$$I = \frac{E}{R}$$

if E remains constant and we increase R, it is obvious that I must be smaller. Similarly, if we reduce R, and keep E constant, then I must get larger.

FINDING E

In some circuits we may know what the current flowing in the circuit and the resistance in the circuit are and have to find the voltage in the circuit. An example of this type of problem is shown in Fig. 21. Here the current is 2 amps and the resistance is 15 ohms. We want to find the value of E.

Ohm's Law can be rearranged mathematically into the form

$$E = I \times R$$

We usually drop the multiplication sign and simple write the formula as:

$$E = IR$$

The term IR means I × R; the multiplication sign is understood, even though it is not shown. Using this form of Ohm's Law we get:

$$E = 2 \times 15$$
$$= 30 \text{ volts}$$

Thus, the value of the voltage applied to the circuit must be 30 volts. If we want to, we can check this out using the other form of Ohm's Law:

$$I = \frac{E}{R}$$

substituting 30 for E and 15 for R we get a current of 2 amps, and since this agrees with the value given, the value of voltage which we determined must be correct.

Notice that the current in Fig. 21 is given in amps and the resistance in ohms. Sometimes the current may be given in milliamperes or microamperes and the resistance might be in K-ohms or megohms. In either case we must convert back to the basic units. Milliamperes and microamperes must be converted to amperes and K-ohms and megohms must be converted to ohms. An example of this type of problem is shown in Fig. 22. Here the current is given in milliamperes and the resistance in ohms.

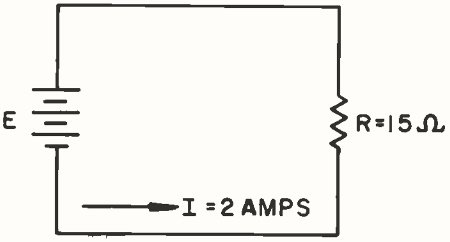

Fig. 21. A simple circuit where I = 2 amps and R = 15Ω.

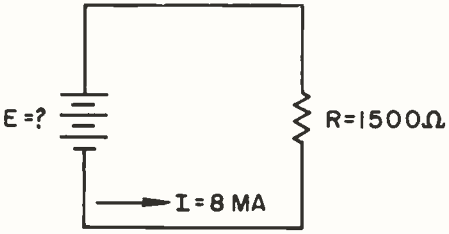

Fig. 22. Find E where I = 8 ma and R = 1500Ω.

Doing the problem shown in Fig. 22, we can first convert the current I which is 8 ma to amps by dividing by 1000. We do this by moving the decimal point three places to the left and get as the current, .008 amps. Now substituting these values in Ohm's Law we can find the voltage

$$E = IR$$
$$= .008 \times 1500$$
$$= 12 \text{ volts}$$

This involves a decimal multiplication, which is not too difficult to perform. However, if you want to avoid the decimal multiplication the easy way to do this is to simply write 8 milliamps as 8/1,000 amps. Now substituting the value of 8/1,000 in the formula we get

$$E = \frac{8}{1000} \times 1500$$

$$E = 8 \times \frac{1,500}{1,000}$$

$$E = \frac{12,000}{1,000}$$

Now cancelling three zeros above and below the division line we get

$$E = \frac{12,\cancel{0}\cancel{0}\cancel{0}}{1,\cancel{0}\cancel{0}\cancel{0}}$$

$$E = 12 \text{ volts}$$

If in Fig. 22 the resistance had been expressed in K-ohms it would be written 1.5 K-ohms. To convert this to ohms we multiply by 1,000. Instead of actually performing the multiplication we could then write the problem as:

$$E = \frac{8}{1,000} \times 1.5 \times 1,000$$

Now we can cancel the 1,000 above and below the division line and simply multiply 8 × 1.5 and our answer is 12 volts.

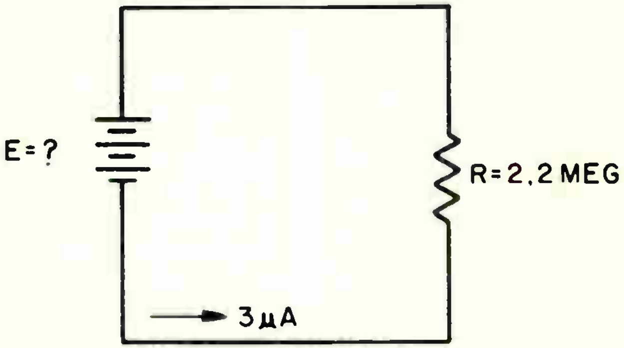

Fig. 23. Find E where I = 3 µa and R = 2.2 megohms.

In the example shown in Fig. 23 the current is given in microamps and the resistance in megohms and we have to find the voltage. We can convert microamperes to amperes by dividing the current by 1,000,000 and megohms to ohms by multiplying the resistance by 1,000,000. Thus substituting the formula:

$$E = I \times R$$

$$E = \frac{3}{1,000,000} \times 2.2 \times 1,000,000$$

$$= \frac{3 \times 2.2 \times 1,000,000}{1,000,000}$$

Here we simply cancel the 1,000,000 above and below the division line and multiply 3 × 2.2 and get our answer 6.6 volts. It is far simpler to do the problem this way than it is to convert to amps and ohms. These same techniques can be used regardless of what units the current and resistance are in. Remember that if the current is given in milliamperes simply write it over 1,000 and this will convert it to amps. If it is given in microamperes write it over 1,000,000 and this will convert it to amps. If the resistance is given in K-ohms multiply it by 1,000 to convert it to ohms and if it is given in megohms multiply it by 1,000,000 to convert it to ohms. Then before doing anything else look for numbers above and below the division line that can be cancelled and then perform the remaining multiplication.

FINDING R

We can rearrange Ohm's Law to find the resistance in a circuit if we know the voltage and the current. To do this we use Ohm's Law in the form:

$$R = \frac{E}{I}$$

Let us go back to the circuit shown in Fig. 15. Here the voltage is 20 volts and we found that the current is 10 amps. Now let us use Ohm's

Law to see what value of resistance we get using these values of voltage and current.

$$R = \frac{E}{I}$$

$$R = \frac{20}{10}$$

$$= 2 \text{ ohms}$$

As you see, the value obtained for the resistance is the value given originally so that we know that our calculation is correct.

When the voltage is given in volts and the current given in amps, determining the resistance in the circuit is quite simple. However, often the current will be in milliamps or microamps. In this case we must convert the current to amps in order to use the formula.

To convert milliamps to amps we divide by 1,000. We can do the same thing simply by multiplying the voltage by 1,000 and using the current in milliamperes in the formula. Thus the formula for resistance becomes

$$R = \frac{E \times 1{,}000}{I \text{ (in ma)}}$$

If the current is given in microamps we can multiply the voltage by 1,000,000 and then use the current in microamperes in the formula. Then the formula becomes

$$R = \frac{E \times 1{,}000{,}000}{I \text{ (in } \mu\text{a)}}$$

in microamperes.

Multiplying the voltage by 1,000 when the current is in milliamperes and by 1,000,000 when it is in microamperes eliminates the necessity of performing a decimal division. It is usually easier to divide by whole numbers and then multiply the result by either 1,000 or 1,000,000 than it is to perform the conversion to amperes first and then perform a decimal division. An example of a problem where the current is in milliamperes is as follows: find the resistance in a circuit where the voltage is 3 volts and the current is 3 milliamperes. Using the formula:

$$R = \frac{E \times 1{,}000}{I \text{ (ma)}}$$

$$R = \frac{3 \times 1000}{3}$$

$$R = 1000 \text{ ohms}$$

An example where the current is in microamperes is: find the resistance in a circuit where the voltage is 8 volts and the current 100 microamperes.

Using the formula:

$$R = \frac{E \times 1{,}000{,}000}{I \text{ (}\mu\text{a)}}$$

$$R = \frac{8 \times 1{,}000{,}000}{100}$$

the easiest way to do this problem is to divide the top and bottom by 100 simply by cancelling the 100 on the bottom and removing two zeros from the 1,000,000 and then we have

$$\begin{aligned} R &= 8 \times 10{,}000 \\ &= 80{,}000 \text{ ohms} \end{aligned}$$

SUMMARY

In this section of this lesson you have seen how the current in a circuit is affected by the voltage and the resistance in the circuit. We found that increasing the voltage increased the current and decreasing the voltage decreased the current. We said that the current varies directly as the voltage. In the case of the resistance in the circuit we found it had the opposite effect on the current. Increasing the resistance in the circuit decreases the current and decreasing the resistance increases the current. We say that the current varies inversely with the resistance.

We saw the three important forms of Ohm's Law and how you can use it in solving problems involving voltage, current and resistance in a circuit. If any two of these three quantities are known, you can use Ohm's Law to find the other.

You should remember the three forms of Ohm's Law. You will use them over and over again, so it would be worthwhile to take time now to memorize them. The three forms are:

$$I = \frac{E}{R}$$

$$E = IR$$

$$R = \frac{E}{I}$$

Remember that to use Ohm's Law the voltage must be in volts, the current in amps and the resistance in ohms. We showed you simple ways of getting around the problem of performing decimal operations in each type of problem. As you do the self-test questions do not hesitate to go back to the section of the lesson that dealt with the particular kind of problem you are working on and review how we worked the problem. It is not so important for you to memorize how to do these problems as it is to be able to do them with the aid of the examples given in the textbook. You will not be able to remember all you will learn about electronics either during your course or after you have completed your course, but the important thing is to remember the basic fundamentals and then know where to find the other facts that you may need.

If you find that you are puzzled by one of the self-test questions and you can't work it out even after reviewing the lesson, find the answer to the question at the back of the book and see how we did the problem. Then close the book and try to do the problem yourself and other problems of the same type without referring to the answers again. Don't be discouraged if you don't get the right answer every time or if you have trouble remembering the various forms of Ohm's Law at first. Make a determined effort to memorize them and after you have used them a number of times you will find that they will remain in your mind.

SELF-TEST QUESTIONS

(au) Give the form of Ohm's Law that is used when you know the voltage and the current and want to find the resistance.

(av) Write the Ohm's Law formula that is used when you know the current and resistance in a circuit and want to find the voltage.

(aw) Write the Ohm's Law formula used when you know the voltage and resistance in a circuit and need to find the current.

(ax) In a circuit such as Fig. 15, find the current if the voltage is 15 volts and the resistance is 3 ohms.

(ay) In a circuit like Fig. 15, find

the current if the voltage is 12 volts and the resistance is 6,000 ohms.

(az) In a circuit like Fig. 15 find the current if the voltage is 28 volts and the resistance 7,000 ohms.

(ba) In a circuit like Fig. 15 find the current if the voltage is 15 volts and the resistance 300 K-ohms.

(bb) Find the voltage in a circuit like the one in Fig. 21 where the current is 3 amps and the resistance is 6 ohms.

(bc) Find the voltage in a circuit like the one shown in Fig. 21 where the current is 20 ma and the resistance 1,000 ohms.

(bd) Find the voltage in a circuit like the one shown in Fig. 21 when the current is 18 ma and the resistance is 3K-ohms.

(be) Find the voltage in a circuit like Fig. 21 when the current is 47 μa and the resistance 200,000 ohms.

(bf) Find the voltage in a circuit like Fig. 21 when the current is 58 μa and the resistance 330K-ohms.

(bg) Find the voltage in a circuit like Fig. 21 when the current is 6 μa and the resistance 2 megohms.

(bh) In a simple series circuit if the applied voltage is 12 volts, and the current is 4 amps, what is the resistance in the circuit?

(bi) Find the resistance in the circuit if the applied voltage is 24 volts and the current 8 ma.

(bj) Find the resistance in the circuit if the applied voltage is 45 volts and the current flowing is 15 ma.

(bk) If the voltage applied to a circuit is 34 volts, and the current flowing is 170 μa, what is the resistance in the circuit?

(bl) If the voltage applied to a circuit is 144 volts, and the current flowing in the circuit is 120 μa, what is the resistance in the circuit?

(bm) Fill in the missing words in the following statement: if the voltage applied to a circuit is increased, the current will _____, and if the voltage applied to a circuit is decreased, the current will __________.

(bn) Fill in the missing words in the following: if the resistance in a circuit is increased, the current will ______, and if the resistance in a circuit is decreased, the current will _____.

ANSWERS TO SELF-TEST QUESTIONS

(a) 4 amps. If the original current was 1 amp and the number of electrons increased by four times the new current must be 4 amps.

(b) 3 amps × 1.4 = 4.2 amps.

(c) 7 amps × 1.4 = 9.8 amps.

(d) 7 amps ÷ 1.4 = 5 amps.

(e) 21 amps ÷ 1.4 = 15 amps.

(f) $6.00 = 600 cents.

(g) 350 cents = $3.50.

(h) 2 amps = 2000 ma. To perform the conversion we write 2 amps as 2.000 and then move the decimal point three places to the right and get 2000. In performing a conversion of this type, another way to look at it simply is adding three zeros.

(i) 6 amps = 6000 ma.

(j) 3.5 amps = 3500 ma. Again, we have simply moved the decimal point three places to the right; 3.5 amps = 3500 ma.

(k) .42 amps = 420 ma.

(l) .037 amps = 37 ma. Moving the decimal point three places to the right, we get 037, and since the zero has no significance we simply write the answer as 37 ma.

(m) .002 amps = 2 milliamps. Moving the decimal point three places to the right we get 002. ma and we drop the two zeros to the left of the 2 since they have no significance.

(n) 46 ma = .046 amps. Here we move the decimal point three places to the left. In order to do this we add a 0 to the left of the 4; thus 46 ma becomes .046 amps.

(o) 822 ma = .822 amps. To convert from the smaller unit to the larger unit we move the decimal point three places to the left.

(p) 1327 ma = 1.327 amps. Again, we simply move the decimal point three places to the left.

(q) 2 amps = 2,000,000 µa. To convert from amps to µa we have moved the decimal point six places to the right. To do this we must add the six zeros.

(r) .0017 amps = 1700 µa. Moving the decimal point six places to the right, we have to add two zeros to the right of the 7 in order to do this and .0017 can be written .001700 and then we move the decimal point six places to the right and get 1700 µa.

(s) 20 µa = .00002 amps. To convert from the smaller unit to the larger unit we move the decimal point six places to the left. In order to move it six places we have to add four zeros to the left of the 2.

(t) 147 µa = .000147 amps. Again, we add zeros to the left of the 1 and move the decimal point six places to the left to convert from microamps to amps.

(u) .26 ma = 260 µa. To convert from milliamps to microamps we move the decimal point three places to the right. In order to move it three places we have to add a zero to the right of the 6 so .26 ma becomes 260 µa.

(v) .031 ma = 31 µa. Again, to convert from the larger unit ma to the smaller unit microamperes we move the decimal point to the right. Thus, .031 ma becomes 031. µa. The 0 to the left of the 3 has no significance so we drop it and write the answer as 31 µa.

(w) 6100 µa = 6.1 ma. To convert from the smaller unit to the larger unit we move the decimal point to the left - thus when we move it three places to the left 6100 µa becomes 6.1 ma.

(x) 927 µa = .927 ma. Moving the decimal point three places to the left 927. µa becomes .927 ma.

(y) 327,000 µa = 327 ma. To convert from the smaller unit to the larger unit we move the decimal point three places to the left. Thus, 327,000 µa becomes 327 ma. To convert the 327 ma to amps we again move the decimal point three places to the left and get .327 amps.

(z) - 45 volts.

(aa) Terminal 1 is + 45V, and terminal 2 is - 45V.

(ab) The peak voltage between terminal 1 and ground will be 20 × 1.4 = 28 volts. It will be positive during one half cycle and negative the next half cycle.

(ac) + 60 volts. The two batteries are connected in series aiding, and therefore their potentials add, 15 + 45 = 60 volts. The terminal is positive because it's connected directly to the positive terminal of one of the batteries.

(ad) 0 volts. The two batteries are connected in series opposing and therefore the battery voltages subtract. Since both batteries are 22-1/2 volts the net value of the voltage between terminal 1 and ground will be 0.

(ae) + 22-1/2 volts. The two batteries are connected to oppose each other; thus their voltages subtract. 45V - 22-1/2V = 22-1/2V. The polarity will be that of the higher voltage battery, which is the 45 volt battery. Since its positive terminal is connected to terminal 1, then terminal 1 will be positive.

(af) - 1.5 volts. The two batteries are connected in series opposing and therefore their voltages subtract, 4.5 volts - 3 volts = 1.5 volts. The polarity will be that of the larger battery and since the negative terminal of the 4.5 volt battery connects to terminal 1, terminal 1 will be negative. Reversing the batteries had no effect on the polarity because we simply reversed their positions, keeping their polarities as shown in Fig. 9C. It makes no difference which position the battery is in insofar as the total voltage is concerned; as long as they are opposing each other you subtract to get the voltage produced by the two in series. In the circuit as shown in Fig. 9C, the polarity of terminal 1 is - 1.5 volts just as it is when the position of the two batteries is changed.

(ag) 30 volts when the two are aiding and 0 volts when the two are opposing. When the peak generator voltage has the same polarity as the battery voltage the total voltage will be the sum of the two voltages, 15V + 15V = 30V. When the generator has the opposite polarity to the battery, the two voltages will subtract. 15V - 15V = 0V.

(ah) +35 volts when they are aiding and - 5 volts when they are opposing.

When the peak generator voltage has the same polarity as the battery voltage, the two voltages add, 20V + 15V = 35V. When the two voltages oppose, the polarity of the generator will be - 20V with respect to terminal 1. Therefore the voltage between terminal 1 and ground will be 15V - 20V = - 5V.

(ai) - 75V when they aid and + 15V when they oppose. When the peak generator voltage has the same polarity as the battery voltage, the two voltages add. 30V + 45V = 75V. Since the negative terminal of the battery is connected to terminal 1, it will be - 75V with respect to ground. When the generator voltage opposes the battery voltage the peak voltage between terminal 1 and ground will be - 30V + 45V = + 15V.

(aj) + 30 volts when they are aiding and + 10 volts when they are opposing. When the peak generator voltage aids the battery voltage, the two voltages add. + 20V + 10V = + 30V. When the peak generator voltage opposes the battery voltage will have, + 20V - 10V = + 10V.

(ak) - 75V when they are aiding and

- 15V when they are opposing. When the two voltages have the same polarity their voltages add. 45 + 30 = 75V and since the negative terminal of the battery connects to terminal 1, terminal 1 will be negative. Another way of looking at this is to write the battery voltage as - 45V and the generator voltage as - 30V and add the two together. - 45V - 30V = - 75V. When the two voltages oppose the generator voltage subtracts from the battery voltage. 45V - 30V = 15V. Since the battery voltage is higher than the generator voltage the polarity of terminal 1 will be the polarity of the battery which is minus and therefore it will be -15V. Another way of doing this is to write the voltages down with their polarity. Here we have -45V + 30V = - 15V.

(al) The current will decrease. As a matter of fact, if we double the resistance in the circuit, the current will be cut exactly in half.

(am) Carbon resistors, wire-wound resistors and metal oxide film resistors are the three most widely used types of resistors in electronics.

(an) 4.7 K-ohms. To convert 4,700 ohms to K-ohms, you move the decimal point three places to the left. This is the same as dividing by 1,000 and getting 4.7 K-ohms.

(ao) 5.6 megohms. To convert 5,600,000 ohms to megohms you must move the decimal point six places to the left. This is the same as dividing by 1,000,000.

(ap) 330K-ohms. There are 1,000 ohms in a K-ohm and 1,000,000 ohms in a megohm. Therefore there must be 1,000 K-ohms in a megohm. To convert megohms to K-ohms you multiply by 1,000 and to do this you move the decimal point three places to the right. Thus, .330M = 330K.

(aq) 2,200,000 ohms. There are 1,000,000 ohms in a megohm and therefore to convert 2.2 megs to ohms you must multiply by 1,000,000. To do this you move the decimal point six places to the right.

(ar) 8,200 ohms. There are 1,000 ohms in a K-ohm and therefore to convert K-ohms to ohms, you multiply by 1,000. You do this by moving the decimal point three places to the right.

(as) .680 megohms. There are 1,000 K-ohms in a megohm and therefore to convert K-ohms to megohms you must divide by 1,000. To do this you simply move the decimal point three places to the left.

(at)

The symbol for resistance is shown above. There are probably more resistors used in electronics equipment than any other parts, so it is extremely important that you remember this symbol. The resistance of a resistor is usually indicated by writing the resistance either directly above or directly below the resistance symbol. The value may be given in ohms, K-ohms or megohms depending upon the size of the resistor. Usually the shortest form is used in order to conserve space on the diagram.

(au) $R = \frac{E}{I}$

(av) $E = IR$

(aw) $I = \frac{E}{R}$

(ax) 5 amps. To solve this problem you use the formula:

$$I = \frac{E}{R}$$

and substituting 15 volts for E and 3 ohms for R we get

$$I = \frac{15}{3}$$

$$= 5 \text{ amps}$$

(ay) The current will be 2 ma. We use the formula:

$$I = \frac{E}{R}$$

Since dividing 6,000 into 12 would be a decimal division, we can multiply by 1,000 and get our answer directly in milliamperes. When we do this we have:

$$I\ (\text{ma}) = \frac{12}{6{,}000} \times 1{,}000$$

$$I = \frac{12{,}000}{6{,}000}$$

and cancelling three zeros above and below the line we get:

$$I = \frac{12}{6}$$

$$= 2 \text{ ma}$$

(az) The current in this case will be 4 ma. You use exactly the same method as in the preceding example; since dividing 7,000 into 28 will involve a decimal division you can multiply by 1,000 and get your answer directly in milliamperes. In this problem we have:

$$I = \frac{28}{7{,}000} \times 1{,}000$$

$$I = \frac{28{,}000}{7{,}000}$$

and then cancelling three zeros above and below the line we have:

$$I = \frac{28}{7}$$

$$= 4 \text{ ma}$$

(ba) In this problem if we multiplied by 1,000 to get our answer in milliamperes, we would still have a decimal division because we must convert 300K to ohms by multiplying it by 1,000. Thus we would have:

$$I = \frac{15}{300 \times 1000} \times 1{,}000$$

The 1,000 above the division line would simply cancel the 1,000 below the division line and we would have to divide 300 into 15. So instead of converting our answer directly to milliamperes it would be better to convert to microamperes. Now the problem becomes:

$$I = \frac{15}{300 \times 1000} \times 1{,}000{,}000$$

$$I = \frac{15{,}000{,}000}{300{,}000}$$

and now cancelling five zeros above the line and five zeros below the line we have

$$I = \frac{150}{3} = 50\ \mu a$$

(bb) The voltage will be 18 volts. We use the formula:

$$E = IR$$

and substituting 3 amps for I and 6 ohms for R we get:

$$E = 3 \times 6$$
$$= 18 \text{ volts}$$

(bc) In this example the current is 20 ma, and we must convert this to amps. The easiest way to do this is to simply divide it by 1,000. Therefore we will substitute $\frac{20}{1000}$ for I in the formula and 1000 for R. Using the formula:

$$E = IR$$

$$E = \frac{20}{1000} \times 1{,}000$$

$$E = \frac{20{,}000}{1{,}000}$$

and now we simply cancel three zeros above the line and three zeros below the line and we get:

$$E = 20 \text{ volts}$$

(bd) In this problem, the current which is in milliamps must be converted to amps by dividing it by 1,000 and the resistance which is in K-ohms must be converted to ohms by multiplying it by 1,000. Using the formula to find the voltage we have:

$$E = \frac{18}{1000} \times 3 \times 1000$$

This can be written:

$$E = \frac{18 \times 3 \times 1000}{1000}$$

and now we simply cancel the 1000 above the line and the 1000 below the line and we get as our answer:

$$E = 18 \times 3$$
$$= 54 \text{ volts}$$

(be) In this example the current which is given in microamps must be converted to amps by dividing it by 1,000,000. Thus our problem becomes:

$$E = \frac{47}{1{,}000{,}000} \times 200{,}000$$

Now you can cancel five zeros above the line and five zeros below the line and we get:

$$E = \frac{47 \times 2}{10} = \frac{94}{10} = 9.4 \text{ volts}$$

(bf) In this example, the current which is in microamperes must be converted to amps by dividing it by 1,000,000, and the resistance which is given in K-ohms must be converted to ohms by multiplying it by 1,000. Thus using the formula to find the voltage we have:

$$E = \frac{58}{1{,}000{,}000} \times 330 \times 1{,}000$$

$$E = \frac{58 \times 330 \times 1000}{1{,}000{,}000}$$

We have four zeros above the division line so we can cancel four zeros below the line and then our problem becomes:

$$E = \frac{58 \times 33}{100}$$

and now multiplying 58 × 33 we get:

$$E = \frac{1914}{100} = 19.14 \text{ volts}$$

(bg) In this example the current, which is in μa, must be converted to amps by dividing it by 1,000,000, and the resistance which is in megohms, must be converted to ohms by multiplying it by 1,000,000. Thus to find the voltage we have:

$$E = \frac{6}{1{,}000{,}000} \times 2 \times 1{,}000{,}000$$

$$E = \frac{6 \times 2 \times 1{,}000{,}000}{1{,}000{,}000}$$

and now we can simply cancel the 1,000,000 above the division line with the 1,000,000 below the division line and our voltage becomes

$$E = 6 \times 2 = 12 \text{ volts}$$

(bh) 3 ohms. To solve a problem of this type we use the formula:

$$R = \frac{E}{I}$$

In substituting 12 volts for E and 4 amps for I we get:

$$R = \frac{12}{4}$$

$$= 3 \text{ ohms}$$

(bi) In this example, the current is given in milliamperes and we must convert it to amps. We can do this by multiplying the voltage by 1,000. When we do this we have:

$$R = \frac{24 \times 1{,}000}{8}$$

$$R = \frac{24{,}000}{8}$$

$$= 3{,}000 \text{ ohms}$$

(bj) We use the same procedure in this example as we did in the preceding example. We multiply the voltage by 1,000 and this is the equivalent of converting the current which is in ma to amps. Therefore our problem becomes:

$$R = \frac{45 \times 1{,}000}{15}$$

$$R = \frac{45{,}000}{15}$$

$$= 3{,}000 \text{ ohms}$$

(bk) In this example, the current is given in microamperes. To convert the current to amperes we can multiply the voltage by 1,000,000 and then proceed with our problem.

$$R = \frac{34 \times 1{,}000{,}000}{170}$$

$$R = \frac{34{,}000{,}000}{170}$$

$$R = \frac{3,400,000}{17}$$

$$= 200,000 \text{ ohms.}$$

(bl) This example is the same as the preceding example; the current is in microamperes and we must convert it to amps. We do this by multiplying the voltage by 1,000,000. Our problem therefore becomes:

$$R = \frac{144 \times 1,000,000}{120}$$

$$R = \frac{144,000,000}{120}$$

$$R = \frac{14,400,000}{12}$$

$$R = 1,200,000 \text{ ohms.}$$

If we wish to convert this value to megohms we can do so by dividing by 1,000,000, in which case our answer becomes 1.2 megs.

(bm) The completed statement, which is very important, is as follows: If the voltage applied to a circuit is increased, the current will increase, and if the voltage applied to a circuit is decreased, the current will decrease.

(bn) The complete statement, which describes how resistance affects the current in a circuit, is as follows: if the resistance in a circuit is increased, the current will decrease, and if the resistance in a circuit is decreased, the current will increase.

LOOKING AHEAD

You have reached a point where you have learned about voltage, current and resistance and have started to study simple circuits. You used the three forms of Ohm's Law in performing calculations in simple circuits.

In the next lesson, you will put some of these simple circuits together to form more complex circuits and you will see that even more complex circuits follow the same rules that were followed in these simple circuits. You have already come a long way in your studying of electronics and you will add considerably to your knowledge in the next lesson.

Lesson Questions

Be sure to number your Answer Sheet B103.

Place your Student Number on every Answer Sheet.

Most students want to know their grade as soon as possible, so they mail their set of answers immediately. Others, knowing they will finish the next lesson within a few days, send in two sets of answers at a time. Either practice is acceptable to us. However, don't hold your answers too long; you may lose them. Don't hold answers to send in more than two sets at a time, or you may run out of lessons before new ones can reach you.

15 1. If a 9 volt battery and a 6 volt battery are connected in series aiding, what will the output voltage of the two batteries be?

3 2. If a 6 volt battery and a 3 volt battery are connected in series opposing, what will the output voltage be?

3. If a battery and a generator are connected as shown in Fig. 10A, and the battery voltage is 6 volts and the peak generator voltage is 6 volts, what will the maximum positive potential reached at terminal 1 be?

4. If in the circuit shown in Fig. 10A, the battery voltage is 6 volts and the generator peak voltage is 9 volts, will terminal 1 ever be negative with respect to ground - if so how much?

5. What are the three types of resistors commonly used in electronic equipment?

6. Give the three forms of Ohm's Law.

7. If the current flowing in a circuit is 2 amps, when the voltage is 50 volts, what will the current be if the voltage is reduced to 25 volts?

8. If the current flowing in a circuit is 50 ma when the resistance is 1,000 ohms, what will the current be if the resistance is reduced to 500 ohms?

9. If the voltage applied to a circuit is 4 volts, and the resistance in the circuit is 2,000 ohms, what will the current be?

10. If the current flowing in a circuit is 3 ma and the resistance is 6,000 ohms, what will the voltage be?

GETTING YOUR 'SECOND WIND'

After an opening burst of speed, a champion long-distance runner drops down to a steady natural pace. This brief period of relaxation releases that reserve of power called "second wind." He is then able to overtake and pass the now nearly exhausted leaders in the race.

No matter what you are doing, you can always do it better once you get your second wind. Instead of fighting that sleepy feeling which sometimes comes when you are studying, stop and relax for a few minutes so as to release your own supply of reserve power. Here are some ways to relax, all worth trying.

Get up and exercise for a few minutes. Get a drink of cold water. Step outside for a few deep breaths of fresh air. Take a brisk walk up and down the road or once around the block.

If you "shake yourself awake" in one of these ways, you'll find it isn't at all hard to get that second wind which enables you to study longer and makes the going easier. Then you'll get in some real worthwhile studying -- then you'll get things done!

SERIES AND PARALLEL CIRCUITS

B104-1

STUDY SCHEDULE

By dividing your study into the steps given below, you can get the most out of this part of your NRI Course in the shortest possible time. Check off each step when you finish it.

☐ 1. **Introduction** . . . . **Pages 1 - 3**
In this section you learn the difference between series and parallel circuits.

☐ 2. **Series Circuits** . . . . **Pages 3 - 13**
You learn about resistance in series circuits and about voltage drops. You learn about the very important relationship between the voltage drops in a series circuit and the source voltage.

☐ 3. **Parallel Circuits** . . . . **Pages 13 - 21**
You learn how to find the resistance of a parallel circuit and you study voltage and current in parallel circuits.

☐ 4. **Series-Parallel Circuits** . . . . **Pages 21 - 31**
You learn how to solve problems involving series parallel circuit combinations.

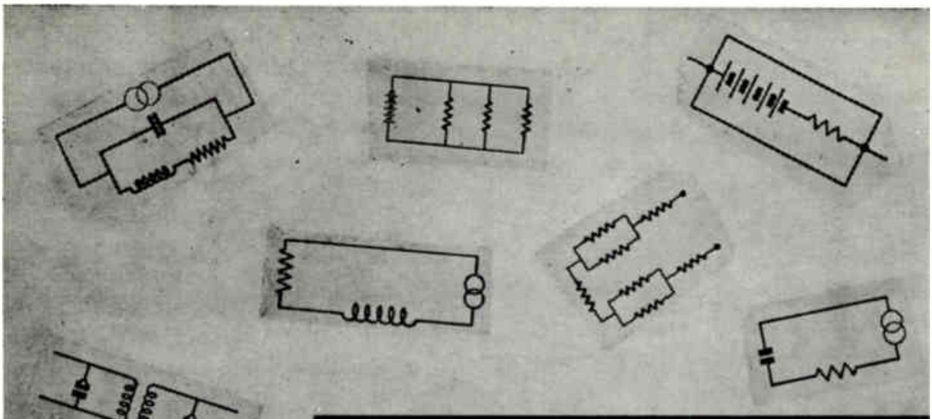
☐ 5. **Answers to Self-Test Questions** . . . . **Pages 31 - 36**

☐ 6. **Answer the Lesson Questions.**

☐ 7. **Start Studying the Next Lesson.**

NATIONAL RADIO INSTITUTE, WASHINGTON, D.C. 20016

P115M575 1975 EDITION Litho in U.S.A.



SERIES AND PARALLEL CIRCUITS

So far you have been studying relatively simple circuits. However, in spite of this, you have learned a great deal about electricity. You have studied voltage, current and resistance and the units that are used to measure them. You know that the units in which current is measured are the ampere, milliampere and microampere. The units used to measure voltage are the volt, the millivolt, the microvolt and the kilovolt. The units used to measure resistance are the ohm, K-ohm and megohm. You should be familiar with all these quantities at this time; you should know what they mean and how to convert from one unit to another.

You have also studied Ohm's Law and how it relates voltage, current and resistance. If you know any two of these values, you should be able to use Ohm's Law to find the third.

So far the circuits that you have studied have been relatively simple circuits. In almost all cases they have been series circuits. By a series circuit, we mean that the parts are connected so that there is only one path through which current can flow. In other words, if a resistor is connected between the negative and positive terminals of a battery, the electrons must leave the negative terminal of the battery, flow through the resistance to the positive terminal of the battery and then through the battery back to the negative terminal. There is only one path through which the current can flow.

There are other series circuits in addition to a circuit with only one resistor. A series circuit may have a number of resistors such as the circuit shown in Fig. 1. The circuit is called a series circuit, because like the simple circuits you have studied, the parts are connected in series so that electrons must flow first from the negative terminal of the battery through R_1, and then through R_2 and finally through R_3 back to the positive terminal of the battery and then through the battery back to the negative terminal. Electrons flow through one part after the other, in series. The series circuit is a very important circuit in elec-

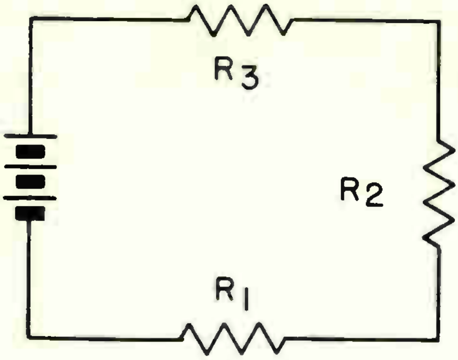


Fig. 1. A series circuit.

tronics; make sure that you understand what is meant by a series circuit.

In addition to a series circuit, we have what is known as a parallel circuit, such as is shown in Fig. 2. Here we have three resistors connected in parallel across the battery. We say that they are in parallel because there are three parallel paths through which current from the battery can flow. Electrons leaving the negative terminal of the battery can flow through either R_1, R_2, or R_3 and then back to the positive terminal of the battery and through the battery back to the negative terminal.

In this lesson you are going to study both series and parallel circuits. Both are important in electronics. Many circuits found in electronic equipment are series circuits; many circuits are parallel circuits. Some circuits are combinations of both series and parallel circuits.

When resistors are connected in series, such as in Fig. 1, you sometimes need to find the total resistance of the resistors. Similarly when they are connected in parallel as in Fig. 2, sometimes you have to find the effective value of the three resistors in parallel. We will learn how to do both in this lesson and you will learn how current flow is affected by connecting resistors both in series and in parallel.

In the first section of the lesson we will go into series circuits in considerable detail, and then in the second section we will go into parallel circuits. After we have completed both series and parallel circuits, we will study circuits that are combinations of both series and parallel circuits. As you may well realize, it is extremely important that you understand everything covered in series circuits first, and then what is covered in parallel circuits later. If there are some points that give you trouble, be sure to restudy the parts of the lesson you are in doubt about before going on. If you cannot work out the problem yourself, be sure to write to NRI and get additional help. If you do not master series circuits you will have trouble with parallel circuits. If you leave some points unclear in parallel circuits, then when you go on to study combinations of series and parallel circuits you will have difficulty with

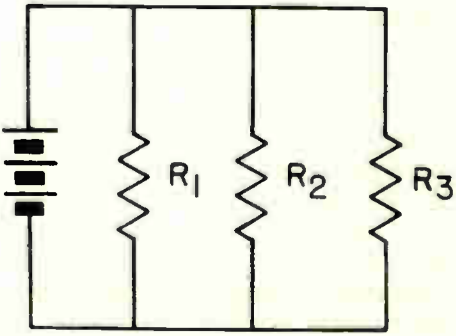

Fig. 2. A parallel circuit.

them. Learning electronics is simply a matter of taking one simple circuit at a time, learning how it works and then building on that knowledge. If you miss some of the basic fundamentals, you will have difficulty with more advanced circuits.

Be sure you can answer the self-test questions at the end of each section. These questions will test you on each section, and they are a good indication of whether or not you have mastered the material covered. Now, let us go ahead and study series circuits.

Series Circuits

A series circuit is a circuit in which there is only one path for electrons to flow. In a series circuit, such as we saw in Fig. 1, the current flowing is the same at all parts in the circuit. In other words, the current flowing through R_1 is equal to the current flowing through R_2; equal to the current flowing through R_3 and equal to the current supplied by the battery. The leads or conductors connecting the resistors and batteries together are also carrying the same current as is flowing through the resistors. This is one of the important things you should remember about a series circuit. There is only one path for electrons to flow, and the current flow in the circuit must be the same at all points in the circuit.

When we have resistors connected in a circuit such as in Fig. 1, we say that the resistors are connected in series. Now, let us see what effect these resistors connected in series have on the current flow in the circuit.

RESISTORS IN SERIES

In Fig. 3 we have shown a circuit that is identical to Fig. 1, except that in Fig. 3 we have given the battery a voltage of 15 volts and given each resistor a definite value. When the resistors are connected in series in this way, each resistor opposes the flow of current in the circuit. The total opposition to current flow will be equal to the sum of the resistances of the individual resistors. Thus, when resistors are connected in series, we can say that their total resistance is equal to the sum of the resistances. In this particular case we can express this mathematically as:

$$R_T = R_1 + R_2 + R_3$$

This formula can be used for find-

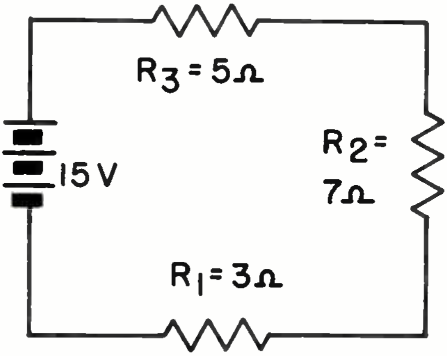

Fig. 3. A series circuit.

ing the resistance of any number of resistors connected in series. The total resistance is always equal to the sum of the individual resistors. Thus if you have five resistors connected in series and want to know the total resistance of the five in series you simply add the resistances together. Similarly, if there are ten resistors connected in series, to find the total opposition to current flow you simply add the value of the ten resistors together.

The opposition to current flow in the circuit will be equal to the total resistance of the resistors in series. In Fig. 3, the total resistance is:

$$R_T = 3 + 7 + 5 = 15 \text{ ohms}$$

Therefore, the three resistors connected in series offer the same opposition to current flow in the circuit as a single 15-ohm resistor would offer.

To find the current that will flow in the circuit you use Ohm's Law. You use it in the form:

$$I = \frac{E}{R}$$

When you have a number of resistors in series, R becomes the total value of these resistors, or R_T. In the circuit shown in Fig. 3, $R_T = 15$ ohms, and therefore in this circuit, the total current flow will be:

$$I = \frac{15}{15} = 1 \text{ amp}$$

The example given in Fig. 3 was comparatively simple, because the resistance values were all small and we did not get involved in any decimal divisions in finding the current. A somewhat more difficult example of a series circuit is shown in Fig. 4. However, this should not cause any more difficulty in finding the total resistance in the circuit than the example in Fig. 3, nor should it cause you any more difficulty in finding the total current flowing in the circuit, if you use the procedures you learned in the preceding lessons.

The first step in finding the total current that will flow in this circuit is to find the total resistance. To do this, you must convert all the resistance values to ohms. $R_1 = 1200$ ohms. $R_2 = 1.5$K-ohms. To convert this to ohms you multiply by 1000; thus 1.5 × 1000 = 1500 ohms. R_3 is given as 1800 ohms. R_4 is 1.2K-ohms, and again to convert this to ohms you multiply by 1000 and get 1200 ohms. Similarly, R_5 which is 3.3K-ohms is equal to 3300 ohms.

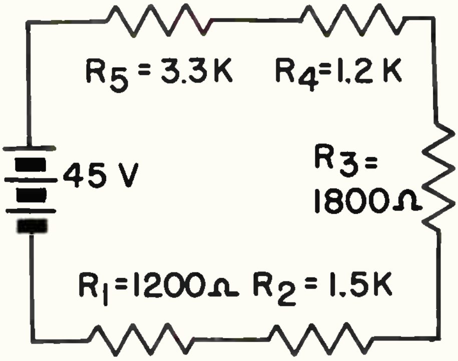

Fig. 4. A series circuit with five resistors.

Now you simply write down the values of these resistances as shown in Fig. 5, and then add the five values to get the total resistance in the circuit.

As shown in Fig. 5, the total resistance of the five resistors connected in series is 9000 ohms. Now, we use Ohm's Law to find the current that will flow in the circuit. We use the form,

$$I = \frac{E}{R}$$

If we substitute the values of 45 volts for the voltage, and 9000 ohms for the resistance, we will see that we immediately are involved with a decimal division. However, you will remember from the preceding lesson that you could multiply by 1000 and get the current directly in milliamperes. Once you do this the problem becomes:

$$I = \frac{45}{9000} \times 1000$$

and we can cancel three zeros above and below the division line so that our problem is

$$I = \frac{45}{9}$$

$$= 5 \text{ ma}$$

Any series circuit problem can be solved in the same way. To find the current flowing in the circuit you find the total resistance in the circuit and then divide this total resistance into the voltage applied. This will give you the total current flow in the circuit.

MEASURING VOLTAGES

Voltages are measured by means of an instrument called a voltmeter. To measure the voltage across a battery, a generator or a circuit, you connect the voltmeter directly across the part where you want to measure the voltage.

$$\begin{array}{r} 1200 \\ 1500 \\ 1800 \\ 1200 \\ \underline{3300} \\ 9000 \end{array}$$

Fig. 5. Total value of the five resistors in Fig. 4.

To measure dc voltages, you use a dc voltmeter. A dc voltmeter has one terminal marked with a minus sign and the other terminal marked with a plus sign. To measure the voltage across the battery shown in Fig. 6, you connect the minus terminal of the meter to the negative terminal of the battery and the plus terminal of the meter to the positive terminal of the battery. When you connect a meter across a 30-volt battery such as shown in Fig. 6, the meter pointer will move up the scale and indicate a voltage of 30 volts. Don't worry about how the meter works now - we will go into that later. The important point to see here is that you connect the minus terminal of the meter to the minus terminal of the battery and the plus terminal of the meter to the plus terminal of the battery.

Now looking at Fig. 6, you see that

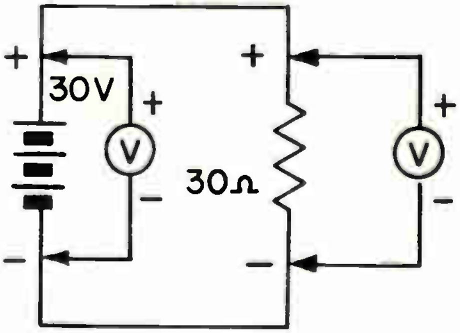

Fig. 6. Measuring voltage in a simple series circuit.

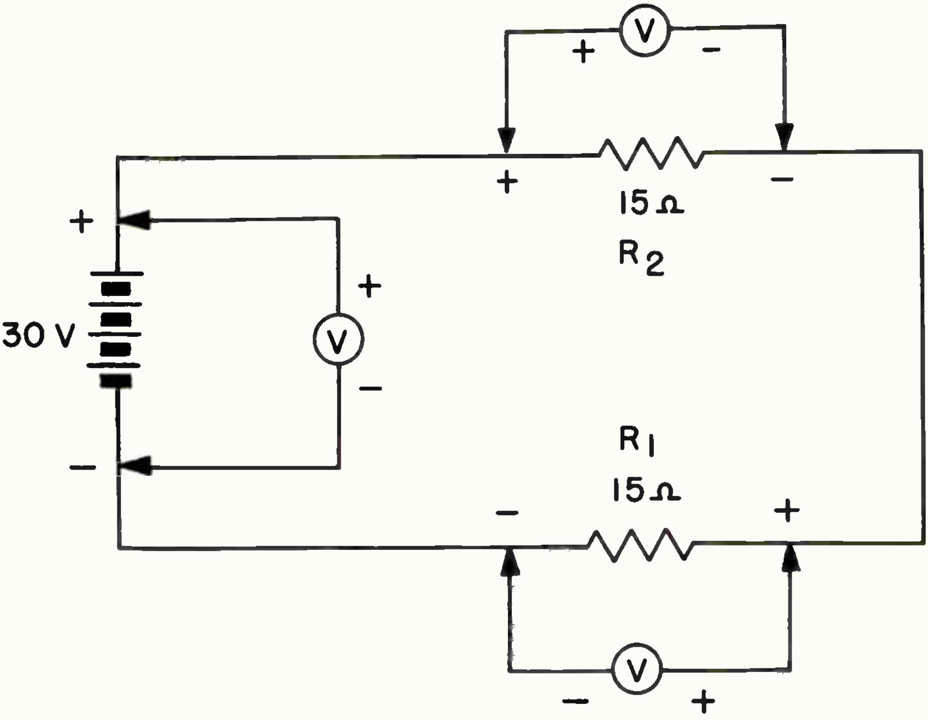

Fig. 7. Measuring voltage across series resistors.

the resistor is connected directly across the battery. Suppose we wanted to measure the voltage across the resistor, how would we do it?

Since the resistor is connected directly across the battery we would actually be reading the battery voltage if we connect the meter across the resistor. Therefore the meter must be connected across the resistor as shown in Fig. 6. The minus terminal of the meter must be connected to the end of the resistor that connects to the negative terminal of the battery and the plus terminal of the meter must be connected to the end of the resistor that connects to the plus terminal of the battery. Again, since the meter and resistor are both connected directly across the battery, the meter would indicate that the voltage was 30 volts.

Now, let us look at Fig. 7. Here, instead of a single 30-ohm resistor, we have two 15-ohm resistors connected in series across the 30-volt battery. Since the total resistance offered by the two 15-ohm resistors will be 30 ohms, insofar as the battery is concerned, the circuit will appear exactly like the one in Fig. 6. If we use Ohm's Law we would find that the current in both cases was 1 amp. If we measure the voltage across the battery, we connect the meter across the battery in exactly the same way as we connected it in Fig. 6.

If we want to measure the voltage across the two resistors in series, we would connect the negative terminal of the meter to the terminal of R_1 that connects to the negative terminal of the battery and the plus terminal of the meter to the terminal of R_2 that connects to the plus terminal of the battery. The meter would indicate 30 volts across the two resistors, because once again we are in effect simply connecting the meter across the battery. However, if the voltage across the two resistors in series is 30 volts, then it is logical to assume that the voltage across one resistor is only half this value or 15 volts. Indeed, if we connect the meter across R_1 we would find that the voltage is 15 volts, and if we can connect the meter across R_2 we would find that the voltage across R_2 is 15 volts.

To measure the voltage across one of these resistors, we connect the meter as shown. Notice that when measuring the voltage across R_1, the minus terminal of the meter must be connected to the end of the resistor that connects to the negative terminal of the battery, and the plus terminal of the meter is connected to the other end. This indicates that there is a voltage across R_1 having a polarity as shown in Fig. 7. To measure the voltage across R_2, we connect the meter with the plus terminal to the end of the resistor that connects to the positive terminal of the battery and the minus terminal of the meter to the other end of R_2. This indicates that the voltage across R_2 has the polarity shown.

We know that the current flow in this circuit will be 1 amp. We can prove that there should be a voltage of 15 volts across each of these resistors by using Ohm's Law. Ohm's Law states that if you know the resistance and current in a circuit you can find the voltage. You know that the resistance of R_1 is 15 ohms and you know that the current flowing through it is 1 amp. Putting these values in Ohm's Law we get:

$$E = IR$$

$$E = 1 \times 15 = 15 \text{ volts}$$

In the same way you could calculate the voltage across R_2 and you would find that it is also 15 volts. However, it is not necessary to do this because you know that the voltage across the series combination of R_1 and R_2 must be 30 volts since they are connected across the 30-volt battery, and that if the voltage across one of the resistors is 15 volts, the voltage across the other must be 15 volts also. In addition, in any circuit where you had equal resistors and the same current flows through the resistors, the voltage drops across the resistors must be equal.

We have taken this example one step further in Fig. 8. Here we have put three 10-ohm resistors in series across the 30-volt battery. Once again, you know that the total resistance in the circuit will be the sum of the individual resistors, which again is 30 ohms. Therefore the current flow in the circuit will be 1 amp and the voltage across each resistor will be 10 volts. To measure these voltages, you connect the meter across the individual resistors as shown. Notice that the negative or minus terminal of the meter always connects to the end of the resistor closest to the negative terminal of the battery and the positive or plus terminal of the meter connects to the end of the resistor closest to the positive terminal of the battery.

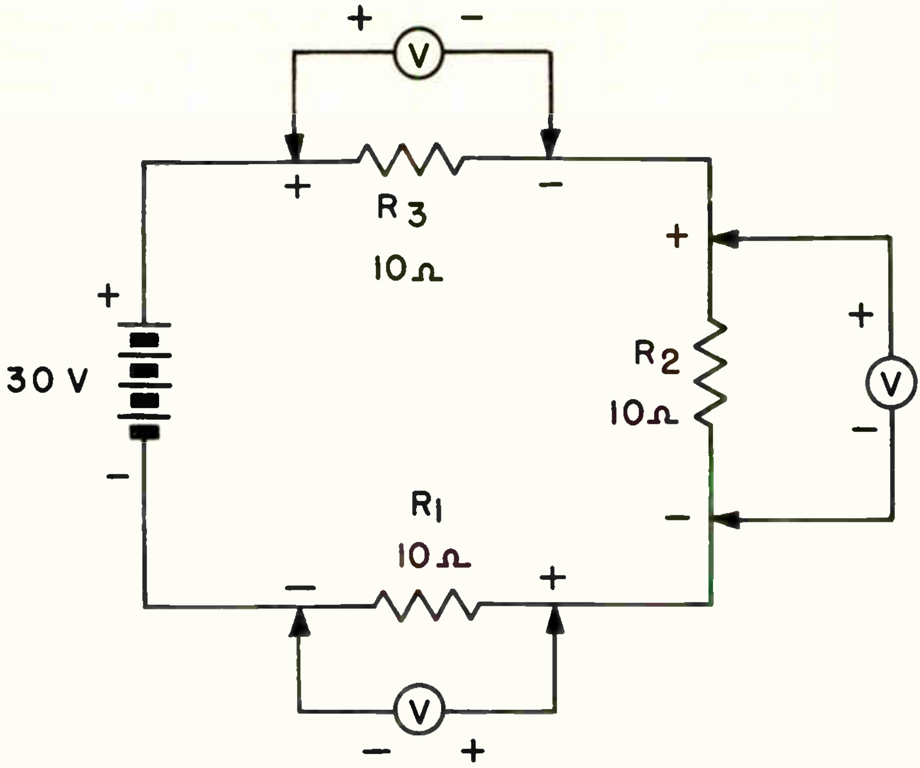

Fig. 8. Voltage polarities across three series resistors are as shown.

Across each resistor there will be a voltage, and in this case the voltage across each resistor will be 10 volts. The voltage across each resistor will have the polarity shown on the diagram.

VOLTAGE DROP

In referring to the voltage across the resistors in a circuit such as Fig. 8, we say that part of the voltage is used or dropped across each resistor. We refer to the voltage across a resistor as a "voltage drop". It is important that you remember this term, since we will use it over and over again. We say that the voltage is "dropped" across a resistor, and we refer to the voltage across each resistor as a "voltage drop".

In a series circuit such as the one shown in Fig. 8, the sum of the voltage drops will always be equal to the source voltage. This means that the voltage drop across R_1, plus the voltage drop across R_2, plus the voltage drop across R_3 will be equal to the battery voltage. This is true regardless of what the battery voltage is and regardless of the value of the resistors used in the series circuit. The sum of the voltage drops in a series circuit will always be equal to the source voltage.

Sometimes we have occasion to trace through a series circuit such as the one shown in Fig. 8 and record the voltages across the individual parts in the circuit. Let us do this starting at the minus terminal of the battery. The first part we come to is R_1 and the voltage across R_1 is 10 volts. Now the question becomes, should we write this as minus 10 volts or plus 10 volts? In tracing through the series circuit, we trace from the minus end of R_1 to the plus end. Let us say that all voltage encountered tracing from minus to plus will be indicated as positive voltages. Therefore the voltage drop across R_1 is + 10 volts. Now we come to R_2, and the voltage across it is also 10 volts. Since we are tracing from the minus end of the resistor to the plus end we indicate the voltage across this resistor as + 10 volts too. Next, we come to R_3 and the voltage across it is 10 volts and we are tracing it in the same way, from the minus end of the resistor to the plus end so we indicate this voltage as + 10 volts. Now as we continue to trace through the circuit we come to the positive terminal of the battery. Now we trace through the battery from the positive terminal to the minus terminal - in other words we are tracing through the battery in the opposite direction from which we traced through the resistors. Therefore since we have called the other voltages plus voltages, we must indicate this as -30 volts. Now if we add the voltages around the circuit we have

+ 10 volts + 10 volts + 10 volts - 30 volts =

+ 30 volts - 30 volts = 0

This brings us to another important rule or law in electronics known as Kirchhoff's Law. It states that the sum of the voltages in a closed circuit is 0. In other words, when you trace around a complete series circuit such as is shown in Fig. 8, and add the voltages with the proper polarity, the sum of these voltages will be 0. This is essentially the same as the statement that the sum of the voltage drops in the circuit will be equal to the source voltage. We have gone through both statements even though they are essentially the same, because you will run into both in your studies of electronics and it's important that you know what they mean and know that they are really saying the same thing.

Knowing that the sum of the voltage drops in a series circuit is equal to the source voltage will enable you to find the voltage across a resistor in an example such as the one shown in Fig. 9. Here you are given the

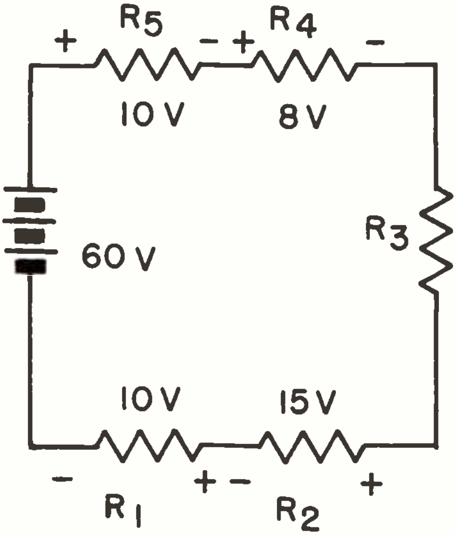

Fig. 9. The voltage across R_3 can be found in the above circuit.

source voltage as 60 volts. You are given the voltage across four of the resistors and want to find the voltage across R_3. You know that the sum of the voltage drops across the five resistors must be equal to 60 volts. So you add the voltage drops that are known across the four resistors. This will give you

$$10 + 15 + 8 + 10 = 43 \text{ volts}$$

Since the sum of the five voltage drops must be equal to 60 volts and the voltage drops across the four resistors total 43 volts, then you know that the voltage drop across R_3 must be equal to 17 volts.

Being able to work simple problems like this in series circuits will be helpful to you. In some electronic equipment parts may be buried in such a way that it is practically impossible to get at them with a voltmeter. You might want to measure the voltage across such a part. Sometimes, while it is impossible to get at the particular part across which you want to measure the voltage, you can measure the source voltage across this part and a number of other parts in series. Then if you can measure the voltage drop across the other parts and subtract these voltage drops from the source voltage, you can determine what the voltage drop is across the part in which you are interested. Being alert to such simple things as this is often what makes the difference between an expert technician who is able to get at the source of trouble in a piece of equipment quickly, and a technician who sort of blunders around trying first one thing and then the other, servicing more or less by a hit-and-miss procedure.

TUBE AND TRANSISTOR CIRCUITS

Often vacuum tube and transistor circuits are simple series circuits. In Fig. 10, we have shown two examples of such circuits. Looking at

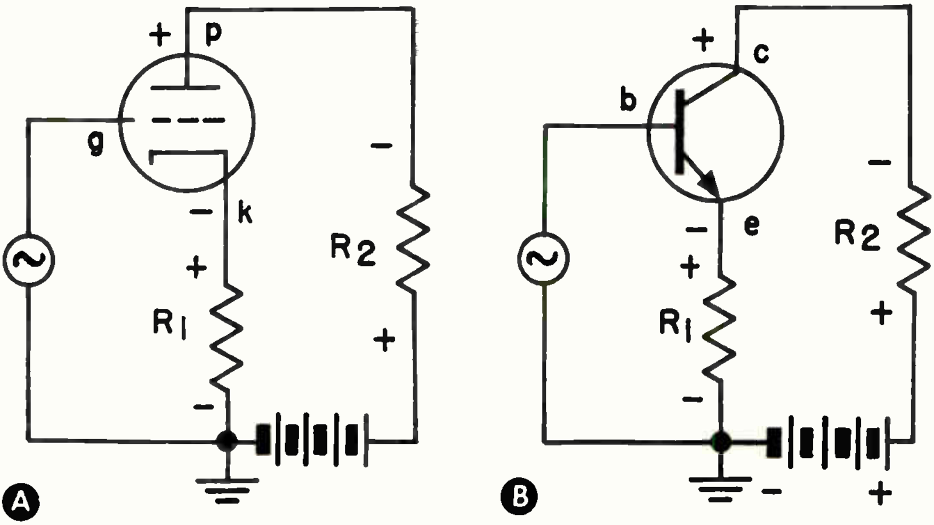

Fig. 10. A series tube circuit is shown at A; a series transistor circuit at B.

Fig. 10A first, here we see a triode vacuum tube. Some of the parts that are normally found in the circuit have been omitted for simplicity. The circuit that we are interested in is the series circuit made up of the battery, R_1, the tube and R_2. Electrons leave the negative terminal of the battery and flow through R_1 to the cathode of the triode tube. We use the letter k to designate the cathode. The cathode is heated to a red heat by the heater inside the cathode. (We have not shown the heater on the diagram because it is not part of the series circuit in which we are interested.) The electrons fly off the heated cathode and travel over to the plate of the tube. From the plate the electrons flow through R_2 back to the positive terminal of the battery and through the battery back to the negative terminal. Thus we have a series circuit consisting of R_1, the vacuum tube, R_2 and the battery. Across each of these parts there will be a voltage drop. The voltage drop across R_1 will have the polarity shown; the end that connects to the negative terminal of the battery will be negative and the end of the resistor that connects to the cathode of the tube will be positive. There will be a voltage drop between the cathode and the plate of the tube; the cathode will be negative and the plate positive. There will be a voltage drop across R_2, the end of the resistor that connects to the plate of the tube will be negative, and the end that connects to the positive side of the battery will be positive. By using a dc voltmeter and connecting it with the proper polarity we can actually measure these voltage drops, and if we use the right kind of meter so it will not upset the performance of the circuit, we will find that the sum of these voltage drops is equal to the battery voltage.

In Fig. 10B, we have shown a transistor circuit. We have also left out some of the parts in this circuit to simplify it. The series circuit we are interested in consists of R_1, the transistor, R_2, and the battery. In this circuit, electrons leave the negative terminal of the battery and flow through R_1 to the emitter (marked e) of the transistor. Here they flow from the emitter to the base (marked b), and from the base to the collector (marked c), and from the collector through R_2 back to the positive terminal of the battery, and through the battery back to the negative terminal. We have a series of voltage drops around the circuit as shown by the polarities marked on the diagram. Again, we can measure the voltage drop across R_1, the voltage drop between the emitter and collector of the transistor and the voltage drop across R_2, and the sum of these three voltage drops will be equal to the battery voltage.

These simple series circuits are typical of the series circuits you will find in all types of electronic equipment. You will find that the current flowing through these simple circuits is extremely important. The generator connected between the grid and ground of the tube circuit and between the base and ground in the transistor circuit causes the current through these circuits to vary, and this varying current is what makes it possible for the tube and the transistor to amplify the signal. The generator in each case is representing a small signal input, such as might be obtained from a microphone or from a preceding stage. An amplified signal will appear across R_2 in each case. We will go into detail on how these devices amplify later. The important thing for you to see at this time is the simple series circuits involved and to realize how important it is that you are able to recognize series circuits and remember the important facts about them.

SUMMARY

Series circuits are extremely important; you will find all kinds of them in electronic equipment. You must be able to recognize a series circuit. It is a circuit in which electrons leave the negative terminal of the voltage source and flow through a number of parts, one after the other, to the positive side of the voltage source and through the voltage source back to the negative terminal.

Remember what is meant by a voltage drop. It is the voltage that appears across any part in a series circuit. You must also be able to indicate the polarity of the voltage drop across a part. The end of the part that is closest to the negative terminal of the voltage source will be negative, and the end of the part that is closest to the positive terminal of the voltage source will be positive.

Remember the two important rules about the voltages in a series circuit. The sum of the voltage drops in a series circuit is equal to the source voltage. Another way of expressing the same rule is that if you add the voltages with the correct polarity, the sum of the voltages around a series circuit will be equal to 0.

If there are any parts of the preceding section that are not clear to you, it would be worthwhile to go over the entire section again, before trying the self-test questions. These early lessons are the most important lessons in your course. A thorough understanding of basic circuits will help you all the way through your course; it will make later lessons comparatively easy. On the other hand, if you do not understand these basic circuits, then you will have difficulty all the way through your course. After you have mastered the material covered in this section answer the self-test questions. If you find that you cannot answer one of the self-test questions, don't hesitate to go back and review. These questions are put in the lesson to help you determine whether or not you know as much as you should about the section. By going back and finding the answer to a self-test question that you cannot answer, you will be reviewing a part of the lesson that is not clear to you. This will help you master the important parts of the lesson.

SELF-TEST QUESTIONS

(a) What is a series circuit?

(b) How do you connect a dc voltmeter to a battery to measure the battery voltage?

(c) Draw a simple series circuit consisting of a battery and three resistors. Label the resistor that connects to the negative terminal of the battery R_1, and the resistor that connects to the positive terminal of the battery R_3. Label the resistor between R_1 and R_3, R_2.

(d) Indicate the polarity of the voltage drops across the resistors in the series circuit you have drawn.

(e) If R_1 equals 3 ohms, R_2 equals 4 ohms and R_3 equals 5 ohms, what is the total resistance of the three resistors connected in series?

(f) If the total current flowing in your series circuit is 2 amps, find the voltage drop across each of the three resistors in the circuit.

(g) What is the source voltage in the series circuit you have drawn?

(h) In a series circuit in which four resistors are connected across a battery, the battery voltage is 35 volts. The voltage drop across one resistor is 5 volts, across another resistor it is 7 volts, and across a third resistor it is 10 volts. What is the voltage drop across the fourth resistor?

(i) In a vacuum tube circuit such as shown in Fig. 10A, the voltage drop across R_1 is 3 volts, the voltage drop across R_2 is 125 volts, and the source voltage is 250 volts. What is the voltage between the plate and cathode of the tube?

(j) In a transistor circuit such as shown in Fig. 10B, the voltage drop across R_1 is .2 volts. The voltage drop across R_2 is 3.6. volts. The battery voltage is 6 volts. What is the voltage drop between the emitter and collector of the transistor?

(k) Draw a series circuit with a battery and five resistors like the one shown in Fig. 4. R_1 equals 120 ohms, R_2 equals 150 ohms, R_3 equals 180 ohms, R_4 equals 120 ohms and R_5 equals 330 ohms. The battery voltage is 18 volts. Find the total resistance in the circuit and then find the current flowing in the circuit, and finally find the voltage drop across each resistor and label the polarity of the voltage drop.

Parallel Circuits

You might think of a parallel circuit as the opposite of a series circuit. In a series circuit, current flows through one part after the other in the circuit. There is only one path for current flow and the current is the same in all parts of the circuit. In a parallel circuit, a different current can flow through each branch of the circuit. If two resistors are connected in parallel there are two paths through which current can flow; if three resistors are connected in parallel then there are three paths through which current can flow, and the current flowing in each path or branch of the circuit can be different.

Parallel circuits might seem a little confusing at first, but actually they are quite simple even though there are some important rules

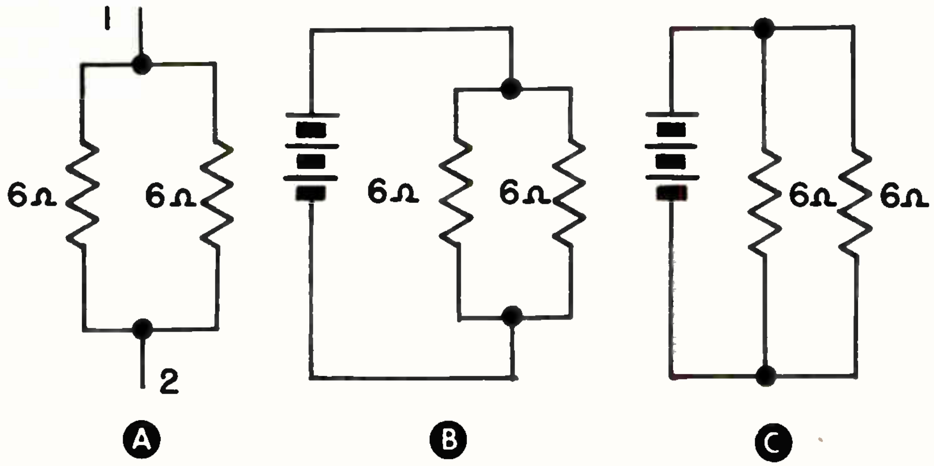

Fig. 11. Simple parallel resistor circuits.

which govern their performance. Once you learn these rules you will see that parallel circuits are no more difficult to understand than series circuits.

In the preceding section we learned that when two resistors were connected in series that their total resistance was equal to the sum of their resistances. We have a somewhat different situation in parallel circuits, so let us see exactly what happens.

RESISTORS IN PARALLEL

Often in electronic equipment two or more resistors may be connected in parallel. We need to be able to find the effective resistance of two resistors connected in parallel.

In Fig. 11A, we have shown two 6-ohm resistors connected in parallel. Between terminals 1 and 2 of these resistors there will be some net value of resistance. We can connect these two resistors in parallel across a battery as shown in Fig. 11B, and a certain current will flow in the circuit. The current that will flow in the circuit will depend upon the battery voltage, and the net resistance of the two resistors connected in parallel.

We can see better what is happening if we redraw the circuit as shown in Fig. 11C. Here we see clearly that each resistor is connected directly across the battery. Therefore there will be a current path from the negative terminal of the battery to the first 6-ohm resistor, through this resistor, and back to the positive terminal of the battery. The amount of current that will flow will depend upon the voltage of the battery, and the resistance of the resistor, which in this case is 6-ohms. There will be a similar path from the negative terminal of the battery and through the second resistor and back to the positive terminal of the battery.

Since the two resistors are of equal value, for a given battery voltage, equal currents will flow through the two resistors. Let us suppose that the battery voltage is 6 volts. Then, the current flowing through either of the 6-ohm resistors will be 1 amp. This means that the total current flowing in the circuit will be 2 amps, 1 amp through each resistor.

Now, since we know the battery voltage and the total current flowing, we can substitute these values in Ohm's Law and find the effective resistance in the circuit. Using

$$R = \frac{E}{I}$$

$$R = \frac{6}{2} = 3 \text{ ohms}$$

Thus the resistance of two 6-ohm resistors connected in parallel is 3 ohms - notice that it is one half the resistance of either resistor.

You can set up other examples of equal resistors connected in parallel, and you will find that it always works out that the total resistance of the resistors in parallel is equal to one half the resistance of either resistor.

You might wonder about our selecting a voltage of 6 volts to work out this problem. We selected 6 volts simply to make the division easy. We could select any voltage; the current through each resistor would be different, but the result will always be the same. For example, suppose we select a battery voltage of 18 volts. Then, from Ohm's Law, the current through each resistor will be three amps, and therefore the total current flowing in the circuit will be 6 amps. When we substitute these values into Ohm's Law we find that once again the total resistance in the circuit is 3 ohms. Selecting a voltage like this is an easy way of finding the resistance of two resistors connected in parallel: there is another method that can be used which we will show you later.

You can use the same procedure in finding the total resistance of two unequal resistors connected in parallel. For example, suppose we have a 4-ohm resistor and an 8-ohm resistor connected in parallel as shown in Fig. 12A. We can simply set up a simple circuit such as shown in Fig. 12B and then assume a convenient battery voltage which

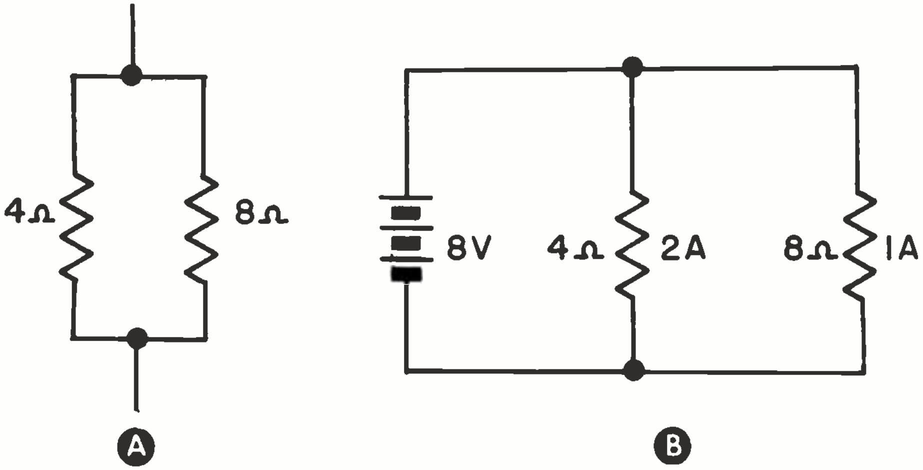

Fig. 12. Finding the value of 4Ω in parallel with 8Ω.

in this case might be 8 volts. With a voltage of 8 volts, a current of 2 amps will flow through the 4-ohm resistor and a current of 1 amp, will flow through the 8-ohm resistor. Therefore the total current flow in the circuit will be 3 amps. Now to find the total resistance we divide 3 amps into 8 volts and get 2.67 ohms.

In the examples shown in Figs. 11 and 12, it was easy to pick a voltage into which the resistance values can be divided to give convenient values of current. Sometimes this is not so easy and then we use another method of finding the value of resistors connected in parallel. We use the formula

$$R_t = \frac{R_1 \times R_2}{R_1 + R_2}$$

This formula states that the total resistance of two resistors connected in parallel is equal to the product of the resistance of the two resistors divided by the sum of the resistance of the two resistors.

For example, using the two 6-ohm resistors that we used in Fig. 11, in this formula we get

$$R_t = \frac{6 \times 6}{6 + 6}$$

$$R_t = \frac{36}{12} = 3 \text{ ohms}$$

This formula is particularly useful in finding the value of larger resistors. For example, find the value of 2400 ohms in parallel with 800 ohms. Substituting these values in the formula we get

$$R_t = \frac{2400 \times 800}{2400 + 800}$$

$$R_t = \frac{1920000}{3200}$$

and now cancelling two zeros above the division line and two zeros below the division line, we have

$$R_t = \frac{19200}{32} = 600 \text{ ohms}$$

Often you will have more than two resistors connected in parallel and want to find the total resistance of the group. In Fig. 13A we have shown three resistors in parallel. In Fig. 13B we have shown them connected across a battery. If we assume a battery voltage of 24 volts, then we will get a whole number for the current flowing through each resistor. The current through the 6-ohm resistor would be 4 amps, the current through the 8-ohm resistor would be 3 amps, and the current through the 12-ohm resistor would be 2 amps. This will give us a total current of 9 amps. Now using Ohm's Law we can find the total resistance

$$R = \frac{E}{I}$$

$$R = \frac{24}{9} = 2.666+ \text{ ohms}$$

which we round off to 2.7 ohms.

Another way to find the total resistance of three resistors in parallel is to use the formula first for two of the group, finding the parallel resistance, and then using the formula again with the result and the third resistor in parallel with the parallel resistance of the first two resistors.

In the example, if we find the resistance of the 6-ohm and 12-ohm resistor in parallel first, we will have less work to do with fractions. Using the formula, we find that 6 ohms in parallel with 12 ohms is

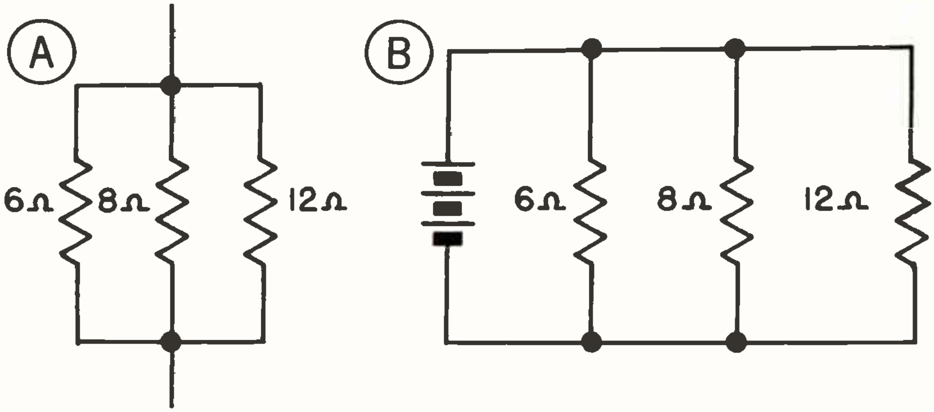

Fig. 13. A parallel circuit with three current paths.

$$R_t = \frac{6 \times 12}{6 + 12}$$

$$R_t = \frac{72}{18} = 4 \text{ ohms}$$

Thus the value of a 6-ohm resistor in parallel with a 12-ohm resistor is 4 ohms. Now we find the value of 4 ohms in parallel with 8 ohms, which we did previously and we find

$$R_t = \frac{4 \times 8}{4 + 8}$$

$$R_t = \frac{32}{12} = 2.666+ \text{ ohms}$$

Again we round it to 2.7 ohms.

If you have four or five resistors connected in parallel you can use the same formula, simply grouping them together in pairs and then substituting the parallel resistance in the formula. For example, in the case of five resistors you might find the value of R_1 and R_2 in parallel and then the value of R_3 and R_4 in parallel. Next, find the parallel resistance of the R_1-R_2 combination in parallel with the R_3-R_4 combination, and when you get the answer to the value of these four resistors in parallel, find the value of the four of them in parallel with R_5. When working out a problem of this type, sometimes it is worthwhile to look for groups that will work out in even numbers before starting the problem, and this will save some work. For example, look at the five resistors in parallel in Fig. 14.

In this example, if we group together R_1 and R_2 we get

$$R_t = \frac{12 \times 24}{12 + 24}$$

$$R_t = \frac{288}{36} = 8 \text{ ohms}$$

Therefore we can consider R_1 and R_2 as a single 8-ohm resistor. Now notice that the value of R_4 is 8 ohms, so let us consider the parallel combination of R_1 and R_2 which is equal to 8 ohms, with R_4. We can use the formula to find the value, but if we remember that the value of equal resistors in parallel is equal to one half the resistance of either resistor

ALSO! → $\frac{1}{R_{eq}} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \cdots \frac{1}{R_N}$

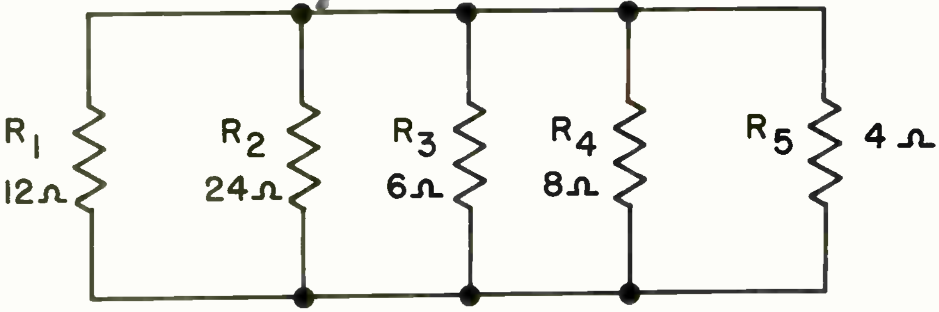

Fig. 14. Five resistors in parallel.

we know immediately that the parallel combination is equal to 4 ohms.

Now we consider the parallel combination of R_1, R_2 and R_4 as a single 4-ohm resistor. We now find the value of it in parallel with R_5, which is also a 4-ohm resistor, and we know immediately that the value of this combination is 2 ohms. Now we know that R_1, R_2, R_4 and R_5 in parallel have a resistance of 2 ohms. Now all we need to do is find the value of 2 ohms in parallel with R_3, which is 6 ohms, and we use the formula to do this.

$$R_t = \frac{6 \times 2}{6 + 2}$$

$$R_t = \frac{12}{8} = 1.5 \text{ ohms}$$

You can work this problem out by grouping other resistors together first; try working it out grouping R_1 and R_3 together first, get the value of this combination, and next get the value of R_2 and R_4 in parallel. After you have done this decide for yourself which two you should group together next to make your calculation as easy as possible, and then find the value of this combination in parallel with the remaining resistance to see if you get the same answer of 1.5 ohms.

Before leaving this section on resistors in parallel, there are a few other important points that you should notice.

Notice that in each of the examples given in Figs. 11, 12, 13 and 14 the total resistance of the resistors in parallel is less than the resistance of the smallest resistor. This is always true in a parallel circuit. Whenever you connect two or more resistors in parallel, the resistance of the parallel combination will always be less than the resistance of the smallest resistor, regardless of the value of the resistors connected in parallel.

If you look back at Fig. 11 you can see why this is so. You know from Ohm's Law that

$$R = \frac{E}{I}$$

Whenever you connect a resistor across a battery, a current flows in the circuit and for a given value of voltage a certain current will flow. If the voltage remains constant in the circuit and the current increases, then the resistance must get smaller. Whenever you connect a second resistor across a first resistor the current increases because there is a second path through which current can flow. Therefore when you connect two resistors in parallel and the value of E remains the same, the value of I increases and therefore the value of R must get smaller.

Sometimes when two resistors are connected in parallel, one resistor is so much larger than the other that practically all of the current flowing in the circuit flows through the smaller resistor. For example, if a 1000-ohm resistor is connected in parallel with a 1-ohm resistor and the two are connected across a battery, one thousand times as much current will flow through the 1-ohm resistor as through the 1000-ohm resistor. The current flowing through the 1000-ohm resistor would be such a small percentage of the total current flow in the circuit that it could be ignored. For all practical purposes, the total resistance of the two resistors in parallel can be considered as 1 ohm.

In most electronic circuits exact calculations are not necessary because most of the parts have a reasonable tolerance. If we want to get an approximate value of a group of resistors connected in parallel, we can usually ignore any resistor that is more than ten times larger than the smallest resistor in the circuit. Thus, if you had a 2-ohm, a 4-ohm and a 50-ohm resistor connected in parallel and wanted to get the approximate resistance of the parallel combination, you could ignore the 50-ohm resistor because it is more than ten times the resistance of the 2-ohm resistor. The value of the resistance you would obtain by ignoring this resistor would not differ appreciably from the value you would obtain if you did not ignore it and found the exact resistance of the parallel combination. Keep this in mind, because sometimes it will save you some unnecessary work if you are interested in finding only the approximate resistance of a group of resistors in parallel and do not need to know the exact resistance.

VOLTAGE AND CURRENT IN PARALLEL CIRCUITS

In a series circuit, the current is the same in all parts of the circuit. The voltage drop across a part in a series circuit depends upon the resistance of the part.

In a parallel circuit we have essentially the opposite situation. In a parallel circuit, since the parts are connected directly across each other, the voltage across each part must be the same. This means that the voltage across all the parts in a parallel circuit is the same. You cannot have two parts connected in parallel and have unequal voltages across them.

The current that will flow through each part in a parallel circuit will depend upon the voltage applied across the parallel circuit and the resistance of the part. Since each branch of a parallel circuit can have a different resistance, then we can have a different current flowing in each branch of the circuit.

Therefore, you should remember that in a parallel circuit the voltage will be the same across each part in the circuit. The current through each branch of the circuit will depend on the resistance of the branch. The highest current will flow through the branch having the lowest resistance and the lowest current will flow through the branch having the highest resistance. The total current flowing in a parallel circuit is equal to the sum of the currents flowing through the individual branches.

SUMMARY

Parallel circuits are widely used in electronic equipment and you will see many examples of them later in your course.

There are several important things you should remember about resistors in parallel. Remember that when two or more resistors are connected in parallel the total resistance of the parallel combination will always be less than the resistance of the smallest resistor.

When two equal value resistors are connected in parallel, the total resistance will be equal to one half the resistance of either resistor. If three equal value resistors are connected in parallel, the total resistance will be one third the resistance of either resistor, and if four equal value resistors are connected in parallel, the total resistance will be one quarter the resistance of any one resistor.

We can find the resistance of two resistors connected in parallel by using the formula

$$R_t = \frac{R_1 \times R_2}{R_1 + R_2}$$

In a parallel circuit the voltage across all branches of the parallel circuit will be equal. The current flow in each branch of the circuit will depend upon the resistance of the circuit, the highest current will flow through the lowest resistance branch, and the lowest current will flow through the highest resistance branch.

Now answer the self-test questions on this section of the lesson; they will be a good review for you.

SELF-TEST QUESTIONS

(l) What is the total resistance of two 50-ohm resistors connected in parallel?

(m) What is the total resistance of a 24-ohm resistor connected in parallel with a 12-ohm resistor?

(n) If a 3-ohm and a 4-ohm resistor are connected in parallel across a 12-volt battery, what will be the total current flow from the battery, and what will be the total resistance of the 3-ohm and 4-ohm resistance in parallel?

(o) If two 8-ohm resistors are connected in parallel with a 1000-ohm resistor, what will be the resistance of the parallel combination?

(p) If two resistors, R_1 and R_2, are connected in parallel across a battery and a current of 1 amp flows through R_1 and a current of 2 amps flows through R_2, which is the larger resistor? How much larger is it than the other resistor?

(q) If a 5-ohm resistor and a 10-ohm resistor are connected in parallel across a battery, and the current through the 5-ohm resistor is 2 amps, find the voltage across the 10-ohm resistor and the current that will flow through it. What is the total current flowing in the circuit? What is the battery voltage?

(r) Complete the following statement: in a parallel circuit, the voltages across all branches of the parallel circuit will be __________.

(s) In a parallel circuit, the current through each branch of a parallel circuit will depend upon ______________ of the branch. The largest current will flow through the branch having the ______ resistance, and the smallest current will flow through the branch having the __________ resistance.

Series-Parallel Circuits

In radio and television transmitters and receivers as well as in all types of electronic control devices you will find many series circuits and many parallel circuits. However, in addition to these two types of circuits you will find many circuits that are combinations of series and parallel circuits. These types of circuits are called series-parallel circuits.

An example of a series-parallel circuit is shown in Fig. 15. In this circuit, the two resistors, R_2 and R_3, are connected in parallel. Any current flowing in the circuit, when it reaches the junction of R_2 and R_3 has two paths through which it can flow. Part of the current can flow through R_2 and part of it can flow through R_3. The exact percentage of the current that will flow through each resistor will depend upon their relative size. If the resistors are equal, half the current will flow through R_2 and half of it will flow through R_3. On the other hand, if one of the resistors is much larger than the other, most of the current will flow through the smaller resistor and only a small percentage of the current will flow through the larger resistor.

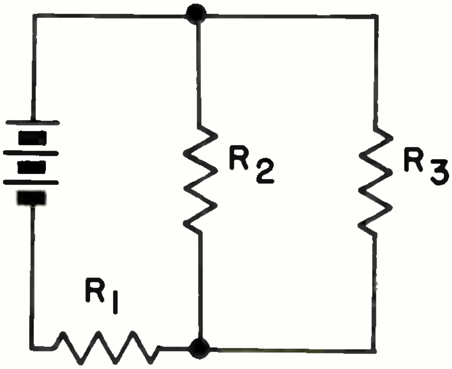

Fig. 15. A series-parallel circuit.

The two parallel resistors R_2 and R_3 are connected in series with the resistor R_1 and with the battery. Thus, part of the circuit is a simple series circuit and part of it is a parallel circuit.

In a circuit of this type, electrons leave the negative terminal of the battery and flow through the resistor R_1. The current divides after it flows through R_1, and part flows through R_2 and part flows through R_3. Then the current joins at the junction of the two resistors and flows back to the positive terminal of the battery and through the battery back to the negative terminal.

In solving for values of current, voltage and resistance in a series-parallel circuit, we use the rules

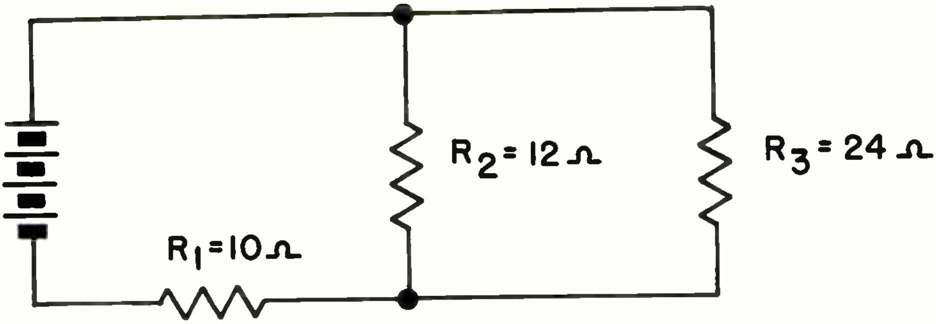

Fig. 16. A series-parallel circuit.

that apply to a series circuit for the series part of the circuit, and the rules that apply to a parallel circuit for the parallel part of the circuit. Actually, it is no more difficult to work with this type of circuit and find voltages, current etc., than it is with a simple series or a simple parallel circuit. However, there is a certain order in which you must proceed when working with circuits of this type. Once you become familiar with this type of circuit, you will see that it is not as complicated as it might look, and also learning about series-parallel circuits will make simple series and simple parallel circuits that much easier for you.

Now let us go ahead and study this type of circuit in detail.

RESISTANCE IN SERIES-PARALLEL CIRCUITS

In Fig. 16 we have shown a series-parallel circuit similar to the one shown in Fig. 15. In this example, R_1, which is called a series resistor, is equal to 10 ohms. R_2 and R_3 are called the parallel resistors. R_2 has a resistance of 12 ohms and R_3 has a resistance of 24 ohms. Now, we want to find the total resistance in the circuit. In other words, we want to find out how much resistance there is in the circuit limiting the current flow from the battery.

To find the total resistance of a series-parallel circuit of this type, the first step is to find the resistance of the parallel branch. To do this, we use the formula

$$R_p = \frac{R_2 \times R_3}{R_2 + R_3}$$

and we substitute the values of 12 ohms for R_2 and 24 ohms for R_3 and get

$$R_p = \frac{12 \times 24}{12 + 24}$$

$$R_p = \frac{288}{36} = 8 \text{ ohms}$$

Now, we know that the total resistance of R_2 in parallel with R_3 is 8 ohms. Insofar as the circuit is concerned, these two resistors could be replaced by a single 8-ohm resistor, as shown in Fig. 17. Notice the symbol we have used to indicate R_2 in parallel with R_3. The two parallel lines between R_2 and R_3 mean "in parallel with".

Once we replace the parallel combination of R_2 and R_3 with the equivalent resistance, we have a simple series circuit. As you will remember, the total resistance of a series circuit is equal to the sum of the individual resistances. In this case, the total resistance will be 10 + 8 = 18 ohms. This is the total resistance of the equivalent circuit shown in Fig. 17, and it is also the total resistance seen by the battery in the series-parallel circuit shown in Fig. 16.

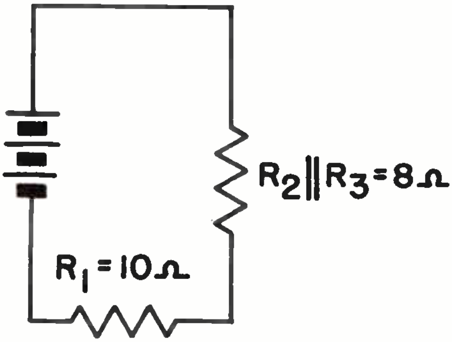

Fig. 17. Series equivalent of circuit of Fig. 15.

So far the circuits we have been dealing with have been very simple series-parallel circuits. In some circuits we will have several series resistors and several parallel branches. The parallel branches may consist of any number of resistors. A more complicated series-parallel circuit is shown in Fig. 18. To find the total resistance seen by the battery in this circuit, we will use exactly the same method as we used to find the total resistance in the circuit shown in Fig. 16. The first thing we will do is find the effective resistance of the parallel branches and then redraw the circuit replacing the parallel branches by single series resistors and then find the total series resistance. Now let us go through this problem step by step.

Notice that in the circuit shown in Fig. 18 we have two series resistors, R_1 and R_5. We also have two parallel branches. One parallel branch is made up of the three resistors R_2, R_3 and R_4, and the other

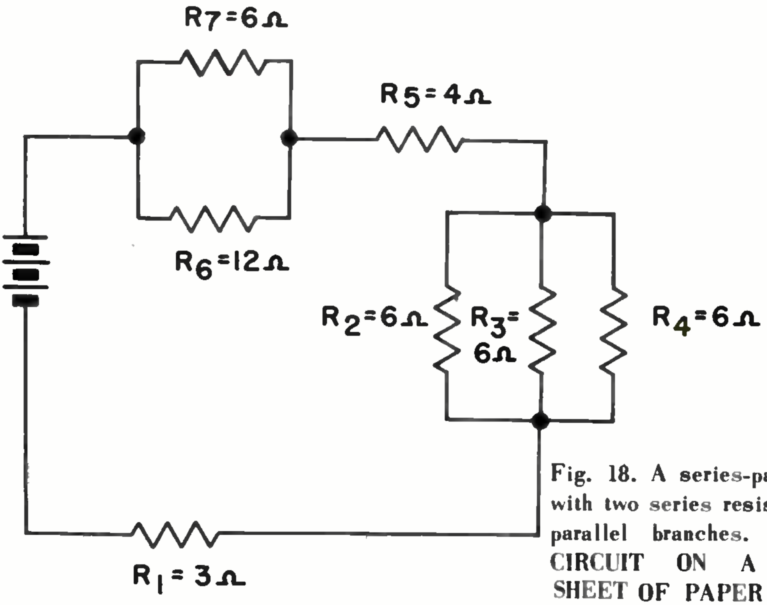

Fig. 18. A series-parallel circuit with two series resistors and two parallel branches. COPY THIS CIRCUIT ON A SEPARATE SHEET OF PAPER FOR QUICK REFERENCE.

parallel branch is made up of the two resistors R_6 and R_7.

Our first step in solving this problem is to find the resistance of the parallel branches. Let us take the branch made up of the three resistors first. If you will remember from the preceding section, we mentioned that when two equal value resistors are connected in parallel, the total resistance is equal to one half the resistance of either resistor. When three equal value resistors are connected in parallel the total resistance is one third the value of one of the resistors. From this we know immediately that the total resistance of the three six-ohm resistors in parallel is 2 ohms.

However, you might not remember this rule, or the resistors might not be of equal values. In this case you simply use the formula and find the resistance of two of the resistors in parallel. This would give you

$$R = \frac{6 \times 6}{6 + 6}$$

$$R = \frac{36}{12} = 3 \text{ ohms}$$

Now this gives you the value of two of the resistors in parallel and you combine this value with the remaining resistor to get the total resistance of the combination. Thus

$$R_t = \frac{3 \times 6}{3 + 6}$$

$$R_t = \frac{18}{9} = 2 \text{ ohms}$$

Therefore the resistance of the parallel branch made up of the three 6-ohm resistors is 2 ohms. As far as the circuit is concerned, we can replace these three resistors by a single 2-ohm resistor.

Now let us go ahead and find the value of the 12-ohm and 6-ohm resistors in parallel. Again, using our formula we get

$$R_t = \frac{12 \times 6}{12 + 6}$$

$$R_t = \frac{72}{18} = 4 \text{ ohms}$$

Therefore R_6 and R_7 can be replaced by a single 4-ohm resistor without affecting the total resistance of the circuit.

Now we can redraw the circuit shown in Fig. 18 as we have redrawn it in Fig. 19. In place of the three parallel resistors we have inserted a single 2-ohm resistor, and in place of resistors R_6 and R_7 we have inserted a 4-ohm resistor. Now we have a simple series circuit, and to get the total resistance of the circuit we simply add the resistance of the individual resistors. Therefore the total resistance in the circuit is

$$R_t = 3 + 2 + 4 + 4 = 13 \text{ ohms}$$

This same procedure can be used for solving any series-parallel circuit configuration. In fact, the circuit shown in Fig. 18 could consist of four parallel branches in series. There could be a resistor in parallel with R_1 and another resistor in parallel with R_5. In this case you would have a series circuit made

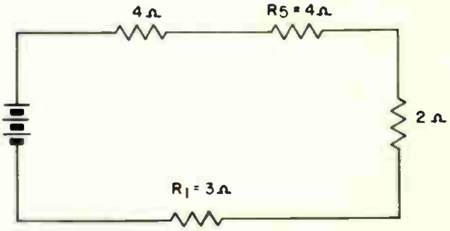

Fig. 19. Series equivalent of circuit of Fig. 18.

up of four parallel branches connected in series. To solve a circuit of this type you use the same procedure. Find the total resistance of each parallel branch, and then draw the equivalent circuit as we did in Fig. 19 and then total the resistance of the parallel branches to get the total resistance in the circuit.

Now let us see how the current behaves in a series-parallel circuit.

CURRENT IN SERIES-PARALLEL CIRCUITS

In a series-parallel circuit such as shown in Fig. 18, the current must be the same in every series part of the circuit. By this we mean that a certain current leaves the negative terminal of the battery and flows through R_1. Then the current reaches the parallel combination of R_2, R_3 and R_4. The total current flowing through this parallel combination must be equal to the current leaving the negative terminal of the battery and the current flowing through R_1. The same current must flow through R_5 and the same current must flow through the parallel combination of R_6 and R_7.

To help us see better what is happening to the current in the circuit, let's assume that the battery voltage in Fig. 18 is 78 volts. We picked this value because it will enable us to avoid any decimal divisions.

We have already found that the total resistance of the circuit - that is, the resistance that the battery sees - is 13 ohms. Therefore, we can use this to find the current that will flow in the circuit. Using the formula

$$I = \frac{E}{R}$$

and substituting 78 volts for E and 13 ohms for R we have

$$I = \frac{78}{13} = 6 \text{ amps}$$

This means that the current leaving the negative terminal of the battery is 6 amps. Since R_1 is in series with the battery, the current flowing through R_1 must also be 6 amps. The current flowing through the parallel combination of R_2, R_3 and R_4 must also be 6 amps. However, there are three paths here through which the current can flow. Since the three resistors are of equal value, then one third of the current will flow through each branch. This means that 2 amps will flow through R_2, 2 amps through R_3 and 2 amps through R_4.

The current reaching R_5 must flow through this resistor and since the series current is 6 amps, the current flow through R_5 must be 6 amps.

R_6 and R_7 form a parallel branch. Part of the current will flow through R_6 and part of it will flow through R_7. Since R_6 is twice the value of R_7, then the current flow through R_6 will be only half the current flowing through R_7. This means that one third of the current will flow through R_6 and two thirds of it will flow through R_7. Therefore the current flow through R_6 will be 2 amps, and the current flow through R_7 will be 4 amps. The current flowing into the positive terminal of the battery will be 6 amps, and the current flow through the battery itself from the positive terminal to the negative terminal will also be 6 amps.

Now notice how this circuit has

obeyed the laws set down both for series circuits and for parallel circuits. We stated that in a series circuit, the current is the same in all parts of the circuit. R_1 is a part of the series circuit and the current through it is 6 amps. R_2, R_3 and R_4 in parallel form a part of the series circuit and the current through the three in parallel is 6 amps. The current divides because there are three paths, but the total current flowing through the three paths is 6 amps. R_5 does not have any other resistors in parallel with it and therefore the entire current of 6 amps flows through it. R_6 and R_7 in parallel form a part of the series circuit and the total current flowing through the two of them is 6 amps; part of it flows through R_6 and part of it through R_7. The entire 6 amps also flows through the battery. Thus we can say that the current flow in each part of this series circuit is 6 amps.

The current flow also obeys the law of parallel circuits. Whenever the current reaches a parallel branch it divides, and part of it flows through each branch of the circuit. Since R_2, R_3 and R_4 are of equal value, the same current flows through each of the three resistors. In this case, 2 amps flow through each resistor so that the total current flowing in this part of the series circuit is 6 amps. In the case of R_6 and R_7 in parallel, the current again divides and flows through the two resistors in proportion to their resistance. R_6 is twice the resistance of R_7 and therefore only half as much current flows through R_6 as R_7. 2 amps flow through R_6 and 4 amps through R_7. This gives us a total current of 6 amps, once again through this part of the series circuit.

Now that we have looked into resistance and current in series-parallel circuits, let us see what happens to the voltage in these circuits.

VOLTAGE IN SERIES-PARALLEL CIRCUITS

You will remember that in a series circuit, the sum of the voltage drops across the branches of the series circuit is equal to the applied voltage. You will also remember, that in a parallel circuit you have the same voltage across all the parts in parallel. Now let us see what happens in a series-parallel circuit. Let's use the circuit in Fig. 18 so we don't have to figure out the total resistance again, and once again let's assume that the battery voltage is 78 volts. We know that this will cause a current of 6 amps to flow in the circuit.

With a current of 6 amps flowing through R_1, we can find the voltage drop across it. We will refer to this voltage as E_1, the voltage across R_2 as E_2 and so on.

$$E_1 = 6 \times 3 = 18 \text{ volts}$$

We know that the current flowing through R_2 is 2 amps, and using this we can find the voltage across R_2.

$$E_2 = 2 \times 6 = 12 \text{ volts}$$

Since $R_2 = R_3 = R_4$, and the current flowing through each of these resistors is 2 amps, they must have the same voltage drop across each of the resistors. This bears out what we have said before about parts connected in parallel - the voltage drop across them must be the same.

If we stop here and look at Fig. 19, we see that we found the equivalent resistance of R_2, R_3 and R_4 connected in parallel was 2 ohms. In this circuit, the current flowing through this equivalent resistance is 6 amps, and the voltage across it will be 12 volts. Therefore we see that no matter which way we work, either using the total current across the equivalent resistance or the actual current through one branch of the parallel circuit, we should get the same value of voltage across the parallel circuit.

The voltage across R_5 will be

$$E_5 = 6 \times 4 = 24 \text{ volts}$$

The voltage across R_6 will be

$$E_6 = 2 \times 12 = 24 \text{ volts}$$

We know that the current through R_7 is 4 amps and so we can also calculate the voltage across this resistor to see that we have the same voltage as across R_6. The voltage across R_7 is

$$E_7 = 4 \times 6 = 24 \text{ volts}$$

Now, let us add the voltage drops around the circuit to see what the total voltage drop is. The voltage drop across R_1 is 18 volts. The voltage drop across the parallel combination of R_2, R_3 and R_4 is 12 volts. The voltage drop across R_5 is 24 volts and the voltage drop across the parallel combination of R_6 and R_7 is also 24 volts. Now adding these voltages we will get the total voltage drop in the circuit

$$E_t = 18 + 12 + 24 + 24 = 78 \text{ volts}$$

The series-parallel circuit thus obeys the law we stated for the voltage drops in a series circuit. The sum of the voltage drops across each of the series branches in a series-parallel circuit is equal to the source voltage. The voltage drop across each of the parts in a parallel branch is equal. Thus we can see that the rules we have set up for voltages in series and in parallel circuits apply also to series-parallel circuits.

Now, if you plan to become a radio-TV service technician, this is as far as you have to go with series-parallel circuits. However, if you want to go ahead and get your FCC license, or if you plan on working in industry, you should be able to solve some simple problems in series-parallel circuits. You will have to solve these problems to get your FCC license. Often when applying for positions in industry, examinations are given and frequently these examinations have one or two problems involving solutions of parallel series and series-parallel circuits. For the technician who wants to get his FCC license or wants to work in industry, and for the radio-TV service technician who wants to learn more about series-parallel circuits we will go through a typical problem in the next section. Remember, if your interest is radio-TV servicing only, you do not have to go through this section unless you want to.

PROBLEMS IN SERIES-PARALLEL CIRCUITS

In Fig. 20 we have shown a series-parallel circuit that is only slightly more complicated than the one shown in Fig. 18. In this circuit you are given the values of all the resistors

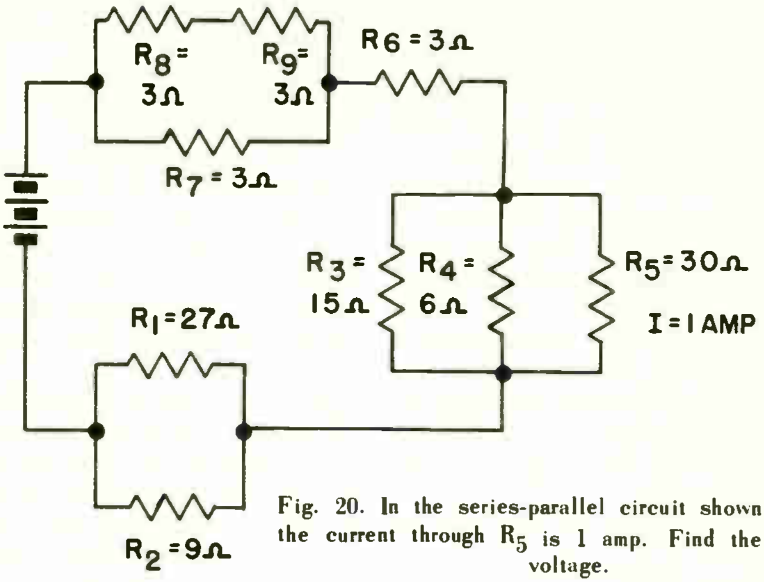

Fig. 20. In the series-parallel circuit shown above, the current through R_5 is 1 amp. Find the source voltage.

and also the information that the current flowing through R_5 is 1 amp. The problem is to find the source voltage.

At first glance, you might think that this is impossible, but actually it is not nearly as difficult as it might appear at first. Let us look at the information we have about R_5.

We know that the resistance of R_5 is 30 ohms, and that the current flowing through it is 1 amp. From this we can calculate the voltage across R_5 using Ohm's Law. We use the formula

$$E = IR$$

and for I substitute 1 amp and for R, 30 ohms, and we will get

$$E = 1 \times 30 = 30 \text{ volts}$$

Since R_3 and R_4 are in parallel with R_5, this means that the voltage across R_3 and the voltage across R_4 is also 30 volts. Now that we know the voltage across these two resistors, and their value, we can find the current flowing through them. We will use I_3 for the current through R_3 and I_4 for the current through R_4 and so on throughout the problem.

$$I_3 = \frac{30}{15} = 2 \text{ amps}$$

$$I_4 = \frac{30}{6} = 5 \text{ amps}$$

Now we know that the current flowing through R_3 is 2 amps, through R_4 is 5 amps, and the current flowing through R_5 is 1 amp. Thus the total current flowing through the three parallel branches is

$$I_t = 2 + 5 + 1 = 8 \text{ amps}$$

Since this combination of three resistors forms one branch in series circuit, now we know that the series current must be 8 amps. We can immediately calculate the voltage drop across R_8 using this information.

$$E_8 = 8 \times 3 = 24 \text{ volts}$$

Now we know that the voltage drop across R_8 is 24 volts and the voltage drop across the parallel combination of the three resistors is 30 volts. We know that the source voltage will be equal to the sum of the voltage drops around the series circuit so if we can find the voltage drop across the parallel combination of R_1 and R_2 and also the voltage drop across the parallel combination of R_7 in parallel with R_8 and R_9, we'll be able to find the sum of the voltage drops and hence the source voltage.

We can find the voltage drop across the parallel combination of R_1 and R_2 quite easily. Notice that R_1 is three times as large as R_2. This means that the current flowing through R_2 will be three times the current flow through R_1. In other words, if the current flow through R_1 is 1 amp, then the current flow through R_2 would be 3 amps which would give us a total of 4 amps flowing through the two resistors. However, we know that the total current flow in the circuit is 8 amps, therefore the current flowing through R_2 must be 6 amps and the current flowing through R_1 must be 2 amps.

Sometimes you can't divide the current flow this easily, but we can still find what the voltage drop across the two resistors must be by finding the resistance of the parallel combination. To do this, we substitute the values of R_1 and R_2 in our parallel formula

$$R = \frac{27 \times 9}{27 + 9}$$

$$R = \frac{243}{36} = 6.75 \text{ ohms}$$

Now we know that the resistance of R_1 and R_2 in parallel is 6.75 ohms and that the current flowing through the parallel combination is 8 amps; we can find the voltage drop across this combination.

$$E = 8 \times 6.75 = 54 \text{ volts}$$

If you noticed that the current flow through R_2 must be 6 amps and the current flow through R_1 must be 2 amps, then you can use either current flow along with the appropriate resistor to get the voltage drop across the parallel combination.

$$E_1 = 2 \times 27 = 54 \text{ volts}$$

and if you use R_2 in the current flow through it, you would get

$$E_2 = 6 \times 9 = 54 \text{ volts}$$

Notice that no matter how you work it out, either finding the total equivalent resistance and using the total current, or using the resistance of either branch and the current flow through it, you always get the same voltage drop across the parallel combination or R_1 and R_2.

Now all we need to do is find the equivalent resistance of R_7 in parallel with R_8 and R_9, and we can find the voltage drop across this combination. The first step is to find the resistance of R_8 in series with R_9. This is simply 3 + 3 = 6 ohms. Now we have a total of 6 ohms in parallel with 3 ohms; we want to find the resistance of this parallel combination. Again, we use our formula for parallel resistors and get

$$R = \frac{3 \times 6}{3 + 6}$$

$$R = \frac{18}{9} = 2 \text{ ohms}$$

Since the parallel combination of R_7 in parallel with R_8 and R_9 has a resistance of 2 ohms, and the current flowing through this combination is 8 amps, we can find the voltage drop across the parallel combination

$$E = 8 \times 2 = 16 \text{ volts}$$

Now we have the voltage drop across each branch in the series-parallel circuit and all we need to do is add these voltage drops - they must be equal to the source voltage. Therefore the total voltage is equal to

$$E_t = 54 + 30 + 24 + 16 = 124 \text{ volts}$$

This is typical of the problems involving the series-parallel circuits that you might have to work out either on an FCC examination or on an examination for employment in industry. Notice that the problem is not difficult; you just start using Ohm's Law in a part of the circuit where you have two of the three quantities, E, I or R, and then find the third. You use this information to learn more about the circuit and work one step at a time. In the circuit shown in Fig. 20 we were able to determine the current flowing in each part of the circuit, the voltage drop in each branch of the circuit, and the total voltage applied to the circuit. If we wanted to, we could also add the resistance of the individual branches of the circuit and find the total resistance of the circuit; or, since we know the total voltage in the circuit we could simply divide this by the current to get the total resistance in the circuit. Solving problems of this type are really not any more difficult than solving simple Ohm's Law problems; they are simply longer because there are more steps involved.

SUMMARY

Series-parallel circuits are important because you will run into them in all types of electronic equipment. In a series-parallel circuit you will have a voltage source in series with a combination of series and parallel components. You may have one series branch and one parallel branch or you may have several of each. In the parallel branches there may be any number of components.

In a series-parallel circuit the total current flow is the same in all series branches of the circuit. In the parallel branches, the sum of the currents in the individual branches must be equal to the series current flow. The voltage drop across all the components in the parallel branch is the same and the voltage drop across the series components will depend upon the resistance of the component and the total current flowing in the circuit.

To find the total resistance in a series-parallel circuit, you reduce the parallel branches to the equivalent series resistance, and then add the series branches with the equivalent resistance of the parallel branches. The total current flow in the circuit can be determined from the source voltage divided by the total resistance of the circuit and the voltage drop across individual parts in the circuit can be found by using Ohm's Law.

Solving problems involving series-parallel circuits is simply a matter of taking one step at a time, making simple applications of Ohm's Law until the entire circuit is solved.

The following self-test questions are designed to help you with series-parallel circuits. If you find that you are having difficulty with one of the problems, be sure to go back and review. Try to work the problem through on your own, but if you find you can't, look for help at the back of the book - the solutions to the problems are given there. If you have to go to the back of the book to try to find out how to do a problem, make sure you understand that problem before tackling the next one; the chances are that if you will do this, then you will be able to work the next problem by yourself.

SELF-TEST QUESTIONS

(t) Draw a series-parallel circuit containing a battery and three resistors in which R_1 and R_2 are in parallel and connected to the negative terminal of the battery, and R_3 is a series resistor and connected to the positive terminal of the battery.

(u) If $R_1 = 20$ ohms and $R_2 = 30$ ohms, and $R_3 = 12$ ohms, find the total resistance in the circuit.

(v) Using the values of R_1, R_2 and R_3 for the preceding problem, if the battery voltage is 48 volts, find the voltage drop across each resistor in the circuit, and the current flow through each resistor.

(w) If in a circuit like the one shown in Fig. 15, $R_1 = 5$ ohms, $R_2 = 10$ ohms and $R_3 = 10$ ohms, what is the source voltage if the current through R_2 is 1 amp.

(x) Find the total resistance in a series-parallel circuit like the one shown in Fig. 18 when $R_1 = 5$ ohms, R_2, R_3 and R_4 are each equal to 12 ohms, $R_5 = 6$ ohms, $R_6 = 48$ ohms and $R_7 = 24$ ohms.

(y) Complete the following statement: In a series-parallel circuit, the current is the ______ in each series branch of the circuit.

(z) Complete the following statement: In a parallel branch of a series-parallel circuit, the sum of the currents through the branches of the parallel circuit is ______ to the total current flowing in the series part of the circuit.

ANSWERS TO SELF-TEST QUESTIONS

(a) A series circuit is a circuit in which the voltage source and the parts are connected, so that current leaving the negative terminal of the voltage source flows through first one part and then another to the positive terminal of the voltage source and then through the source back to the negative terminal.

(b) To measure the voltage of a battery with a dc voltmeter, you connect the negative terminal of the voltmeter to the negative terminal of the battery, and the positive terminal of the voltmeter to the positive terminal of the battery.

(c) See Fig. 1 and Fig. 3. Either figure is correct; they are the same circuit except in Fig. 3 the resistor values are given.

(d) The polarity of the voltage drops across the resistors is indicated in Fig. 8.

(e) The total resistance in the circuit will be equal to the resistance of the sum of the resistors. Therefore

$$R_t = 3 + 4 + 5 = 12 \text{ ohms}$$

(f) To find the voltage across any one of the resistors you simply use Ohm's Law. You know that

$$E = IR$$

You know the value of each of the resistors and the current will be the same through all resistors so you can find the voltage drop across each one.

$$E_{r1} = 2 \times 3 = 6 \text{ volts}$$

$$E_{r2} = 2 \times 4 = 8 \text{ volts}$$

$$E_{r3} = 2 \times 5 = 10 \text{ volts}$$

(g) You can find the source voltage in two ways. You can add the individual voltage drops you obtained in the preceding section and you will find that the source voltage is

$$6 + 8 + 10 = 24 \text{ volts}$$

You can also get the source voltage from the current times the total resistance, which you found to be 12 ohms. Using this you get

$$E = 2 \times 12 = 24 \text{ volts}$$

(h) You know that the sum of the voltage drops in a series circuit is equal to the source voltage. In this example, the source voltage is 35 volts. The voltage drops across the three resistors are 5 volts, 7 volts and 10 volts. Adding these three voltage drops, we get 22 volts. Therefore the voltage drop across the remaining resistor must be 13 volts.

(i) This problem is exactly the same as the preceding problem. In a series circuit, the sum of the voltage drops is equal to the source voltage. The source voltage is 250 volts, and therefore the voltage drops in the series circuit must add up to 250 volts. The voltage drop across R_1 is 3 volts, and the voltage drop across R_2 is 125 volts. Therefore the sum of the voltage drops across R_1 and R_2 is 128 volts. The remainder of the 250 volts must be dropped between the plate and cathode of the vacuum tube. Therefore the voltage drop across the tube must be 122 volts.

(j) This problem is the same as the preceding problem. The voltage drop across R_1 plus the voltage drop across R_2 is equal to 3.8 volts. Since the battery voltage is 6 volts, the difference, which is 2.2 volts, must be the voltage dropped between the emitter and the collector of the transistor.

(k) This problem is a review of just about everything you have learned about series circuits. To find the total resistance in a series circuit you add the resistance of the individual resistors. Therefore

$$R_t = 120 + 150 + 180 + 120 + 330 = 900 \text{ ohms.}$$

To find the current flowing in the circuit you use Ohm's Law in the form

$$I = \frac{E}{R}$$

Substituting 18 volts for E and 900 ohms for R we get

$$I = \frac{18}{900}$$

This will involve a decimal division and so we multiply it by 1000 and get our current directly in milliamperes. Thus our problem becomes

$$I = \frac{18}{900} \times 1000$$

$$I = \frac{18000}{900}$$

Now we cancel two zeros above and below the line and then we have

$$I = \frac{180}{9} = 20 \text{ ma}$$

To find the voltage drop across each of the resistors we use the formula

$$E = IR$$

We will refer to the voltage drop across R_1 as E_1 and the voltage drop across R_2 as E_2 and so on.

$$E_1 = \frac{20}{1000} \times 120$$

Notice that we wrote the current as

$$\frac{20}{1000}$$

The current must be in amperes and we convert 20 milliamperes to amperes by dividing it by 1000. Now continuing with the problem,

$$E_1 = \frac{20 \times 120}{1000}$$

$$E_1 = \frac{2400}{1000}$$

$$E_1 = \frac{24}{10} = 2.4 \text{ volts}$$

$$E_2 = \frac{20}{1000} \times 150$$

$$E_2 = \frac{3000}{1000} = 3 \text{ volts}$$

$$E_3 = \frac{20}{1000} \times 180$$

$$E_3 = \frac{3600}{1000}$$

$$E_3 = \frac{36}{10} = 3.6 \text{ volts}$$

$$E_4 = E_1 = 2.4 \text{ volts}$$

$$E_5 = \frac{20}{1000} \times 330$$

$$E_5 = \frac{6600}{1000}$$

$$E_5 = \frac{66}{10} = 6.6 \text{ volts}$$

Notice that we did not calculate the voltage across R_4. R_4 is equal to R_1 and since in a series circuit the same current flows through the entire circuit then the voltage drop across R_4 must be equal to the voltage drop across R_1. Therefore calculating the voltage a second time would simply be a waste of time. As a matter of fact, sometimes in a problem of this type you can save yourself some work by looking up the resistor values. For, example, if one resistor happened to be twice that of the other, you would know immediately that the voltage drop across it was twice as high as the voltage drop across the first resistor. Similarly if one resistor was three times another you could expect three times as high a voltage drop across it.

(l) 25 ohms. The total resistance of two equal resistors connected in parallel is always one half the resistance of either resistor.

(m) 8 ohms. You find the resistance of the two resistors in parallel by using the formula

$$R_t = \frac{R_1 \times R_2}{R_1 + R_2}$$

and substituting 24 ohms and 12 ohms for R_1 and R_2 you get

$$R_t = \frac{24 \times 12}{24 + 12}$$

$$= \frac{288}{36} = 8 \text{ ohms}$$

(n) The current flow through each resistor can be found from Ohm Law's

$$I = \frac{E}{R}$$

The current through the 3-ohm resistor will be

$$I = \frac{12}{3} = 4 \text{ amps}$$

and the current through the 4-ohm resistor will be

$$I = \frac{12}{4} = 3 \text{ amps}$$

The total current flow will be the sum of these two currents or 7 amps. You can use this value of current and the voltage of 12 volts to find the resistance of the two resistors in parallel,

$$R = \frac{E}{I}$$

$$R = \frac{12}{7} = 1.7 \text{ ohms}$$

(o) 4 ohms. The resistance of two 8-ohm resistors in parallel will be 4 ohms, one half the resistance of either resistor. The 1000-ohm resistor is so large that we can simply ignore it because it will not affect the total resistance of the circuit appreciably. As a matter of fact, if you did consider it and calculated the value of the three in parallel you would find that the resistance worked out to be over 3.98 ohms. This is less than two parts in four hundred, an error which is so small it is insignificant, and it can be ignored.

(p) R_1 is the larger resistor because the smaller current flows through it. Since only half as much current flows through R_1 as through R_2, then R_1 must be twice the size of R_2.

(q) If the current through the 5-ohm resistor is 2 amps, then the voltage across it must be 10 volts. We use Ohm Law's in the form E = IR to determine this voltage. Since the two resistors are in parallel and connected across a battery we know that the battery voltage must be 10 volts, and the voltage across the 10-ohm resistor must be 10 volts. With 10 volts across the 10-ohm resistor, a current of 1 amp will flow through it. We would also know that a current of 1 amp must flow through the 10-ohm resistor since it is twice the size of the 5-ohm resistor, and therefore half the current would flow through it that flows through the 5-ohm resistor. The total current flowing in the circuit must be the sum of the current through the two resistors or 3 amps.

(r) In a parallel circuit, the voltage across all branches of the parallel circuit will be equal.

(s) In a parallel circuit, the current through each branch of a parallel circuit will depend upon the resistance of the branch. The largest current will flow through the branch having the lowest resistance, and the smallest current will flow through the branch having the highest resistance.

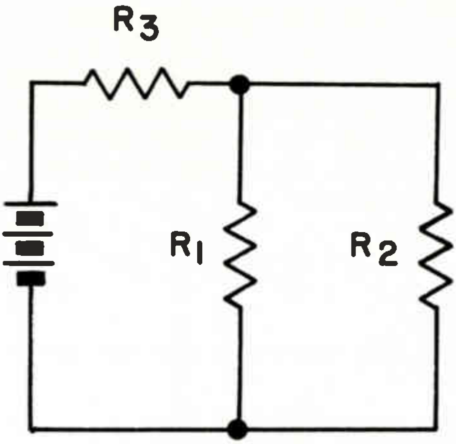

Fig. 21. Answer to Self-Test Question (t).

(t) See Fig. 21.

(u) 24 ohms. The total resistance of the parallel combination of R_1 and R_2 can be found from the parallel resistor formula. Substituting these values we get

$$R_t = \frac{20 \times 30}{20 + 30}$$

$$= \frac{600}{50} = 12 \text{ ohms}$$

This resistance is in series with R_3, which also has a resistance of 12 ohms, so the total resistance in the circuit is 24 ohms.

(v) With a voltage of 48 volts and a total resistance of 24 ohms, the total current flowing in the circuit will be

$$I = \frac{48}{24} = 2 \text{ amps}$$

This means that the voltage drop across R_3 will be

$$E = 2 \times 12 = 24 \text{ volts}$$

Therefore the voltage drop across the parallel combination of R_1 and R_2 must also be 24 volts. The current through R_1 must be

$$I = \frac{24}{20} = 1.2 \text{ amps}$$

The current through R_2 must be

$$I = \frac{24}{30} = .8 \text{ amps}$$

(w) 20 volts. If the current through R_2 is 1 amp, and the resistance of R_2 is 10 ohms, then the voltage across R_2 must be

$$E = 1 \times 10 = 10 \text{ volts}$$

Since R_2 and R_3 are in parallel, then the same voltage must be across R_3, and therefore the same current of 1 amp will flow through it, giving a total current of 2 amps through R_2 and R_3. This current of 2 amps must flow through R_1 and since R_1 has a resistance of 5 ohms, the voltage drop across it must be

$$E = 2 \times 5 = 10 \text{ volts}$$

Since the source voltage in any circuit is equal to the sum of the voltage drops around the circuit, the source voltage in this case must be 20 volts.

(x) The total resistance is 31 ohms. To solve this problem we must find the resistance of R_2, R_3 and R_4 in parallel and also the resistance or R_6 and R_7 in parallel. We can substitute an equivalent for these two parallel groups; then we have a simple series circuit and we can find the total resistance of this circuit simply by adding the individual resistances.

Since R_2, R_3 and R_4 are each 12-ohm resistors, then the total resistance of the three resistors in parallel will be one-third the resistance of any one of the resistances or one-third of 12 which is 4 ohms.

The resistance of the parallel combination of R_6 and R_7 can be found using the parallel resistance formula

$$R_t = \frac{48 \times 24}{48 + 24} = 16 \text{ ohms}$$

Now substituting 4 ohms for the parallel combination R_2, R_3 and R_4 and 16 ohms for the parallel combination of R_6 and R_7 we have a series resistance circuit. The total resistance of this circuit will be

$$R_t = 5 + 4 + 6 + 16 = 31 \text{ ohms}$$

(y) In a series-parallel circuit, the current is the same in each series branch of the circuit.

(z) In a parallel branch of a series-parallel circuit, the sum of the currents through the branches of the parallel circuit is equal to the total current flowing in the series part of the circuit.

Lesson Questions

Be sure to number your Answer Sheet B104-1.

Place your Student Number on every Answer Sheet.

1. What is the total resistance of three 15-ohm resistors connected in series?

2. What is the total resistance of three 15-ohm resistors connected in parallel?

3. A 3-ohm, a 5-ohm and a 4-ohm resistor are connected in series across a battery. The voltage drop across a 3-ohm resistor is 6 volts. What is the battery voltage?

4. If three resistors are connected in series across a 12-volt battery, and the voltage drop across one resistor is 3 volts and the voltage drop across the second resistor is 7 volts, what is the voltage drop across the third resistor?

5. If four resistors are connected in parallel and R_1 equals 12 ohms and R_2 equals 9 ohms, R_3 equals 24 ohms and R_4 equals 18 ohms, what is the resistance of the parallel combination?

6. R_1 and R_2 are two resistors of the same value connected in parallel. This parallel combination is connected in series with R_3, a 10-ohm resistor. The series-parallel network is connected to a 15-volt battery. If the voltage across R_3 is 10 volts, what are the values of R_1 and R_2?

7. If two resistors are connected in parallel, will the voltage drop across the two be (1) equal, (2) greater across the larger resistor, (3) greater across the smaller resistor?

8. Resistors R_1 and R_2 are connected in parallel. The resistance of R_1 is 4 ohms, and the current through it is 2 amps. The current through R_2 is .5 amps. Find the resistance of R_2.

9. Three 6-ohm resistors are connected in parallel. A fourth 6-ohm resistor is connected in series with the parallel combination. The series-parallel network is connected to a battery with the free end of the single 6-ohm resistor going to the positive terminal. Draw a schematic diagram of the circuit.

10. In the circuit of Question 9, if the battery voltage is 8 volts, what will the voltage across the three parallel-connected resistors be?

HOW TO CONCENTRATE

The secret of rapid progress with any course of study lies in being able to concentrate. If your mind wanders from study while you are alone in a quiet room, try moving to a noisy room, or try tuning in an all-musical program on the radio. Stay away from loud conversations, though.

If noise definitely bothers you, however, do your studying in a quiet location. If you feel too sleepy to concentrate, the room may be too hot. Open the windows, and put on a coat if necessary, for it is easier to study in a cool room. Sponge your face, neck and eyes with cold water.

If you have difficulty in understanding a subject, write down an explanation of it in your own words, or try outlining the subject and studying your outline. Underlining important words as you study is another aid to learning.

Try different studying techniques, until you find the one that gives you complete mastery of a subject in the shortest possible time. The faster you master each lesson, the sooner you'll complete the Course and be ready for a good job in electronics.

HOW RESISTORS ARE USED

B105-1

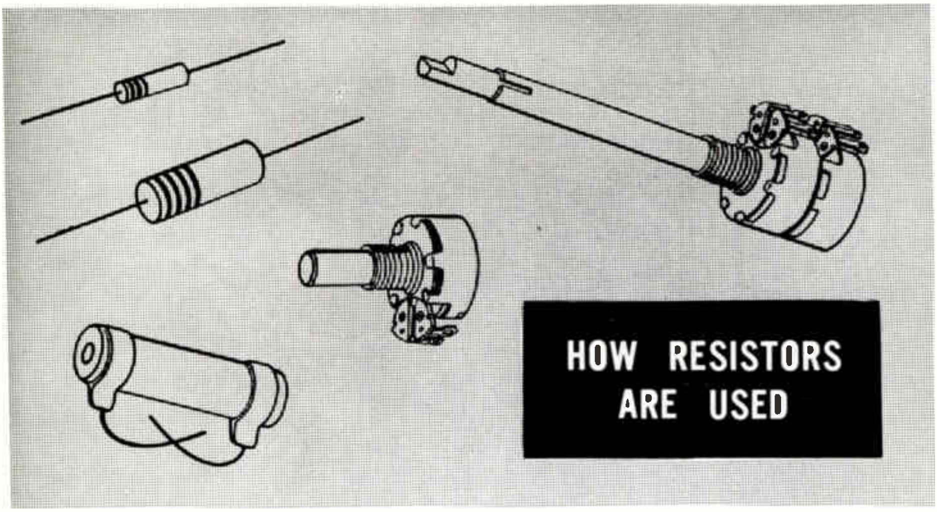
STUDY SCHEDULE

For each study step, read the assigned pages first at your usual speed, then reread slowly one or more times. Finish with one quick reading to fix the important facts firmly in your mind. Study each other step in the same way.

JDL3M1174 **1974 EDITION** **Litho in U.S.A.**



HOW RESISTORS ARE USED

This is the first lesson in your NRI course that will be devoted almost entirely to one electronic part - resistors. In your next lesson you will study coils in detail, and in the following lesson you will study capacitors. These three parts - resistors, coils and capacitors - along with tubes and transistors are the most important parts in electronic equipment. You will find more resistors in electronic equipment than any other part. Therefore it is important that you learn how they are used so that you will be able to tell whether or not a particular circuit is working properly, and also so that you will be able to select a suitable replacement for a resistor in a circuit, when a replacement is needed.

Resistors, coils, and capacitors are important, not only because they are used so often in electronic equipment, but also understanding how these parts work will help you to understand how other parts work. For example, a transformer is nothing more than a group of coils wound on a single core. If you understand how a single coil works, then you will be much better prepared to understand how several of them work when used together to make up a transformer.

Resistors perform in essentially the same way in both ac and dc circuits. However, you will find when you study coils and capacitors that this is not true of these parts. Actually, coils and capacitors have little or no value in dc circuits. They are primarily used in ac circuits. Therefore, when you study coils and capacitors, you will be learning more about these parts, and we will also go into more detail about ac and how it acts in circuits where these parts are present.

WHY RESISTORS ARE IMPORTANT

Resistors are found in practically every piece of electronic equipment. As a technician you will have to replace many resistors. As we mentioned earlier, there are more resistors used in electronic equipment than any other parts.

Sometimes when you have to replace a resistor you will be able to refer to the schematic diagram of the equipment, find the value of the resistor and simply go ahead and install a new resistor in the circuit. However, you will find that on many occasions you will have to work on electronic equipment for which there is no diagram available and the original resistor may have been burned so badly that you will be unable to tell what its value was. Then, you will have to fall back on your knowledge of electronic circuits to decide what size resistor to use. What you will learn in this lesson will prepare you for this type of work.

There are many uses for resistors in electronic equipment. The various electrodes in a tube or transistor used in a piece of electronic equipment do not all require the same operating voltages. However, for economy, the required operating voltages must all be obtained from a single power supply. Resistors are used to drop the voltage to the correct value for the tube or transistor.

Resistors are used to isolate parts from each other, so that one will not interfere with the operation or the action of each other.

Special variable resistors called potentiometers are used to control the volume and tone in radio and TV receivers, to control the picture brightness and contrast in black and white and color TV receivers, and to adjust the tint and color saturation of the picture in color sets.

There is no end to the uses to which resistors are put in electronic equipment, and therefore it is extremely important that you understand how they are used.

TYPES OF RESISTORS

You already know that there are several types of resistors used in electronic equipment. The most frequently encountered resistor is the carbon resistor, which as we mentioned before is simply a carbon compound which is held together by a cement-type of binder. Carbon resistors are made chiefly in 1/2-watt, 1-watt and 2-watt sizes. Occasionally you will run into very small carbon resistors that are 1/3-watt resistors, but these are not used too often. You will learn more about the watt, which is the unit of power measurement, later in this lesson.

You will soon learn to recognize the wattage rating of a resistor by its size. The resistors shown in Fig. 1 are 1/2-watt, 1-watt and 2-watt carbon resistors. The body of the resistor in each case is drawn full size to give you an idea of how big each type of resistor is.

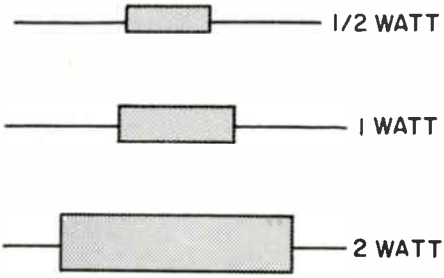


Fig. 1. Relative physical size of the three different wattage carbon resistors usually found in electronic equipment.

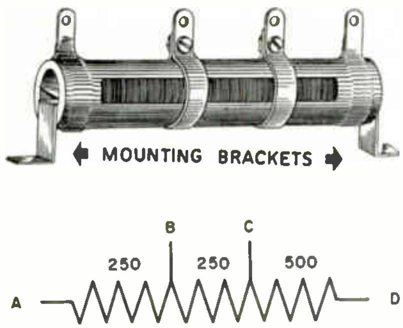

Fig. 2. A tapped wire-wound resistor and its schematic symbol.

In addition to carbon resistors you will run into wire-wound resistors. A wire-wound resistor is made by winding a resistance wire on a form. Wire-wound resistors are found with wattage ratings of 3 or 4 watts up to very high wattage ratings.

In some electronic equipment you will find tapped wire-wound resistors that look like the resistor shown in Fig. 2. The total resistance of this resistor is 1000 ohms. This is the resistance you would measure between terminals A and D. However, there are two taps on the resistor; these are the taps B and C. The resistance between terminal A and B is 250 ohms and the resistance between terminals B and C is 250 ohms. The remaining resistance between terminals C and D is 500 ohms. This type of resistor is usually quite a large resistor and in most cases it is mounted on the chassis by means of mounting brackets which hold it in place. The resistor is so large and heavy that if it were simply held in place by wires connected to the various terminals, the chances are that if the equipment received any jarring or bouncing the resistor would break loose from the wires.

Metal oxide resistors are also widely used in modern electronic equipment. These resistors can be made in higher wattage ratings than carbon resistors, and still have many of the advantages of the carbon resistors. The wire-wound resistors are made by winding wire in the form of a coil on an insulated support such as a ceramic type rod. Since the resistor is made of a coil of wire it takes on some of the characteristics of a coil. In some circuits this may be undesirable and in applications of this type a metal oxide resistor can be used. It is made by depositing a metal oxide film on a ceramic or glass tube or rod. The oxide film is in the form of a continuous path rather than a coil and therefore does not act like a coil.

You will also run into variable resistors such as shown in Fig. 3. The resistor shown in Fig. 3A is a wire-wound type of variable resistor and is usually called a rheostat. Notice that this type of resistor has only two terminals. Another rheostat is shown in Fig. 3B. This rheostat can either be a wire-wound control similar to the one shown in A or it might have a carbon element and a slider that rotates along the

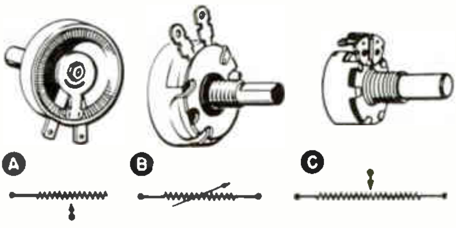

Fig. 3. Variable resistors and the symbols for them. A and B are rheostats, and C is a potentiometer.

carbon element to provide the required resistance between the two terminals. The variable resistor shown in Fig. 3C is called a potentiometer. This variable resistor has three terminals. The resistance between the two outside terminals remains constant and the slider moves on the resistance element so the resistance between the center terminal and the other two may be varied. A control of this type may be a wire-wound control or it can also be a carbon control. Most potentiometers are fairly high resistance units and are carbon controls. However, in some applications, for example in color TV receivers, you will run into some very low resistance potentiometers, and these are wire-wound controls. Potentiometers will be found in all types of electronic equipment.

In electronic equipment you will run into all three types of resistors: carbon, wire-wound, and deposited-film. Most often these will be fixed resistors; in other words, they will have a certain value which cannot be changed.

You will also encounter many tapped resistors; this type resistor is always a wire-wound resistor.

In addition, you will run into variable resistors; these may be either wire-wound or carbon resistors. If a variable resistor has two terminals it is called a rheostat; if it has three terminals it is called a potentiometer.

Thus resistors are classified as carbon, wire-wound, and deposited-film; these resistors may be either fixed, tapped, or variable. Variable resistors are divided into rheostats and potentiometers.

Now let's study some of the important uses of resistors.

Using Resistors To Reduce Voltage

We mentioned earlier that in a radio or TV receiver as well as industrial control equipment, many different operating voltages may be required, and these voltages must be obtained from a single power supply to keep down the cost of the equipment. Resistors are often used to reduce the voltage from the power supply to the required value.

SERIES-DROPPING RESISTORS

One of the most common applications of a resistor where it is used to drop voltage is the series-dropping resistor. In this case, the resistor is placed in series with the load, and the current flowing through it produces a voltage drop across the resistor. Small table model radio receivers are an example in which this use of a resistor may be found. In these radio receivers, the heaters of the various tubes are connected in series and they are operated directly from the power line. However, in some cases, the total voltage required by the heaters connected in series may be somewhat less than the power line voltage. In such a case, a resistor is placed in series with the heaters, and part of the voltage is used up by the resistor so that each tube heater gets the correct voltage.

An example of a circuit of this type is shown in Fig. 4. Here we have four tubes with their heaters connected in series. Notice that three of the tubes operate with a heater voltage of 12.6 volts. When the three tubes are connected in series they will require three times this voltage or 37.8 volts. These three tubes are connected in series with the fourth tube that operates with a heater voltage of 50 volts so that the total voltage required by the four tubes in series is 87.8 volts. However, to operate this string of four tubes from a 120-volt power line means that we have to get rid of approximately 32 volts in some

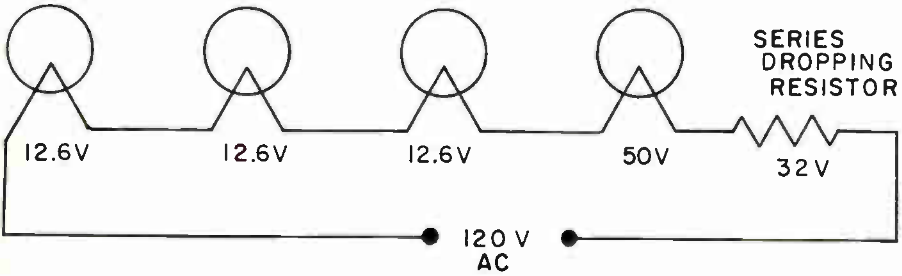

Fig. 4. A series tube heater string, with a series-voltage-dropping resistor.

way in order to get the correct voltage on each tube. Here the series-dropping resistor is connected in series with the tubes. If the tubes operate with a heater current of .15 amps, you can find the value of the resistor required by using Ohm's Law

$$R = \frac{E}{I}$$

and substituting 32 for E and .15 for I, we would find that a resistor with a resistance of 213 ohms would be required. Actually, it probably would be impossible to get a 213-ohm resistor but a 210-ohm or a 215-ohm resistor would certainly be close enough. As a matter of fact, even with a 200-ohm resistor in the circuit, the heater voltage on the tubes would be only slightly over the rated value and should not appreciably affect tube life.

Series-dropping resistors of this type are also to be found in some television receivers. Of course, in the TV receiver there will be far more tubes, and the chances are that the voltage that the resistor must drop will be less than the value in the preceding example, but its purpose is the same, to reduce the line voltage to the value required by the series-heater string.

Series-dropping resistors are also used in dc circuits An example of this type of arrangement is shown in Fig. 5. Here the load, which is represented by R_2, requires an operating voltage of 100 volts. The power supply voltage is 250 volts. The series-dropping resistor R_1 is used to reduce or drop the power supply voltage from 250 volts down to 100 volts for the load. This means that there will be a voltage drop of 150 volts across the series-dropping resistor.

The value of resistance required in R_1 will depend upon the resistance of R_2. Normally the load will have a certain resistance, and when it is operated at the correct voltage a certain current will flow through the resistance. As an example, if the resistance of R_2 is 50,000 ohms, when a voltage of 100 volts is applied across this load, a current of 2 ma will flow through it.

We can use this information to determine the value of the series-voltage-dropping resistor. We know that we must drop a voltage of 150 volts, and since it will be in series with R_2, the current flowing through it will be the same as the current through R_2, in other words 2 ma.

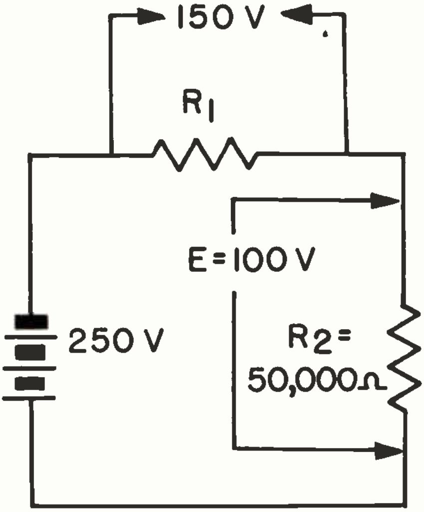

Fig. 5. The series-voltage-dropping resistor is used to reduce the power supply voltage from 250 volts to 100 volts for the load R_2.

We can use this information and Ohm's Law to find the value of R_1.

$$R = \frac{E}{I}$$

$$R = \frac{150}{.002} = 75{,}000 \text{ ohms}$$

In this particular instance we do not even have to resort to Ohm's Law to find the value of R_1. We know the resistance of R_2 is 50,000 ohms and it will have a voltage of 100 volts across it. We want R_1 to have 150 volts across it or 1-1/2 times the voltage across R_2. Therefore the resistance of R_1 must be 1-1/2 times the resistance of R_2. Since R_2 has a resistance of 50,000 ohms, then R_1 must have a resistance of 75,000 ohms.

An arrangement of this type works out very nicely as long as the resistance of R_2 remains constant. However, in many cases in electronic equipment the resistance of the load varies. When this happens, the total resistance in the circuit will vary and this will cause the current to vary. When the current in the circuit varies, the voltage drop across R_1 will vary and when this happens, the voltage across R_2 will also vary. In some cases a fairly wide variation in voltage across R_2 will not present any problem, but there are many applications where we may want to keep the voltage across R_2 reasonably constant. Under these circumstances a simple series-dropping resistor of the type shown in Fig. 5 is not particularly satisfactory.

Let us look at Fig. 6 to see how a variation in the resistance of R_2 can affect the voltage across it. Notice that here we have represented R_2 as the variable resistance load. Suppose the resistance of R_2 goes down to 25,000 ohms. Now, we have a total resistance in the circuit of 25,000 ohms for R_2 and 75,000 ohms for R_1. This means the total resistance in the circuit will be 100,000 ohms. Using Ohm's Law we find that the current will be

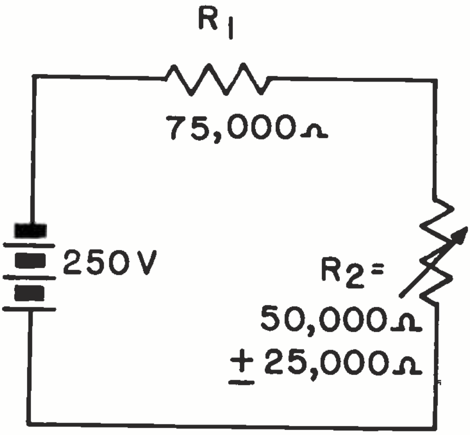

Fig. 6. When the value of R_2 varies, the voltage across it will also vary.

$$I = \frac{E}{R}$$

$$I = \frac{250}{100{,}000} \text{ amps}$$

We can multiply the numerator in this expression by 1,000 and get our answer directly in milliamperes, or perform the division as indicated. If we perform the division as indicated we will find that the current is .0025 amps. If we multiply by 1,000 first, we will get our answer in milliamperes, and in this case

$$I = 2.5 \text{ ma}$$

In either case, we see that the current has increased from 2 ma to 2.5 ma. Now the voltage drop across R_1 will be greater than 150 volts. The actual voltage drop will be 187.5 volts. Since the power supply voltage is 250 volts this leaves us with a voltage of 62.5 volts across the load.

Now let us see what happens when the resistance of R_2 increases. Suppose a resistance of R_2 increases by 25,000 ohms and becomes 75,000 ohms. Now we have R_1 and R_2 in series and since each resistor has a value of 75,000 ohms, half of the voltage will be across each resistor. This means that the voltage across R_2 will increase from 100 volts to 125 volts.

From the preceding we see that if the resistance of R_2 does change, we get quite a substantial voltage variation across the resistor. If the resistance goes down 25,000 ohms, the voltage across the load drops to 62.5 volts, and if the resistance goes up 25,000 ohms, the voltage goes up to 125 volts. A change of this type could appreciably affect the performance of a circuit and in most cases we would have to take steps to prevent such a wide voltage variation.

BLEEDER RESISTORS

Wide voltage variations such as we encountered in the circuit shown in Fig. 6 can be reduced substantially by means of a bleeder resistor. Fig. 7 shows how a bleeder resistor is connected into the circuit. Notice that the bleeder, R_3, is connected in parallel with the load R_2.

The idea in back of the bleeder is to help keep the current flowing through R_1 constant. If the current flowing through R_1 is constant then the voltage drop across it will be constant and this in turn will mean that the voltage across the load will remain constant.

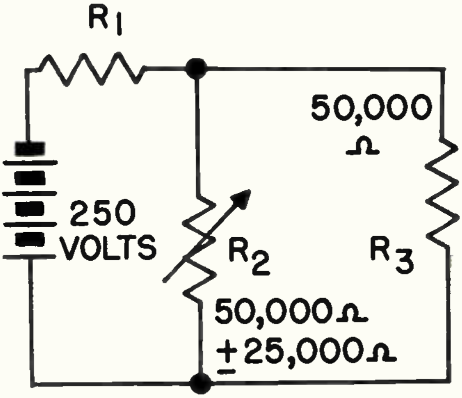

Fig. 7. The bleeder resistor R_3 is connected in parallel with the load R_2 to stabilize the voltage across the load.

The higher the bleeder current, the more closely we can keep the voltage constant across the load. This is due to the fact that if the bleeder current is large, it makes up most of the current flowing through R_1, and since it will remain constant, the current changes through R_1 due to variations in the load resistance will be held to a minimum.

Let us look at an example and see how the bleeder actually can help regulate the voltage. Let us take R_2 with a nominal resistance of 50,000 ohms, as before, and connect a bleeder resistor, R_3, in parallel with R_2. Let us select a bleeder that also has a resistance of 50,000 ohms. As before, we want to maintain the voltage across the load constant at 100 volts.

With a voltage of 100 volts across the load resistor, with its value at 50,000 ohms, the current through the load will be 2 ma as before. Since the bleeder is in parallel with the load, 2 ma will also flow through it. This means that the total current in the circuit will be 4 ma.

Now we need to select a series-dropping resistor, R_1. As before, since the power supply voltage is 250 volts, the series-dropping resistor must drop 150 volts. Going back to Ohm's Law, we have

$$R_1 = \frac{150 \text{ volts}}{.004} = 37{,}500 \text{ ohms}$$

Therefore with a series-dropping resistor of 37,500 ohms we will get a voltage drop of 150 volts across R_1, and with a load, R_2 of 50,000 ohms, and a bleeder of 50,000 ohms we will have a voltage of 100 volts across the load and across the bleeder.

With the load and the bleeder in parallel, the total resistance of the two in parallel will be 25,000 ohms. Remember that they are of equal value and therefore the parallel resistance is one-half the resistance of either resistor. Now let's see what happens when the value of R_2 decreases to 25,000 ohms. We will see how this affects the voltage across the load.

When R_2 goes down to 25,000 ohms, we have the 25,000 ohms load in parallel with the 50,000 ohms bleeder. The parallel resistance of the combination is 16,666 ohms which we can round off to 16,500 ohms to simplify our calculations. Total resistance in the circuit will be 16,500 plus the resistance of R_1, which is 37,500 ohms, or a total of 54,000 ohms. The current that will flow in the circuit can be found from Ohm's Law

$$I = \frac{250}{54{,}000} = .0046 \text{ amps}$$

A current of .0046 amps (4.6 ma) flowing through R_1 will produce a voltage drop of

$$E = .0046 \times 37{,}500 = 172.5 \text{ volts}$$

With a voltage drop of 172.5 volts across R_1, the remainder of the voltage will be dropped across R_2 and the bleeder resistor R_3. Subtracting 172.5 from 250 will give us 77.5 volts. Remember that in the preceding example shown in Fig. 6, when the value of R_2 went down to 25,000 ohms, the voltage across it dropped to 62.5 volts. Simply connecting the bleeder resistor with the same value as the nominal value of R_2 in parallel with the load improved the voltage regulation by 15 volts when the resistance of R_2 went down.

When the resistance of R_2 increases by 25,000 ohms, you will have the load R_2, which will then have a resistance of 75,000 ohms, in parallel with the bleeder R_3, which has a resistance of 50,000 ohms. The parallel combination of a 75,000-ohm and a 50,000-ohm resistor will give us a parallel resistance of 30,000 ohms. This resistance in series with R_1 will give us a total resistance of 67,500 ohms in the circuit. With this resistance in the circuit the current flow in the circuit will be .0037 amps and the voltage drop across R_1 138.75 volts. This means that the remainder of the voltage will appear across the load and bleeder and in this case would be 111.25 volts. This compares with the voltage of 125 volts which we found we would get across the load without the bleeder when the resistance of the load increased by 25,000 ohms.

In other words, without a bleeder connected across the load, as the value of the load resistance varied 25,000 ohms above and below its nominal value of 50,000 ohms, its voltage varied from 62.5 volts to 125 volts. With a 50,000-ohm bleeder connected across the load, when the load resistance varied 25,000 ohms above and below its nominal value, the voltage across the load varied from 77.5 volts to 111.25 volts. You will notice that connecting the bleeder in parallel with the load has had a substantial effect in maintaining a more constant voltage across the load.

The larger the bleeder current, the better the voltage regulation will be. In fact, if the nominal value of R_2 is 50,000 ohms and we put a 5,000-ohm bleeder in parallel with it we get very little voltage change at all as the resistance of R_2 varies between 25,000 and 75,000 ohms. With a bleeder of this size, the total series current flow would be about .022 amps. This would require a series-dropping resistor of approximately 6800 ohms. When the resistance of R_2 dropped from 50,000 ohms to 25,000 ohms, the current in the circuit would increase from .022 amps to slightly less than .023 amps. The increase in the voltage drop across R_1 would be only 4 volts, which means that the voltage drop across the load would change from 100 volts to 96 volts. Similarly, if the resistance of R_2 increased from 50,000 ohms to 75,000 ohms, the current in the circuit would drop only about one half a milliampere and the voltage drop across R_1 would change from 150 volts to approximately 147 volts. Therefore the voltage across the load would increase to 103 volts. As you can see, with a low-resistance bleeder that draws a high bleeder current, the voltage across the load remains almost constant, even with the same variation in the load that produced a wide voltage variation before.

Since a bleeder that draws a large current regulates the voltage so well you might wonder what the problem is. In a circuit where we want to keep the voltage across the load constant, why not simply put a bleeder across the load that will draw a high current and maintain the voltage constant? The answer is that the bleeder current serves no purpose other than to regulate the voltage across the load. In so far as performing any other function is concerned, it is wasted. There is a limit to how much current we can take from a power supply. The more bleeder current we draw the bigger and more costly the power supply must be. Therefore in applications where a bleeder is used, in most cases some compromise is reached and a value of bleeder is selected that will give the voltage regulation required, and no more. Of course in some applications where very precise regulation is required, we have to waste the power in the bleeder in order to get this regulation. In this case, we must build a power supply capable of supplying the required current even though it may be quite costly.

Series-dropping resistors and bleeders are often used in tube and transistor circuits. You have already studied the triode tube and will remember that it has three elements, a cathode, a grid and a plate. The pentode tube is a tube with five elements. It has the same three elements as the triode tube plus a suppressor grid and a screen grid. The suppressor grid is usually connected to B- or to the cathode. The screen grid is connected to B+ and usually operated at a voltage somewhat less than the plate voltage. The voltage required for the screen is obtained through a series-dropping resistor from the same power supply that supplies the plate voltage. If the screen voltage must be maintained constant then you will often find a bleeder in the screen circuit for this purpose.

SUMMARY

Now let us review what you have studied in this section on resistors and how they are used to reduce voltage. Resistors are sometimes used in the heater circuit of small radios or in the heater circuit of television receivers to reduce the line voltage to the value required by series-connected tube heaters. Resistors are also used to reduce the voltage to a load so that the load can be operated from a power supply that has a somewhat higher voltage than the voltage required by the load.

Resistors are used as bleeders to stabilize or regulate the voltage across a load. The bleeder consumes or wastes a certain amount of current, but this extra current that flows through the bleeder remains constant and helps maintain the voltage drop across the series-dropping resistor constant. The larger the current consumed by the bleeder in comparison to the current consumed by the load, the better the regulation across the load will be. However, since the bleeder current is waste current and performs no useful purpose other than to regulate the voltage across the load, we normally do not use any more bleeder current than is necessary to get the degree of regulation that is required across the load. We keep the bleeder current as low as possible in order to keep the cost and size of the power supply as low as feasible. However, in some applications where very precise regulation is required, a large bleeder current is used and we simply have to go to the expense of making the power supply as large as necessary to supply this current along with the load current.

Now to help you be sure that you understand this section of the lesson and to review it, answer the following self-test questions.

SELF-TEST QUESTIONS

(a) What is the purpose of a series-dropping resistor?

(b) If two tubes that each require a heater voltage of 35 volts are connected in series with two additional tubes that require a heater voltage of 6 volts each and the four heaters connected in series are to be operated from a 120-volt power line, how much voltage must the series-dropping resistor drop in order to provide the correct heater voltages for the tubes?

(c) In the preceding example, if the current drawn by the tubes is .3 amperes, what would be the value of the series-dropping resistor to use?

(d) What is the purpose of a bleeder?

(e) Which type of bleeder is more effective, a high-resistance bleeder that draws very little current, or a low-resistance bleeder that draws a substantial current?

(f) What consideration other than regulation must be kept in mind in selecting a bleeder?

(g) If a load, which has a resistance of 20K ohms and requires an operating voltage of 200 volts, is connected across a power supply that has an output voltage of 300 volts, what should the resistance of the series-voltage-dropping resistor be?

Power In Electrical Circuits

We have already mentioned several times that the unit of electrical power is the watt. The watt tells us how much electrical energy or power is being expended or used in a circuit. You have probably run into this unit many times, and you are no doubt familiar with different size light bulbs - they are rated in watts. A 60-watt bulb consumes 60 watts of electrical energy when it is lit. A 100-watt electric bulb consumes 100 watts of electrical energy - almost twice as much power as a 60-watt bulb.

Now let us go ahead and learn more about exactly how much electrical energy the watt represents.

THE WATT

The power in an electrical circuit is equal to the product of the voltage times the current. Expressing this as a formula we have

$$P = E \times I$$

We generally drop the times sign and simply write the formula as

$$P = EI$$

This formula tells us that if a generator is supplying a voltage of 1 volt to a circuit and the current flowing in the circuit is 1 amp, the power being supplied by the generator is 1 watt. If the generator is supplying a voltage of 10 volts and a current of 2 amps, the power being supplied by the generator is 10×2 =20 watts.

From the expression for power we see that the current used by a 100-watt electric light bulb will be slightly less than 1 amp when the bulb is operated from a 120-volt power line. Since the product of the voltage times the current equals 100 watts, we can find the current by rearranging the power formula to

$$I = \frac{P}{E}$$

and substituting 100 watts for P and 120 volts for E

$$I = \frac{100}{120} = .83 \text{ amps}$$

A 60-watt bulb will draw somewhat less current,

$$I = \frac{60}{120} = .5 \text{ amps}$$

The power in an electrical circuit can also be expressed in terms of voltage and resistance or in terms of current and resistance by combining the power formula with Ohm's Law. For example from Ohm's Law we know that

$$E = I \times R$$

If we substitute I × R for E in the power formula we have

$$P = I \times R \times I = I \times I \times R$$

If we drop the times sign and write I × I as I^2 (this is called I squared) we will have the formula

$$P = I^2R$$

You will see this expression many times in electronics. Remember that the term I^2 means I × I. This form of the power equation is often used to determine the wattage rating of a resistor in a circuit where the current through the resistor and the resistance of the resistor are known.

Going back to our original power formula

$$P = E \times I$$

and Ohm's Law in the form

$$I = \frac{E}{R}$$

if we substitute $\frac{E}{R}$ for I we will get

$$P = E \times \frac{E}{R}$$

which we usually write as

$$P = \frac{E^2}{R}$$

where the expression E^2 means E × E. This form of the power equation can be used where we know the voltage across a part and the resistance of the part or circuit.

These three forms of the power formula are extremely important; you will have many occasions to use them. Therefore you should take the time now to memorize them to save having to look them up in the future. Even though you may not have to do a great deal of calculating involving these formulas you should know what the formulas are so you will be able to approximate the power used in a circuit. The three formulas are:

$$P = EI$$

$$P = I^2R$$

$$P = \frac{E^2}{R}$$

WATTAGE RATING OF RESISTORS

Earlier we mentioned that resistors were made with different wattage ratings. When current flows through a resistor a certain amount of power is used, or as we say dissipated. The wattage rating of a resistor tells us how much power the resistor can dissipate. If the power being dissipated by the resistor is greater than its wattage rating, the resistor will soon burn out.

We mentioned previously that carbon resistors are made in 1/2-watt, 1-watt and 2-watt sizes. Also, you will occasionally run into very small carbon resistors that are rated at 1/3-watt.

When we say that a resistor is a 1-watt resistor we mean that the power it can dissipate or handle is 1-watt. This means that the product of the current squared through the resistor times the resistance of the resistor must be equal to 1 watt or less.

Actually, in the case of carbon resistors, it is not a good idea to use them at their maximum rating. Carbon resistors have a tendency to change value if they get too hot. A 1-watt carbon resistor that is actually dissipating one full watt of electric power will get quite warm after it has been in operation for some time. Eventually, this will cause the resistor to change value. There is no way of predicting how much the resistor will change value - the change might be slight and may not affect the performance of the circuit. On the other hand, the change might be large enough to appreciably affect the performance of the circuit. The usual practice is to use resistors having a wattage rating almost double that actually required. In other words, if the power that a resistor must dissipate is 1 watt or slightly over 1 watt then you would use a 2-watt resistor. If the resistor must dissipate approximately 1/2 watt, it is best to use a 1-watt resistor to avoid any possible problem in the future due to the resistor overheating and changing value.

The deposited film type of resistor is made in ratings of 2 watts up to about 10 watts. These resistors are somewhat larger than carbon resistors and are able to handle the larger power. They do not have the tendency to change value that carbon resistors have and therefore can be operated closer to their full wattage rating. However, even in the case of deposited film resistors, most manufacturers usually allow a reasonable safety factor to prevent the resistors burning out after they have been in service for some time. As an example, if the wattage being dissipated by a deposited film resistor is almost four watts, a 5-watt resistor is usually used to provide some safety factor.

There is almost no limit to the wattage ratings in which wire-wound resistors can be made. In radio and television receivers you will seldom find wire-wound resistors rated at higher than 50 watts. However, in radio and TV transmitting equipment and in industrial control equipment you may find wire-wound resistors that are capable of dissipating several thousand watts or more. These high-wattage resistors are made with a large-size resistance wire that can carry the high current and are wound on a large diameter tube in order to provide room for the wire needed to get the required resistance.

The same safety rule for carbon resistors is generally followed in the case of wire-wound resistors. Usually a resistor having approximately twice the wattage rating that the resistor must dissipate is used. Manufacturers follow this practice because the larger wattage resistor will be a larger physical size and better able to get rid of the heat that is produced by the electrical energy that the resistor must dissipate and also because it provides a safety factor - there is far less chance of the resistance wire burning out if the overrated resistor is used.

TRANSFERRING POWER

A common problem in electronics is transferring power from one circuit to another or from one device to another. As an example, consider the output tube or transistor in a radio receiver and the loudspeaker in the receiver. The output tube or transistor develops audio power; in other words it develops sound power in electrical form. The problem is to get the maximum amount of power over to the speaker from the output tube or transistor. Now let us consider what is involved in this power transfer.

The tube or transistor acts as the power source. The speaker acts as a load. Thus we have a situation somewhat similar to a battery with a load connected across it. We have seen this circuit many times.

However, there is one thing we have omitted in the circuits we have looked at before. All electrical parts have resistance. This is true of transistors, tubes, coils, transformers, generators and batteries. The usual practice is to simply represent a battery by the battery symbol. However, to be precise, we should represent it by the battery symbol and a resistor in series with it to represent the internal resistance of the battery. By internal resistance of the battery we mean the opposition that current encounters in flowing from the positive terminal of the battery through the battery to the negative terminal.

In Fig. 8 we have shown a circuit representing a battery with internal resistance and a load connected across the battery. The battery we have shown is a 10-volt battery with an internal resistance of 5 ohms. Thus in any circuit we consider, the total resistance in the circuit will be the resistance of R_1 plus the internal resistance of the battery, which is 5 ohms. This total resistance is the opposition to current flow in the circuit, and is the value we must use in performing any calculations to find the current flowing in the circuit or the power dissipated in the circuit.

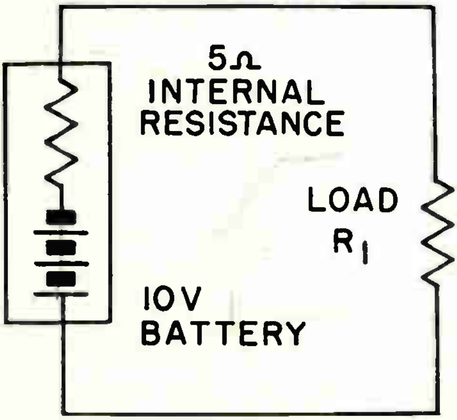

Fig. 8. Circuit representing a battery with internal resistance and a load across the battery.

The fact that the battery has internal resistance brings about several interesting things. First, let us assume that the resistance of R_1 in the circuit is 20 ohms; this means that the total resistance in the circuit will be 25 ohms. Since the battery potential is 10 volts this means that the current flowing in the circuit will be

$$I = \frac{10}{25} = .4 \text{ amps}$$

The .4 amps flowing through the battery resistance will produce a voltage drop across this resistance. This voltage drop will be

$$E = .4 \times 5 = 2 \text{ volts}$$

Thus the actual voltage available at the battery terminals will be only 8 volts. This is quite common in batteries and generators; part of the voltage produced by the battery or generator is lost due to the internal resistance of the device.

Now let us find how much power is actually being supplied by the battery, and how much is being received by the load. The power supplied by the battery is equal to the battery voltage times the current or $P = 10 \times .4 = 4$ watts.

The power being dissipated by the load can best be found by the power formula

$$P = I^2R$$
$$P = .4 \times .4 \times 20 = 3.2 \text{ watts}$$

Now let us replace the 20-ohm resistor that we have in the circuit for R_1 with a 10-ohm resistor and see what happens in the circuit. With a 10-ohm resistor in the circuit the total resistance in the circuit will be 10 ohms plus the 5 ohms internal resistance of the battery or a total of 15 ohms. The value of the current in the circuit will be

$$I = \frac{10}{15} = .67 \text{ amps}$$

Now the power being supplied by the battery will be

$$P = 10 \times .67 = 6.7 \text{ watts}$$

and the power dissipated by the resistor R_1 will be

$$P = .67 \times .67 \times 10 = 4.5 \text{ watts (approximately)}$$

If we replace R_1 with a 6-ohm resistor, we will have a total resistance of 11 ohms in the circuit. This will give us a current flow of .9 amps and the power dissipated in R_1 will be 4.8 watts.

If we substitute a 5-ohm resistor for R_1, the total resistance in the circuit will be 10 ohms and the current will be 1 amp. The power dissipated by R_1 will then be 5 watts. The total power generated by the battery will be 10 watts.

If we substitute a 4-ohm resistor for R_1 the total resistance in the circuit will be 9 ohms and the current flow 1.1 amps. The power dissipated by R_1 will then be 4.8 watts. If we continue to reduce the size of the resistance we will find that the power dissipated by the resistor will continue to go down.

Notice that as we started with a 20-ohm resistor and reduced the size of it to 5 ohms, that the power dissipated by the resistor increased until it reached a maximum value at 5 watts. When we reduced the resistance of the resistor below 5 ohms, the power starts to decrease.

The significant thing to notice here is that we obtain maximum power in the resistor when the resistance of the resistor is equal to the internal resistance of the battery.

This situation will always exist. We will get maximum power in the load when the load resistance is equal to the generator resistance. However, this condition may not always be desirable because the total power being generated by the generator when we have a 5-ohm resistance in the circuit is 10 watts. Since we are dissipating only 5 watts in the resistor, half of the power is being wasted in the battery itself. Thus, when maximum power transfer is being obtained, the over-all efficiency of the system is only 50% - half the power being produced by the source is transferred to the load. With a higher load resistance, the efficiency improves and under some circumstances we may be willing to get something less than full power transfer to get better efficiency. For example, when the value of R_1 was 20 ohms we had a power of 3.2 watts in the resistor and the total power produced by the generator was 4 watts. This is an efficiency of 80%; in other words, 80% of the power produced by the battery is transferred to the load. Even though this is less than the power we get when the load is matched or equal to the battery resistance, the efficiency of the power transfer is much better.

The important point for you to remember from this section of the lesson is that we will get maximum power transfer from a voltage source to a load when the resistance of the load is equal to the internal resistance of the source. Under these conditions we say that the load is matched to the generator. Under these conditions, the efficiency of the power transfer will be 50% - half the power will be dissipated in the load and the other half lost in the generator or the voltage source. Under some circumstances it is better to get somewhat less power transferred from the source to the load in order to get better efficiency.

SUMMARY

This section of this lesson is an extremely important one, and you should be sure that you understand it completely before going on.

You learned that the unit of power is the watt. The power in a circuit can be obtained from any one of the three formulas

$$P = EI$$

$$P = I^2R$$

$$P = \frac{E^2}{R}$$

You should memorize these three formulas; you will need them over and over again in your career in electronics.

Remember that resistors are made in different wattage ratings. Remember too, that carbon resistors have a tendency to change value if they are operated near their maximum wattage rating. If you have to replace a carbon resistor in a piece of electronic equipment you can use the same wattage rating resistor as used by the manufacturer or one having a higher wattage rating, if there is room for the larger resistor in the circuit. The usual safety factor allowed in electronic equipment is to use a resistor having twice the wattage rating that it must dissipate. This will reduce the possibility of resistor failure after the equipment has been in use for some time.

Remember that maximum transfer of power from a generator to a load can be obtained when the resistance of the load matches the resistance of the generator. When maximum power transfer is obtained the efficiency is only 50%; this means that only half the power produced by the generator reaches the load. Under some circumstances we will be satisfied with a somewhat lower power in the load in order to obtain better efficiency.

Now do the self-test questions on this section carefully. If you have difficulty with any of the questions it is a sign that you need to spend more time on this important section.

SELF-TEST QUESTIONS

(h) What is the unit of electrical power or energy?

(i) If a battery has a voltage of

15 volts, and it is supplying a current of 3 amps, what is the power being supplied by the battery?

(j) What do we mean when we say that a resistor is dissipating 10 watts?

(k) If the voltage across a 1000-ohm resistor is 100 volts, how much power is the resistor dissipating?

(l) If the voltage across a 5000-ohm resistor is 50 volts, what is the power dissipated by the resistor?

(m) If the current through a resistor is 2 amps, and the resistance of the resistor is 25 ohms, what is the power dissipated by the resistor?

(n) If the current through a 100K resistor is 10 ma, how much power is the resistor dissipating?

(o) A battery has a voltage of 9 volts and an internal resistance of 3 ohms. What size resistor should be used as a load in order to get maximum power transfer?

(p) A 20-volt battery has an internal resistance of 10 ohms. What size resistor should be be connected across it as a load in order to get maximum power transfer? How much power will be produced by the battery and how much power will be transferred by the load?

Resistor Values

We mentioned earlier that there are more resistors used in electronic equipment than any other parts. A small radio receiver generally has somewhere between ten and fifteen resistors. A black and white TV receiver usually has approximately 50 resistors and a color TV receiver may have twice that many. Usually you can figure that a piece of electronic equipment will have somewhere between three and five resistors at least, for each tube or transistor used in the equipment.

We have already gone into the methods used to indicate the value of a resistor. You know that the unit of resistance is the ohm. If the voltage across a resistor is 1 volt and a current of 1 amp flows through the resistor, the resistance of the resistor is 1 ohm. You will remember this important relationship is expressed in Ohm's Law.

You are also familiar with the fact that large values of resistors are found in electronic equipment and that we use the symbol K to represent 1000 and the letter M for megohms which represents 1,000,000 ohms. Thus a 2,200-ohm resistor will often be marked 2.2K on a diagram and a 4,700,000-ohm resistor will often be marked 4.7M or 4.7 megs.

Since there are 1000 ohms in 1K-ohm and 1,000,000 ohms in a megohm, it follows that there are 1000K-ohms in a megohm. You need to be able to convert between K-ohms and megohms because on some diagrams a resistor having a resistance of 100K-ohms may be marked as .1 meg, and you must realize that both represent the same value. To convert from ohms to K-ohms you move the decimal point three places to the left, and to convert from K-ohms to ohms you move it three places to the right. To convert from ohms to megohms you move the decimal point six places to the left and to convert from megohms to ohms you move it six places to the right. To convert from K-ohms to megohms you move the decimal point three places to the left and to convert from megohms to K-ohms you move it three places to the right. Remember that to convert from the smaller unit to the larger unit you move the decimal point to the left, and to convert from the larger unit to the smaller unit you move the decimal point to the right.

TOLERANCES

The most frequently encountered resistor is the molded-carbon resistor. The molded-carbon resistor is made with three different tolerance values. The resistor is made with a 5% tolerance, a 10% tolerance or a 20% tolerance. The tolerance indicates how much the resistor may vary in resistance from its indicated value. For example, a 100-ohm resistor with a 5% tolerance will be within 5% of 100 ohms. This means that its value might be 5% below or as much as 5% above 100 ohms. 5% of 100 is 5 ohms and therefore the resistance of the resistor may be any value between 95 and 105 ohms.

In this case of a 10% resistor, the value may vary 10% above or below 100 ohms. 10% of 100 is 10 ohms and therefore the resistance of this resistor can be any value between 90 ohms and 110 ohms. A 20% resistor can have a tolerance of 20 ohms and therefore the resistance could be any value between 80 ohms and 120 ohms.

The closer the tolerance of a resistor, the more expensive the resistor is. Thus a 5% resistor is more expensive than a 10% resistor and a 10% resistor is more expensive than a 20% resistor. However, with today's modern automatic resistor making machinery, there is very little difference between the price of a 10% resistor and a 20% resistor and therefore you don't run into too many 20% resistors in electronic equipment any more. There is considerable difference between the price of a 5% resistor and a 10% resistor, and therefore most manufacturers will use 10% resistors wherever they can. The 5% resistors are found only in the more critical circuits where it is important that the value of the resistor be held to a close tolerance.

EIA VALUES

The EIA (Electronic Industries Association) has set up standard carbon resistor values. You cannot buy any value carbon resistor you might want - you have to buy one of the standard values. The standard values are arranged so that you can get a resistor within 5% of any required value. For example, if you determined that in a certain circuit you needed a 53,000-ohm resistor, you cannot buy a 53,000-ohm carbon resistor - they are not made in this size. However, you can buy a 51,000-ohm resistor and a 56,000-ohm re-

Ohms	Ohms	Ohms	Ohms	Ohms	Ohms	Ohms	Ohms	Ohms	Ohms	Megs	Megs

Fig. 9. Standard EIA carbon resistor values.

sistor and therefore you would select one of these two values - the exact one that you would select would depend upon whether you want the resistance to be a little higher than the calculated value or a little lower.

Standard EIA carbon resistor values are shown in Fig. 9. All are available with a 5% tolerance; the values in bold type are also available in 10% tolerances. You normally cannot buy 20% resistors for replacement purposes, but either 5% or 10% resistors are satisfactory replacements.

COLOR CODE

Carbon resistors are identified by means of a color code. There will be three or four colored bands on a carbon resistor. The resistors with only three color bands are 20% tolerance resistors. The resistors with the four color bands will be either 5% or 10% resistors depending upon the color of the tolerance band. If the fourth band is a gold band the resistor has a tolerance of 5%, and if it is a silver band the resistor has a tolerance of 10%.

The color bands are placed on the body of the resistor nearer to one end than the other as shown in Fig. 10. To read the color band, hold the resistor as shown in Fig. 10. The fourth band, if there is a fourth band, will be either gold or silver and it will be on the right and tell you the tolerance of the resistor. To read the value of the resis-

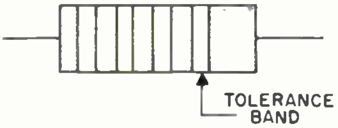

Fig. 10. Resistor values and tolerance are identified by color bands as shown.

Green	5	5	00000
Blue	6	6	000000
Purple	7	7	
Gray	8	8	
White	9	9	

Fig. 11. Standard resistor color code.

tor start at the left end. The first color band gives you the first significant figure of the resistance value. The second color band gives you the second figure and the third tells you how many zeros to add to get the resistance of the resistor.

Values assigned the various colors are shown in Fig. 11. For example, a resistor with (left to right) red, red, black, and gold bands would have a resistance of 22 ohms. The first and second bands each indicate 2; the black band indicates no zeros. The gold band indicates 5% tolerance. If the resistor were colored orange, orange, red, the first and second bands would each indicate 3, and the red band two zeros, so the value would be 3300 ohms or 3.3K. If the fourth band is silver, the tolerance is 10%, if gold 5%. If there is no fourth band, the tolerance is 20%.

If the third color band on a resistor is gold, it indicates that you multiply the first two numbers by .1 to get the resistor value. Thus a resistor coded red, red, gold, gold is 22 × .1 = 2.2 ohms, 5%. If the third color band is silver, you multiply by .01. A resistor coded red, red, silver, gold is 22 × .01 = .22 ohms, 5%.

When you start to work on your experimental kits, you will have to use the color code to identify the various resistors in the kit. It is worthwhile to memorize the color code. However, do not spend a great deal of time trying to do it all at once. Look over the color code shown in Fig. 11 two or three times and learn at least what a few of the colors represent. Then after you have finished this lesson go back and take a look at it again and read it through two or three times. If you will do this several times, this, and working with your experimental kits, will soon teach you the code so that you will know it by heart. In your early experimental kits we will give you the resistance value and the color code to help you learn the code and learn to identify the resistors, but you must learn to do this yourself so you will be able to identify resistors in any electronic equipment you may be called upon to maintain or service.

DEPOSITED CARBON RESISTORS

There is another type of carbon resistor known as the deposited carbon resistor. The carbon resistors that you will run into most frequently in electronic equipment can easily be identified because they are color coded by bands as shown in Fig. 10. The deposited carbon resistors are not made in the same way as these carbon resistors. They are made by depositing a layer of carbon on a form. The layer can be controlled closely and can be varied as necessary in order to make resistors that can be held to a very close tolerance. These resistors are usually made in tolerances of 1% and 1/2%. It is not likely that you will run into this type of resistor in commercial entertainment type equipment such as radio or TV receivers, but you will run into them in meters and test equipment where the accuracy of a meter reading will depend upon the accuracy of the resistors in the equipment. This type of resistor is identified by stamping the value of the resistor on the body of the resistor along with its tolerance. If you should have to repair a meter or some other test instrument and replace one of these resistors, it is important that the replacement have exactly the same resistance and tolerance as the original. Of course, if you have to replace a 100K-ohm, 1% resistor and can't get a 1% resistor, you can use a 1/2% tolerance resistor if one is available. 1/2% and 1% resistors are not nearly as readily available from radio and TV parts wholesalers as are the standard 5% and 10% molded carbon resistors. Often these precision resistors, as they are called, must be obtained by ordering them specially through your parts wholesaler.

SUMMARY

You have reached a point in your course now where you should be able to convert from ohms to K-ohms and megohms or from the larger units back to ohms without any trouble. The reason why it is important that you can convert from one unit to the other is that all three units are used by manufacturers on circuit diagrams and you have to know what is meant when any one of the units is used.

It is important for you to remember that resistors are made in only certain standard sizes and that all molded carbon resistors have certain tolerances. The standard tolerances are 5%, 10% and 20%. You will find mostly 10% resistors used in radio and TV receivers; both 10% and 5% resistors will be found in industrial control equipment.

You should start to learn the resistor color code by memory. You will have to use it over and over again to identify resistors in electronic equipment. However, as we point out don't try to memorize it all at once. Read it through two or three times whenever you think about it and you will soon have it memorized.

Remember that 1% and 1/2% resistors are used in test equipment and if you should have to replace any of these resistors be sure that you use an exact value replacement and a replacement having a tolerance of at least as close as the tolerance of the original.

Now answer the following self-test questions on this section of the lesson.

SELF-TEST QUESTIONS

(q) What is 4.7K-ohms equal to in ohms?

(r) Express .39 megohms in K-ohms and in ohms.

(s) What is 680,000-ohms in K-ohms and in megohms?

(t) A 2200-ohm, 10% resistor actually has a value of 2000 ohms. Is this resistor within its rated tolerance?

(u) A 10,000-ohm resistor has a tolerance of 5%. What is the maximum value resistance that the resistor might actually have and still be within tolerance?

(v) Reading from left to right the color bands on a resistor are orange, white, yellow and gold. What is the value and tolerance of the resistor?

(w) If a resistor is color coded brown, black, green and silver, what is its value and tolerance?

(x) If a resistor is color coded green, blue, orange and gold, what is its value and tolerance?

(y) A resistor is colored red, red, red and silver. What is its value and tolerance?

(z) In a certain piece of test equipment a 100K, 1% resistor has burned out. You have available a 100K, 1/2% resistor. Can you use this resistor as a replacement?

Resistors With Special Characteristics

We have already mentioned one of the important characteristics of carbon resistors, that is the fact that they change resistance with changes in temperature. Carbon itself has what we call a negative temperature coefficient. Most elements that carry electricity have a positive temperature characteristic. This means that if a copper wire is carrying a current and the temperature of the wire increases the resistance will increase - the wire has a positive temperature coefficient. Carbon, as an element, does the opposite - if it is heated, its resistance goes down; it has a negative temperature coefficient.

Most carbon resistors have a negative temperature coefficient. However, sometimes due to the way the resistor is made and due to the type of material used as a binder to hold the resistor together, the resistor might actually have a small positive temperature coefficient. What happens is that the carbon in the resistor has a negative temperature coefficient which tends to cause a resistance to go down with an increase in temperature but the other material has a positive temperature coefficient greater than the carbon temperature coefficient and this causes the resistance to go up when the temperature increases. With the two fighting each other, it is hard to predict what will happen. Some resistors will go down slightly in resistance when they are heated, others will increase slightly in resistance.

Wire-wound resistors and deposited-film resistors in general have a positive temperature coefficient. Their resistance will increase as the temperature is increased.

Actually, as far as a general purpose resistor is concerned, we would prefer to have them with a zero temperature coefficient. In other words, we would like their resistance to remain constant as their temperature changes. Changes in resistance due to temperature changes often produce undesirable results in electronic equipment. However, with modern manufacturing techniques, most carbon, deposited-film and wire-wound resistors have such a low temperature coefficient that any change in their temperature in normal operation will not cause their resistance to change sufficiently to cause any serious problem.

In some special applications, however, it is desirable to have a resistor whose resistance value will change with temperature. In this section of the lesson we are going to briefly study two of these devices.

THERMISTORS

A thermistor is a type of resistor that is made of a material whose resistance value varies with changes in temperature. The material used is a form of a semi-conductor material quite similar to the material used in the manufacture of transistors.

Thermistors have a negative temperature coefficient. This means that as the temperature increases, the resistance of the thermistor decreases. The amount that the resistance of the thermistor will change with a given change in temperature depends upon the type of material from which the thermistor is made.

Thermistors are quite often used in circuits where there is liable to be a large current surge when the equipment is first turned on. An example of this type of application is in the power supply of a television receiver that is designed for operation without a power transformer. When the equipment is first turned on, a very high surge current will flow for a short time. A thermistor placed in the circuit can limit this current to a safe value. As the equipment starts to operate, the current flowing through the thermistor causes it to heat so that its resistance value drops very rapidly and by the time the equipment has reached operating temperature and is ready to operate, the resistance of the thermistor has dropped to such a low value that it has very little effect upon the performance of the equipment. Thermistors of this type may have a resistance of 100 ohms or more when they are cold, and a resistance of only a few

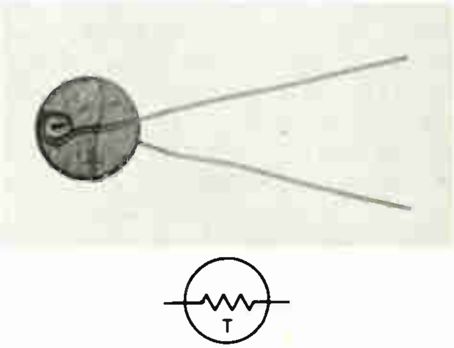

Fig. 12. A typical thermistor, such as might be found in a TV receiver, and its schematic symbol.

ohms when they have reached their normal operating temperature in the receiver.

A photograph of a thermistor such as you might find in the application we mentioned in the television receiver is shown in Fig. 12. Notice that the thermistor is made in the form of a round disc with leads attached to each side of it. The schematic symbol used to represent the thermistor is also shown in Fig. 12.

The thermistor type shown in Fig. 12 is the type you are most likely to encounter in TV receivers. However, there are many other different types. A photo of a number of different types is shown in Fig. 13.

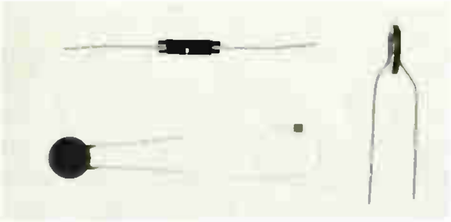

Fig. 13. Thermistors are made in many different shapes as shown above.

These types are often found in industrial electronic equipment. Sometimes they are used to control current surges, in other applications they are used to measure temperatures. You can tell the temperature of the thermistor by measuring its resistance and thus the thermistor can be used for temperature measuring applications.

VARISTORS

Another special type of resistor is the varistor. This resistor is also called a voltage-dependent resistor. This means that the resistance of the device depends upon the voltage across it. In other words, as the voltage across the varistor increases, the resistance of the varistor decreases.

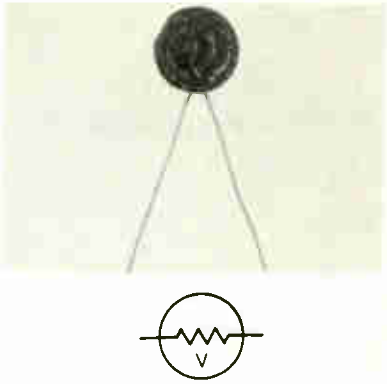

Fig. 14. A typical varistor and its schematic symbol.

Varistors are used in circuits to protect components from damaging high voltage transients. This could cause component failure. With a varistor in the circuit, as the voltage rises the resistance of the varistor decreases, drawing a large current from the voltage source which will lower the voltage.

Varistors will be found in some color TV receivers. A photo of a varistor is shown in Fig. 14 along with the schematic symbol used to identify it. You will notice that the varistor looks very much like a thermistor - as a matter of fact, it is sometimes difficult to tell them apart from their appearance alone.

HIGH-VOLTAGE RESISTORS

In some applications resistors will be used across circuits where there is a comparatively high voltage. Examples of this type of resistor will be found in many television receivers.

High-voltage resistors must be made quite long in order to keep the voltage from jumping across the resistor. Usually the resistance element is placed on a form in the shape of a spiral curve. An example of this type of resistor is shown in Fig. 15A. The resistor is about 2-1/2 inches long and is used in a circuit in a color TV receiver where the operating voltage is in excess of 6000 volts. The resistor is made by putting the carbon on a form shaped like a spiral that winds around the resistor from one end to the other as shown in the drawing in Fig. 15B.

Resistors of this type are made with a spiral type element because they normally have a very high resistance and by spiralling the resistance element around the form in this way it is possible to get a much longer path, and therefore the high resistance needed can be obtained in a reasonable size. The unit shown in the photograph has a resistance of 66 megohms. It would be difficult to get this much resistance in a resistor of this size and type by any method other than the spiral-wound method. If you should have occasion to replace a resistor of this type in a television receiver or in any other device where high voltages are used, you must be sure to use this special type of high-voltage resistor.

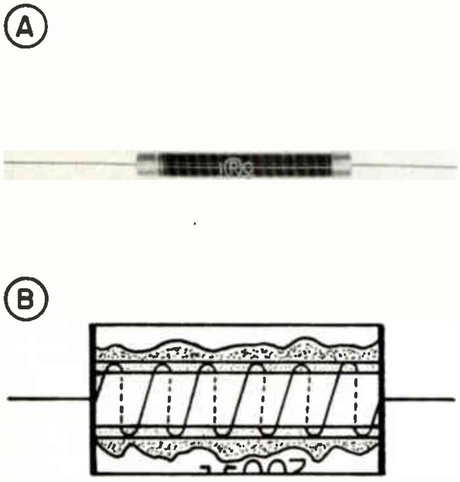

Fig. 15. A high-voltage resistor.

SUMMARY

In this section of the lesson we have briefly studied three special types of resistors - the thermistor, the varistor or voltage-dependent resistor, and the high-voltage resistor. A few years ago these three types of resistors were unknown to the electronics technician, but modern technology has developed these resistors and they are appearing more frequently in modern electronic equipment. Color TV in particular has brought these resistors into considerably more importance.

If you have to replace one of these resistors, you should try to obtain an exact duplicate replacement. Not only is the cold resistance of a thermistor or varistor important, but also the way that the resistance changes either with changes in temperature in the case of the thermistor or changes in voltages in the case of the varistor is important. The manner in which the resistance changes is usually of even more importance than the cold value of the part.

High-voltage resistors are used in circuits where the length of standard resistors is so short that if you tried to use one the voltage would simply arc across the resistor.

These resistors are usually made by the spiralled-carbon method so that a long path can be obtained in order to get a very high resistance.

SELF-TEST QUESTIONS

(aa) What is a thermistor?
(ab) Where are thermistors used?
(ac) Draw the schematic symbol for a thermistor.
(ad) What is a varistor?
(ae) Where are varistors used?
(af) How do you tell the difference between a thermistor and a varistor?
(ag) What is a high-voltage resistor?

Meters

We have already mentioned that resistors made with tolerances of 1% and 1/2% are used in electronic test equipment. Resistors made to these close tolerances are often called precision resistors. Precision resistors are used with meters in order to increase the usefulness of a given meter movement. Since this represents another important use of resistors, and since meters are very important, we are now going to present some of the basic fundamentals about meters.

The meter most frequently used in electronics for current, voltage and resistance measurements is the d'Arsonval* meter. The meter gets its name from the scientist who invented it.

Basically the d'Arsonval meter is a current-indicating device, but by arranging it in suitable circuits it can be used to measure voltage and resistance as well as current.

Let us go ahead and learn how the meter itself works and then we will see what changes we can make in the basic meter to make it more usable.

THE BASIC METER MOVEMENT

A simplified drawing of a d'Arsonval type meter is shown in Fig. 16. Notice that we have a permanent magnet and that the faces of the poles of the magnet have been curved. Between the poles of the magnet we have a coil that is wound on a very light frame. Usually the frame is made of a thin piece of aluminum.

The frame and coil are attached to light-weight pivots, and these pivots fit into jewel bearings. The bearings are securely supported by the meter frame so that the coil and the pivots are held in position and can rotate freely between the poles of the magnet. Attached to each pivot and anchored to the meter frame is a spring. There is a spring on each pivot and these springs are arranged to rotate the coil into approximately the position shown in the figure. Also attached to the pivot is a pointer as can be seen in the drawing. When

*Pronounced dar-son-val. The dar is like ar in car, son like son or sun, and the val like all in ball. d'Arsonval.

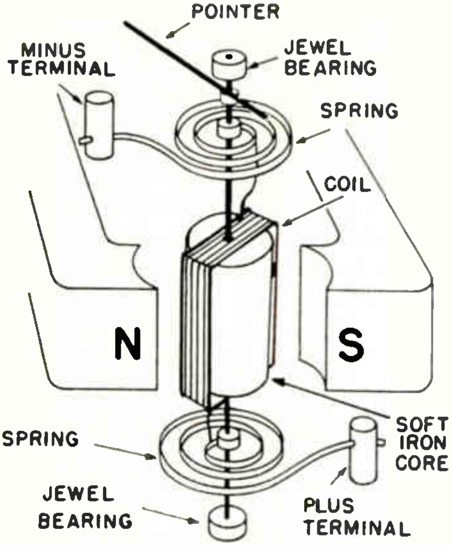

Fig. 16. How a d'Arsonval type of meter is made.

the coil rotates this pointer will rotate in a clockwise direction.

Notice that the ends of the coil are connected to the springs and the other ends of the springs are connected to terminals. One terminal is the negative terminal and the other terminal is the positive terminal.

When a current flows through the meter coil, the coil will become an electromagnet. If the current enters the negative terminal of the meter and leaves the positive terminal a field will be set up in the electromagnet that will be attracted by the field of the permanent magnet. The attraction between the two fields will produce a force called torque that will try to rotate the coil. The torque will cause the coil to rotate in a clockwise direction against the force or torque of the springs until the torque in the coil is balanced by the opposing torque of the springs. The higher the current flowing through the coil, the more torque is produced and the more the coil will be able to rotate against the opposing torque of the springs. As the coil rotates, the meter pointer moves in a clockwise direction and moves up the scale of the meter, indicating the current that is flowing through the coil.

A typical current scale is shown on the meter in Fig. 17. Notice that when the meter pointer moves all the way to the right side of the scale, the current flowing is 1 amp. We call this meter an ammeter because it measures the current in amps. We call it a 1 amp ammeter because a current of 1 amp gives a full scale deflection. If a current of 1/2 amp flows through the meter coil, only half as much torque, or rotating force will be developed, and as a result, the meter pointer will move only halfway up the scale. If the current flowing through the meter coil is one quarter of an amp, then one-fourth the torque needed to produce a full-scale deflection will be produced and the meter pointer will move only one-quarter of the way up the scale.

We mentioned earlier that the coil

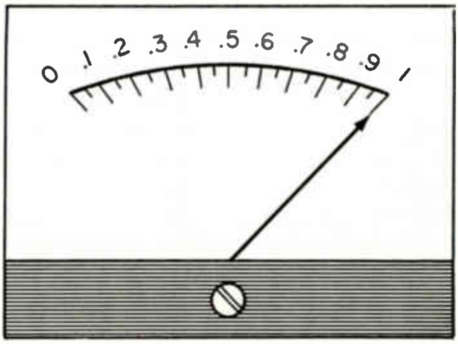

Fig. 17. A 1-amp ammeter.

was generally wound on a lightweight aluminum frame. The aluminum frame acts like a coil made of one turn of wire that is shorted. When a current flows through the meter coil and the coil begins to rotate, the one turn coil made up of the aluminum frame also rotates. As the aluminum frame rotates, it will cut through the field produced by the permanent magnet and a voltage will be induced in it. Although the voltage induced in the one turn coil made up of the frame will be low, a fairly high current will flow through the coil because it has a very low resistance. This in turn sets up a significantly strong magnetic field that opposes the motion of the meter coil. The net effect is that this opposition damps the movement of the coil. It prevents the coil from swinging too rapidly in a clockwise direction - this would cause the coil to swing past the position it is supposed to reach and oscillate back and forth around the position it should reach. The field produced by the current flowing in the aluminum frame will prevent this from happening and as a result the pointer will move upscale at a reasonable speed and indicate the value of current flowing with a minimum of oscillation back and forth past the correct value due to the coil rotating too rapidly when the current is first applied to it.

The d'Arsonval meter can be made very sensitive. By using a very lightweight frame and many turns of very fine wire to wind the coil and keeping the weight of the moving part of the meter as low as possible, it is possible to build a meter of this type that will indicate a current of 50 microamps quite easily. As a matter of fact, d'Arsonval meters that can indicate currents of only a few microamps can be made, but usually the most sensitive d'Arsonval meters used by technicians for routine measurements are 50 microampere meters. More sensitive meters are quite expensive and very delicate and are usually used in laboratory-type measurements rather than in the type of measurements that the service technician will normally make.

MEASURING CURRENT

To measure the current flowing in a circuit, the meter is placed in the circuit so that the current flowing in the circuit must flow through it. Fig. 18 shows how a meter can be connected in a simple series circuit to find the current flowing in the circuit. Notice the schematic symbol for the meter at B. The letter I, for current, may be placed inside of the circle as in the figure. Sometimes the letter A, meaning amperes, is placed in the circle and sometimes MA, meaning milliamperes, is used. µA is also used to indicate microamps.

Before you measure the current in a circuit, you need to have some idea of what the current might be. D'Arsonval meters are made in many different ranges. We already mentioned that this type of meter can be made very sensitive so that it can measure a current of only a few microamperes. If the meter is designed to measure currents in microamperes, it is called a microammeter. Some d'Arsonval meters have a scale on them that indicates the current in milliamperes. This type of meter is called a milliammeter. Still other meters are made to measure higher currents and the scale indicates the current in amperes; this type of meter is called an ammeter. All work on the same principle; they get their different names from the current values they are designed to measure.

If you should connect a microammeter in a circuit where the current flow is several amperes, the current flow through the meter would be so high that either you would burn out the meter coil or else the very strong current flowing through the coil would cause the coil to rotate so violently, that it would either bend the meter pointer by starting too fast or else slam the meter pointer up against the end of the scale and ruin the meter. Therefore, as we mentioned earlier you need to have some idea of what the current flow in the circuit is so you can be sure to use a meter that is capable of measuring the current flowing in the circuit. If you don't know what the current is, you should use the highest range meter you have. You can always put a more sensitive meter in the circuit later, if you find that the current is small and will not damage a more sensitive meter.

We mentioned that meters are available in many different ranges. Actually, meter manufacturers do not make a large number of different meter movements. Instead, they make a few standard meter movements and then extend the range of the meter by means of shunts.

You have already studied parallel circuits and you know that when two resistances are placed in parallel, part of the current will flow through one resistance and part through the other. The coil in a d'Arsonval meter has a certain resistance. For example, if you have a meter that indicates a current of 10 milliamperes and the coil has a resistance of 100 ohms, and if you place a 100-ohm resistor in parallel with the meter, half the current flowing in the circuit would flow through the meter

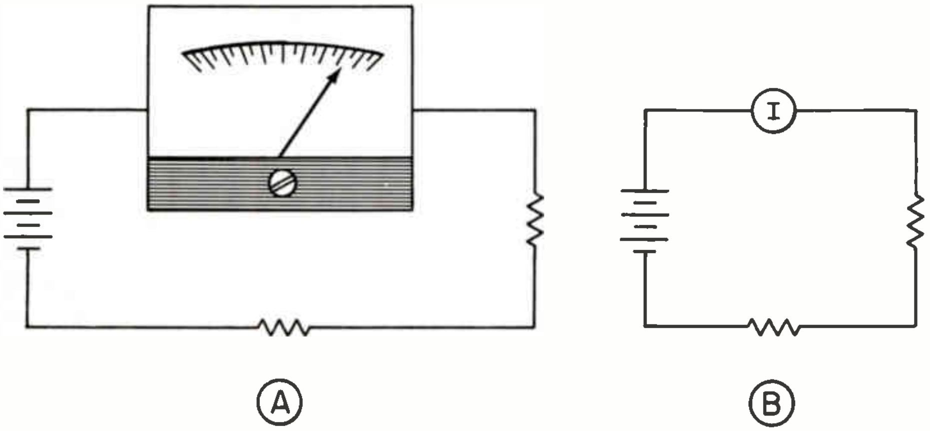

Fig. 18. A meter connected into a series circuit to measure current. Pictorial of meter is shown at A; schematic symbol, at B.

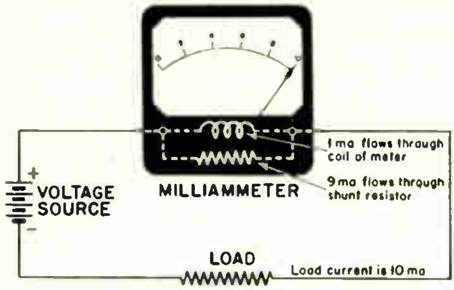

Fig. 19. By adding a shunt resistor, this 0-1 ma dc milliammeter can be made to read current up to 10 milliamperes.

coil and half through the resistance. In this case, if the total current is 10 milliamperes, only 5 milliamperes will flow through the meter coil. The remainder will flow through the shunt resistor. This means that the meter pointer would move only to half-scale.

An example of a meter used with a shunt is shown in Fig. 19. Here the basic meter movement is designed to give a full-scale deflection with a current of 1 milliampere through the coil. The meter has a resistance of 100 ohms. A shunt has been placed across the meter coil having one-ninth the resistance of the coil. Now, the current divides so that nine-tenths of the current will flow through the shunt and one-tenth through the coil. Therefore, it is possible to place a scale on the meter that indicates 10 milliamperes at full scale. When the total current flowing is 10 milliamperes, 1 will flow through the coil and cause the meter to read full scale and 9 will flow through the shunt.

Manufacturers use shunts to provide a large number of meters with different ranges. The chances are if you buy a 50 ma meter and a 500 ma meter, they will both be either 5 ma or 1 ma meters with suitable shunts inside the meter to give the higher ranges.

DC VOLTMETERS

A d'Arsonval meter can be used to read voltages by connecting a resistor in series with the meter. This resistor is called a multiplier. In Fig. 20 we have shown how a d'Arsonval meter can be used with a multiplier to measure voltage. The basic meter is a 1 milliampere meter. This means that at full scale the meter will indicate a current of 1 milliampere. Now, you know from Ohm's Law that when a voltage is applied to a resistance a current will flow through the resistance and the value of the current will depend upon the voltage and on the resistance. If we put enough resistance in series with the meter so that the total resistance is 1000 ohms, then it will take a voltage of 1 volt to cause a current of 1 ma to flow through the resistance and the meter. If we connected the combination across a bat-

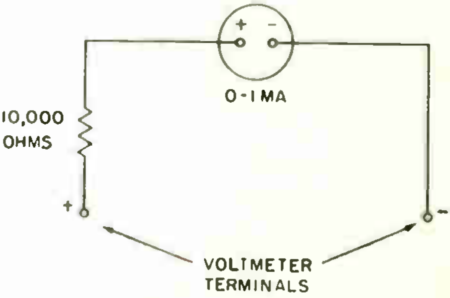

Fig. 20. A dc voltmeter made from a 0-1 ma dc milliammeter and a 10,000-ohm resistor.

tery and the battery voltage was 1 volt, a 1 milliampere current would flow and the meter pointer would indicate full scale. If the voltage was only 1/2 volt, then only half a milliampere would flow in the circuit and the meter pointer would move up to half scale.

If instead of a 1000-ohm resistance we add enough resistance in series with the meter to give us a total resistance of 10,000 ohms, then it would take 10 volts to cause a current of 1 milliampere to flow in the circuit. Under these conditions the meter pointer would again move up to full scale.

With a multiplier in series with the meter we can calibrate the meter directly in volts rather than in milliamperes. With a total resistance of 10,000 ohms in the circuit we can mark the full scale reading as 10 volts and half scale reading as 5 volts and so on. If the total resistance in the circuit is 100,000 ohms then a full scale reading would be 100 volts.

Notice that for each volt we have added a resistance of 1000 ohms in series with the meter. If we want the meter to read 1 volt full scale then we need a total resistance of 1000 ohms. If we want the meter to read 10 volts full scale then we need a total resistance of 10,000 ohms and if we want the meter to read 100 volts full scale then we need a total resistance of 100,000 ohms. We call this type of meter a 1000-ohms per volt meter. We say that the meter sensitivity is 1000 ohms per volt. You will see later that the sensitivity of the meter is important in taking voltage measurements.

The meter we have been discussing so far has been a 1 milliampere meter. However, if instead of using a 1 milliampere meter as a voltmeter we start with a basic meter movement of 50 microamperes we will have a much more sensitive meter. If we convert a 50 u amp meter to a voltmeter when the meter pointer reads full scale, it means that the current flowing through the meter and its multiplier is 50 microamperes. If we want to build a meter that will indicate full scale when a voltage of 1 volt is applied to it, we can use Ohm's Law to find out how much resistance we need in the circuit. Using

$$R = \frac{E}{I}$$

and substituting 1 volt for E and 50 microamperes for I we get

$$R = \frac{1}{.000050}$$

and we can multiply by 1,000,000 to convert this current to amperes and then we will have

$$R = \frac{1 \times 1{,}000{,}000}{50}$$

$$R = \frac{1{,}000{,}000}{50}$$

and now cancelling one zero above and below the line, and dividing 5 into 100,000 we find that

$$R = 20{,}000 \text{ ohms}$$

We say that the sensitivity of this meter is 20,000 ohms per volt. If instead of a 1-volt meter we want a 10-volt meter we need to add ten times as much resistance or a total of 200,000 ohms. If we want a 100-volt meter then we would have to add 100 × 20,000 or 2,000,000 ohms in series with the meter.

Since the higher sensitivity meter actually draws less current from the circuit, the meter will have less tendency to upset the circuit when voltage measurements are taken. This is particularly important in electronic circuits where the resistance is high. If you use a 1,000-ohm per volt meter to take a voltage measurement, the chances are that the meter itself will take more current than is actually being used to operate the circuit. This means that the meter will upset the circuit so that the voltage reading you will obtain will not be the actual voltage that is present in the circuit when the meter is disconnected. On the other hand, a 20,000-ohm per volt meter has twenty times the resistance; it takes far less current from the circuit and is much less likely to upset the voltages in the circuit.

OHMMETERS

An ohmmeter is a device used to measure resistance. Actually, an ohmmeter is nothing more than a d'Arsonval type meter used in conjunction with a battery and a series resistor. A circuit of a typical ohmmeter is shown in Fig. 21.

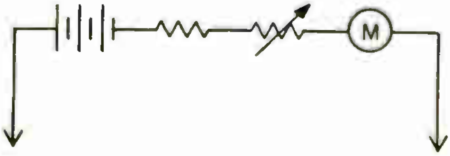

Fig. 21. A schematic diagram of an ohmmeter.

As you can see in the circuit the ohmmeter consists of a 4.5 volt battery, two resistors (one a fixed resistor and the other a variable resistor), and a 1 ma meter. The fixed resistor has a resistance of 4000 ohms. The adjustable resistor has a resistance of 1000 ohms and under normal circumstances you would short the test probes of the ohmmeter together and then adjust the variable resistor to get a full scale reading. If the battery voltage is exactly 4.5 volts, you will get a full scale reading, in other words, a current of 1 ma through the meter when the resistance of the potentiometer is set at slightly less than 500 ohms. With this setting of the potentiometer you will have a total resistance in the circuit of 4500 ohms. The potentiometer is set at a value slightly less than 500 ohms to make up for the internal resistance of the battery and the resistance of the meter. In any case, with a voltage of exactly 4.5 volts, the resistance in the circuit will be 4500 ohms.

Now if you separate the test probes, the circuit will be open and the meter pointer will drop back to 0. If you place a 4500-ohm resistor between the test probes, then the total resistance in the circuit will be 9000 ohms, and the current that will flow in the circuit will be .5 ma. In other words, you will get a half-scale deflection on the meter. If you were measuring the resistance of an unknown value and you got a half-scale reading, you would know immediately that its resistance was 4500 ohms.

As a matter of fact, you can take any current reading that you might get on the meter scale and use Ohm's

Law to calculate the total resistance in the circuit. Knowing that the battery voltage is 4.5 volts, you simply use the formula

$$R = \frac{E}{I}$$

and substitute 4.5 volts for the battery voltage and the value of current indicated on the meter. This will give you the total resistance in the circuit. From this value you subtract 4500 ohms, which is the fixed resistance in the circuit and this will give you the resistance of the unknown resistor.

Instead of going through this procedure of calculating the resistance value each time you make a measurement, these calculations can be worked for various current values and the meter calibrated directly in ohms. This is what is done in an ohmmeter.

If you need to measure higher resistances, you can use a higher battery voltage. For example, if you used a 45-volt battery then you have to put a total of 45,000 ohms in the circuit to get a full-scale meter reading. Then a center scale reading would represent a resistance of 45,000 ohms, instead of 4500 ohms as before.

Another way of building a meter that will give higher resistance readings conveniently is to use a more sensitive meter. If you use a 50 microamp meter, you will need a total resistance in the circuit of 90,000 ohms to give you a full-scale reading. Thus with this type of meter, a center scale reading will indicate a resistance of 90,000 ohms.

MULTIMETERS

A multimeter is simply a meter in which a single d'Arsonval type meter is arranged with a series of switches, resistors and batteries, so that by rotating the switches it can be used to perform a large number of functions. One switch is usually called the function switch. By putting this switch in the correct position, you can use the meter either to measure voltage, current or resistance. The other important switch on the multimeter is called the range switch. This switch controls the full-scale reading that you will obtain on the meter. In other words, with the switch in one position, when you are measuring voltage, a full-scale reading might indicate 10 volts. With the switch in another position the full-scale reading might indicate a voltage of 100 volts, and in a third position it might indicate a voltage of 500 volts.

Multimeters are widely used by service technicians because the basic d'Arsonval meter movement is quite expensive, and it is more economical to use a single meter with suitable switches and resistors to perform all types of measurements than it is to have a number of separate meters for different measurements.

SUMMARY

As an electronics technician, you will not have to know how meters are designed or built. You should understand the basic operation of a meter so that you will know how it works - this will help you use it to the best advantage. You must know that meters are very delicate and must be handled carefully. If you drop a meter or bang it hard you are liable to knock the pivots out of the jewel bearings, in which case the meter pointer will stick as it moves upscale.

You must avoid overloading a meter. The coiled springs in a meter are made of phosphor bronze. If they are overloaded they overheat and their shape is distorted. If adjacent turns of a spring touch enough, friction is produced to upset the meter accuracy.

Technicians seldom have to take current measurements, but you should know how to connect a meter in order to take a current measurement. You must remember to use a meter that is capable of measuring the current in a circuit. If you have no idea what the current is you should start with the largest meter you have first and then work down to a smaller range meter after you are sure that the current is low enough not to damage it.

Voltage measurements are probably the most important measurement to the technician. You need to know how to take a voltage measurement and you need to understand what effect the meter sensitivity will have on the accuracy of the voltage measurement. A meter with high sensitivity will take less current from the circuit and there will be less chance of the meter upsetting the circuit so that you will obtain an erroneous voltage measurement.

When you start working on your kits, you will use your meter to take both current and voltage measurements. You will learn how to read the scale on the meter - we will not go into it in this lesson because it will be much easier to learn to read the scale when you actually have the meter in front of you.

SELF-TEST QUESTIONS

(ah) What is the name given to the basic meter movement most frequently used in voltage, current and resistance measurements?

(ai) What causes the pointer of a meter to move upscale when a current flows through the meter?

(aj) What force must the coil in a meter overcome before it can rotate?

(ak) What purpose, other than to hold the coil, does the aluminum frame on which the coil is wound serve?

(al) How is a meter connected to measure current flowing in a circuit?

(am) How do you connect a voltmeter in order to measure the voltage across a part?

(an) Which type of voltmeter will upset the circuit performance less, a 1000-ohm-per-volt meter or a 10,000-ohm-per volt meter?

ANSWERS TO SELF-TEST QUESTIONS

(a) A series-dropping resistor drops the available voltage to the value required by the load.

(b) 38 volts. The two 35-volt tubes will require a total voltage of 70 volts in series, and the two 6-volt tubes will require an additional 12 volts, giving a total required voltage of 82 volts. Subtracting 82 volts from the 120-volt power line gives us a voltage of 38 volts which the series-dropping resistor must drop.

(c) 126.6 ohms. Using Ohm's Law to find the value resistor we have a voltage of 38 volts and a current of .3 amps. Using the formula

$$R = \frac{E}{I}$$

and substituting the values for current and voltage we get

$$R = \frac{38}{.3} = 126.6 \text{ ohms}$$

Since it would be impossible to obtain a resistor of this value you use the nearest standard size which is 130 ohms. If you get 126 or 127 ohms as your answer your answer is close enough; when you went to buy a resistor you would simply have to take a resistor having a resistance as close as you could get to the calculated value.

(d) A bleeder is used to regulate or help maintain constant the voltage across a load.

(e) A bleeder that draws a substantial current will be more effective than a high-resistance bleeder that draws only a small current. The greater the bleeder current in proportion to the load current, the more effective the bleeder will be insofar as regulating the load voltage is concerned.

(f) The current consumed by the bleeder is wasted current insofar as performing any other useful function other than regulating the voltage across the load is concerned. Since the more current you draw from a power supply, the larger the components (hence the more expensive they must be), the bleeder current should be no larger than necessary to give you the regulation required. Excessive bleeder current with regulation better than is required is costly and can run the cost of the power supply substantially higher than necessary.

(g) 10K ohms. You can determine the resistance of the series-dropping resistor two ways. The easy way: if you notice that the voltage across the load is 200 volts and you have to drop 100 volts across the dropping resistor, you can see that the resistance of the dropping resistor must be half the resistance of the load. The other way is to calculate the current through the load resistor using Ohm's Law. Once you have the current you can then calculate the size resistor required as the series-dropping resistor to drop 100 volts. From Ohm's Law the current through the load will be

$$\frac{200}{20{,}000} = .01 \text{ amps}$$

Now to find the value of the dropping resistor you have to use the formula

$$R = \frac{E}{I}$$

$$= \frac{100}{.01} = 10K \text{ ohms.}$$

(h) The watt.

(i) 45 watts. You use the formula

$$P = E \times I$$

and substituting 15 for E and 3 for I we get

$$P = 15 \times 3 = 45 \text{ watts.}$$

(j) When we say a resistor is dissipating 10 watts, we mean that the resistor is using 10 watts of electrical energy. We say it is dissipating the power because it changes the power from electrical energy to heat. It is taking 10 watts of electrical energy out of the circuit and converting it to heat.

(k) 10 watts. To find the power dissipated by the resistor we use the formula

$$P = \frac{E^2}{R}$$

Remember that $E^2 = E \times E$. Substituting 100 for E and 1000 for R we have

$$P = \frac{100 \times 100}{1000}$$

and cancelling three zeros above the line and three zeros below the line we have:

$$P = 10 \text{ watts.}$$

(l) 1/2 watt. Again, to solve this problem we use the formula:

$$P = \frac{E^2}{R}$$

Substituting 50 volts for E and 5000 ohms for R we have

$$P = \frac{50 \times 50}{5000} = \frac{2500}{5000} = 1/2 \text{ watt.}$$

(m) 100 watts. To solve this problem we use the formula

$$P = I^2R$$

substituting 2 for I and 25 for R we have

$$P = 2 \times 2 \times 25 = 100 \text{ watts.}$$

(n) 10 watts. To solve this problem we must convert milliamps to amps and K-ohms to ohms and then use the formula

$$P = I^2R$$

10 ma = .01 amps.
100K = 100,000 ohms.

Substituting these values in the formula we get

$$P = .01 \times .01 \times 100{,}000$$
$$P = .0001 \times 100{,}000.$$

To multiply 100,000 by .0001 we simply move the decimal point four places to the left thus

$$P = 100{,}000 \times .0001 = 10 \text{ watts.}$$

(o) 3 ohms. Maximum power transfer will be obtained when the load resistance is equal to the battery resistance.

(p) You would use a 10-ohm resistor to get maximum power transfer to the load; resistance should equal the battery resistance. With a 10-ohm load resistance, the total resistance in the circuit will be 20 ohms, and therefore the current flow in the circuit will be

$$I = \frac{20}{20} = 1 \text{ amp.}$$

The total power produced by the battery will be

$$P = E \times I$$
$$P = 20 \times 1 = 20 \text{ watts.}$$

The power transferred to the resistor can be found using the formula

$$P = I^2R$$
$$P = 1 \times 10 = 10 \text{ watts.}$$

(q) 4700 ohms.

(r) .39 megohms equals 390K-ohms; .39 megohms is also equal to 390,000 ohms.

(s) 680,000 ohms equals 680K equals .68 megs.

(t) The resistor is within its rated tolerance. A 2200-ohm resistor with a tolerance of 10% may vary as much as 220 ohms above or below its indicated value. Subtracting 220 from 2200 gives us 1980 as the lower limit of the resistor. Since 2000 ohms is between this lower limit and the indicated value of the resistor, the resistor is within tolerance.

(u) 10,500 ohms. 5% of 10,000 ohms is 500 ohms. Therefore the maximum value that the resistor can have and still be within tolerance will be 10,000 plus 500 equals 10,500 ohms.

(v) 390,000 ohms, which is also equal to 390K-ohms. The tolerance is 5%.

(w) 1,000,000 ohms or 1 megohm. The tolerance is 10%.

(x) 56,000 ohms or 56K-ohms. The tolerance is 5%.

(y) 2200 ohms or 2.2K-ohms. Its tolerance is 10%.

(z) Yes. The 1/2% resistor has a closer tolerance than the 1% resistor. This means that it will vary less from the indicated value than the 1% resistor - in other words it is a better resistor. You can always use a better resistor - one with a closer tolerance as a replacement.

(aa) A thermistor is a special resistor with a negative temperature coefficient. In other words, as the resistor heats, its resistance will decrease.

(ab) Thermistors are used in circuits in which high current surges are often obtained when the equipment is first turned on. The high cold resistance of the thermistor limits the initial current surge. As the thermistor heats up, the resistance drops so that it has very little effect on the circuit performance.

(ac) See Fig. 12.

(ad) A varistor is a voltage-dependent resistor. A voltage-dependent resistor is a resistor whose resistance depends upon the voltage applied across it. If the voltage increases, the resistance of the varistor decreases.

(ae) Varistors are used in circuits where sudden increases of voltage could damage components or otherwise upset the performance of the circuit. With a varistor in the circuit, as the voltage increases, the resistance of the varistor decreases, drawing a large current from the voltage source. The increased current drain tends to lower the voltage to a safe level.

(af) Often you cannot tell the difference between a thermistor and a varistor simply by looking at them. You should refer to the schematic diagram of the equipment in which they are used to identify each type.

(ag) A high-voltage resistor is a resistor made for use in high voltage circuits. The resistor is longer than most resistors in order to prevent a voltage arc across the resistor. High-voltage resistors are usually made by the spiral-wound carbon technique in order to provide a carbon path long enough to produce the required resistance.

(ah) The d'Arsonval meter.

(ai) The current flowing through the meter coil sets up a magnetic field. This field working with the magnetic field of the permanent magnet in the meter produces a torque which causes the coil and its frame to rotate. The meter pointer is attached to the coil frame and so the meter pointer moves upscale.

(aj) The opposing torque of the springs. The springs are used to hold the meter coil and pointer in a 0 position when no current flows through the coil, and to oppose the movement of the coil when current flows through the coil.

(ak) The aluminum frame acts as a shorted turn. The motion of the coil in the magnetic field of the permanent magnet induces a voltage in the coil which opposes the movement of the coil and frame. This tends to damp the coil movement and prevent its oscillating or swinging back and forth past the indicated value.

(al) The meter is connected in series with the circuit to measure current flowing in the circuit.

(am) You connect the voltmeter directly across the part where you want to measure the voltage. The voltmeter must be connected with the proper polarity; the negative side of the meter must be connected to the end of the part that is connected closest to the negative terminal of the voltage source, and the positive terminal must be connected to the end of the part closest to the positive terminal of the voltage source.

(an) A 10,000-ohm-per-volt meter will have less effect on the circuit because it will take less current from the circuit when you take a voltage measurement.

Lesson Questions

Be sure to number your Answer Sheet B105-1.

Place your Student Number on every Answer Sheet.

Most students want to know their grade as soon as possible, so they mail their set of answers immediately. Others, knowing they will finish the next lesson within a few days, send in two sets of answers at a time. Either practice is acceptable. However, don't hold your answers too long; you may lose them. Don't hold answers to more than two sets at a time or you may run out of lessons before new ones can reach you.

1. Name three important kinds of wire-wound resistors.

2. What is a series-voltage-dropping resistor?

3. A 750-ohm load must be operated with a voltage of 75 volts. The output voltage from the power supply is 125 volts. What value of series-dropping resistor should be used to drop the power supply voltage to the correct value for the load?

4. A 15-volt battery is supplying a current of 3 amps to a load. What is the power the battery is supplying?

5. The voltage across a 5000-ohm resistor is 100 volts. How much power is the resistor dissipating?

6. What is the purpose of a bleeder?

7. What is a thermistor?

8. Express the following resistance values in ohms:
   (a) 2.2K, (b) 470K, (c) 3.3 megs, (d) .17 megs. (e) .47 megs.

9. An ammeter has a full scale reading of 1 amp and an internal resistance of 1 ohm. A separate external 1-ohm shunt is connected in parallel with the meter. If the meter and shunt are connected into a circuit, and the meter indicates a current of .5 amps, what current is actually flowing in the circuit?

10. What do we mean when we say that a meter has a sensitivity of 1000 ohms per volt?

A PLAN FOR YOUR FUTURE

In a radio interview a few minutes after a championship heavyweight boxing match, one of the fighters stated his plans for the future as follows:

> "I'm going to get myself in shape, fight my own fights, and listen to nobody!"

You can use these dynamite-packed words as your plan for the future, too. Here's the way:

"GET MYSELF IN SHAPE." You're doing this right now, because the NRI Course gets you in shape for a career in electronics. But remember that it takes the complete NRI Course, with all its associated practical work, to get you completely in shape.

"FIGHT MY OWN FIGHTS." In real life, the only person who can bring you success is YOU yourself. Expecting somebody else to do your work and fight for your success is just wishful thinking.

"LISTEN TO NOBODY." Even friends and relatives will at times ridicule your studies -- they can't help it, because seeing you get ahead makes them feel uncomfortable about their own laziness. So, remember human nature, and don't give anyone a chance to discourage you.

HOW COILS ARE USED

B106

STUDY SCHEDULE

By dividing your study into the steps given below, you can get the most out of this part of your NRI Course in the shortest possible time. Check off each step when you finish it.

☐ 1. **Introduction** .... **Pages 1 - 3**
Here we describe how coils are used, different types of coils, and basic coil action.

☐ 2. **Magnetic Circuits** .... **Pages 4 - 9**
Similarities between magnetic circuits and electrical circuits are brought out.

☐ 3. **Using Coils to Produce Voltage** .... **Pages 10 - 16**
You learn how flux linkages can be changed to produce voltage, and you study Lenz's Law of coils.

☐ 4. **Inductance** .... **Pages 16 - 23**
We take up the basic property of coils and learn about self-induced voltages and mutual inductance.

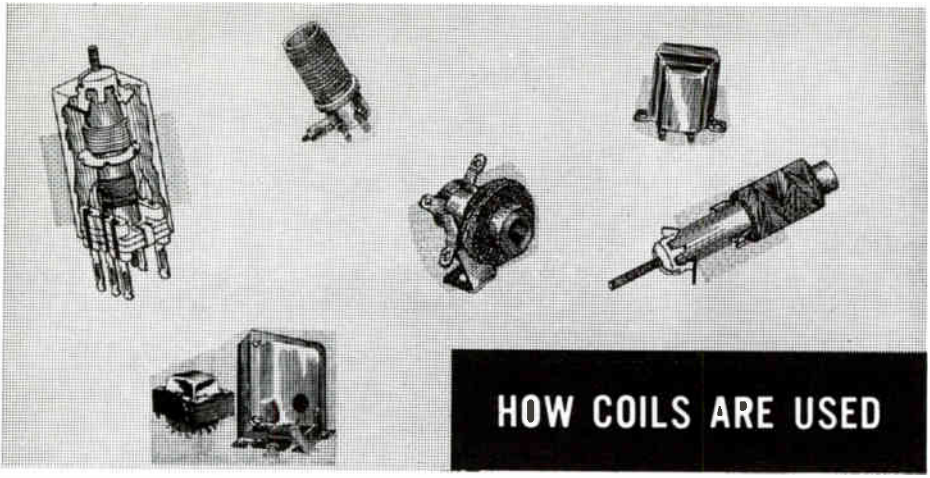
☐ 5. **Ohm's Law for Coils** .... **Pages 24 - 36**
You learn how to find the current in an ac circuit by using vectors or mathematics and you also study Kirchhoff's Voltage Law, the importance of phase and what the Q of a coil is.

☐ 6. **Answers to Self-Test Questions** .... **Pages 36 - 40**

☐ 7. **Answer the Lesson Questions.**

☐ 8. **Start Studying the Next Lesson.**

JDL3M1174 1974 EDITION Litho in U.S.A.



HOW COILS ARE USED

Coils are important to the electronics technician because they are used in all types of electronic equipment. They are used in many different ways to perform different jobs. Many different types of coils are used in electronic equipment - some coils may have only one or two turns whereas other coils may have several thousand turns. You will find all types of coils in industrial electronic equipment, in radio and television receivers, and for that matter, in practically every type of electronic equipment you will encounter. Since you will find coils used in all types of electronic equipment, it is important for you to understand what they are used for and how they work.

HOW COILS ARE USED

During the daytime you can probably find somewhere between ten and twenty-five different stations operating on the standard broadcast band on your radio receiver. During the evening hours you can probably find even more stations coming in. Coils are used with capacitors in special circuits called resonant circuits to enable you to select one signal and reject the signals from the other radio stations. Similarly, coils are used in television receivers to enable you to tune from one channel to another. The coils used for this purpose in radio receivers will have many turns on them whereas the coils used to select the different channels in a TV receiver will have only a few turns on them.

Coils are used in power supplies to help smooth the pulsating dc output from a rectifier to pure dc. Coils used for this purpose are called filter chokes or simply chokes. They act to permit direct current to flow through them without any opposition, but offer a high opposition to ac current or any change in the amplitude of the direct current.

Coils are used to produce motion. You have already seen an example of this in the d'Arsonval meter. The current flowing through the coil produces a magnetic field which acts with the field from the permanent magnet to cause the coil to rotate. Coils are used in motors in much the same way; the magnetic field produced in a coil wound on a form called an armature opposes or attracts the field produced by a stationary magnet and the armature rotates. Coils are also used in generators to produce electricity; rotating the coil so that the turns of the coil cut through the magnetic lines of force produced by the field or stationary magnet of the generator results in a voltage being induced in the turns of the coil.

Coils are used in transformers. You already know that a transformer is nothing more than two or more coils wound on a common core. If ac is fed to one of the coils, which we call the primary coil, a voltage will be induced in the other coil, which we call the secondary coil. If the secondary coil has more turns on it than the primary coil, the total voltage produced by the secondary coil will be higher than the primary voltage, but if the secondary coil has fewer turns on it than the primary coil, the voltage produced by the secondary winding will be lower than the voltage applied to the primary coil.

TYPES OF COILS

We have already mentioned that a coil used to select the various channels in a TV receiver may have only a few turns. In fact, a coil used in a UHF TV tuner is often made with a wire shaped something like a ribbon rather than a round piece of wire. The material is usually silver plated to cut down losses and the total coil will consist of about three quarters of a turn with a diameter of about an inch and a half. On the other hand, in a long wave receiver (a receiver designed to receive stations lower in frequency than the standard radio broadcast band) you may find coils wound on a form about an inch in diameter and having close to one thousand turns. Both coils perform the same task - they are used along with capacitors to select one radio frequency signal and reject others.

We mentioned that choke coils were used in power supplies to help provide smooth dc. A choke coil of this type found in a typical color TV receiver will be wound on an iron core. The coil itself will usually have several hundred turns and the complete assembly may weigh two or three pounds. On the other hand, the choke coil used for the same purpose in a large radio transmitter will be much larger. The iron core itself will be much larger and a much larger size of wire will be used because the wire will have to carry a heavier current. Chokes of this type will weigh one hundred pounds or more.

You will also run into small chokes called radio frequency chokes (abbreviated rfc). A radio frequency choke may have only a few turns and may be completely self-supporting or it may have several hundred turns and be wound on some nonmagnetic type of material. The number of turns required on a radio frequency choke depends on the frequency at which the choke is to be used and how much opposition it must offer to the flow of radio frequency currents through it. Generally speaking, the higher the frequency at which the choke is to be used, the fewer the number of turns the choke will have.

In spite of the great difference in the size of the coils we have described, their operation is basically the same. Thus it is important for you to understand the basic facts about how a coil works. Once you have learned these facts you will know exactly what a coil does in the circuit whether it is a small coil having two or three turns or a large coil with many turns wound on an iron core.

COIL ACTION

In its simplest form a coil is nothing more than one or two turns or loops of wire, usually wound in a circular or helical (spiral) shape. If the coil is self-supporting so that it has no core other than air, it is called an air-core coil. If the coil is wound on a cardboard, ceramic, or non-magnetic type of material, it is also called an air-core coil. The cardboard form or ceramic form are used only to hold the turns of wire in place, and have no appreciable effect on the performance of the coil. On the other hand, if the coil is wound on a form made up of a magnetic type of material such as iron, it is called an iron-core coil. Air-core coils are frequently placed inside metal shields or housings to prevent their picking up interference from outside sources or producing interference in other circuits. These shields may have some effect on the performance of the coils, but it is quite different from the effect of an iron-core and so they are still considered as air-core coils.

You already know that when a current is flowing through a wire there is a magnetic field around the wire as shown in Fig. 1A. The current produces magnetic lines of force, which are also known as magnetic flux or flux lines. When the wire is bent into a loop as shown in Fig. 1B, the magnetic lines of force all go through the loop in the same direction. This concentrates the magnetic flux around the loop. If, instead of being bent into a single loop, the wire is bent into a number of loops so that the coil has a number of turns, additional magnetic flux will be created, which will result in a stronger magnetic field.

Because of the magnetic flux, the coil offers more opposition to the flow of alternating current than it does to the flow of direct current. You will see in this lesson why this is so. Once you understand why a coil offers more opposition to ac than to dc, you will have a good understanding of how a coil works.

Since the operation of a coil depends upon the magnetic flux produced by the coil, it is important that you know more about magnetic circuits. Therefore, before going ahead with our study of coils, we will study magnetic circuits.

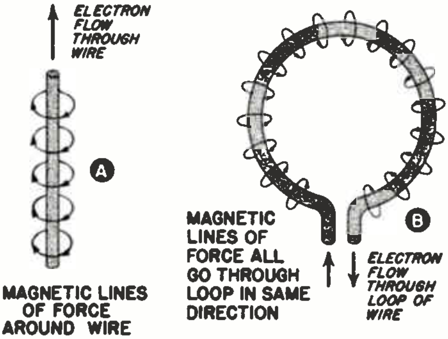


Fig. 1. When current flows through a wire, magnetic lines of force are set up around the wire as at A. When the wire is bent into a loop, the lines of force all go through the loop in the same direction, as shown at B.

Magnetic Circuits

You already know that the magnetic lines of force produced by a current flowing through a coil exist only as long as current flows. Once the current flowing through the coil stops, the magnetic lines of force will disappear.

Another important fact is that the magnetic lines of force are complete loops, having no ends. Notice that in Fig. 1, the magnetic lines of force around the wire and around the single coil were represented as complete loops. When two turns of wire are placed close together, the magnetic lines of force form complete loops around the two turns as shown in Fig. 2. Fig. 3 shows a coil made up of a number of turns and shows how the lines of force come out of the left of the coil and circle around to the right end of the coil. Notice that all of the lines of force are actually complete loops. We have not tried to draw all the magnetic lines of force that exist around the coil having a current flow through it. The coil may have thousands of such magnetic lines each forming a complete loop and passing through all or part of the coil and radiating out from the ends of the coil. The path of these magnetic lines of force is the magnetic circle of the coil. Although most of the lines of force will be concentrated near the coil, some will extend quite some distance from it.

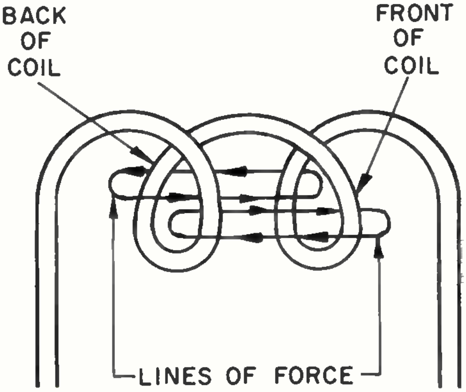

Fig. 2. Lines of force loop around both turns of the coil.

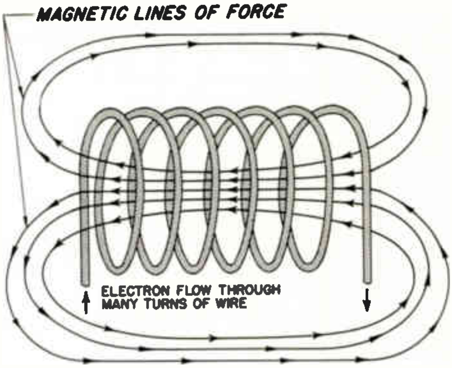

Fig. 3. When current flows through a coil, magnetic lines of force are produced. These are complete loops, passing through and around the coil.

AIR-CORE COILS

As we mentioned previously, some coils are completely self-supporting or wound on a cardboard or ceramic form. The purpose of these forms is simply to support the turns of wire making up the coil. Cardboard or ceramic serves no useful purpose as far as the operation of the coil is concerned. The actual core of the coil is simply air. This means that the lines of force must travel through air. This is the basic definition of an air-core coil: it is a coil in which the lines of force must travel through air or some other material that acts just like air insofar as the magnetic lines of force are concerned.

IRON-CORE COILS

Frequently a coil is wound on an iron or steel form or on a cardboard form with an iron or steel slug inside it. The iron or steel core makes a better magnetic circuit than air, and there will be a greater number and concentration of the magnetic lines of force. This means there will be more flux lines produced by the coil. This type of coil is called an iron-core coil. In coils designed for use in a power line or at audio frequencies, the iron-core is made up of thin strips of iron or steel called "laminations." These pieces of steel are fitted together to make a core, as shown in Fig. 4. As you can see, the core actually surrounds the coil and goes through the center as well. Fig. 5 shows how such a coil is constructed. This type of construction is used rather than a solid iron or steel core because it is more efficient. You will learn more about this in a later lesson.

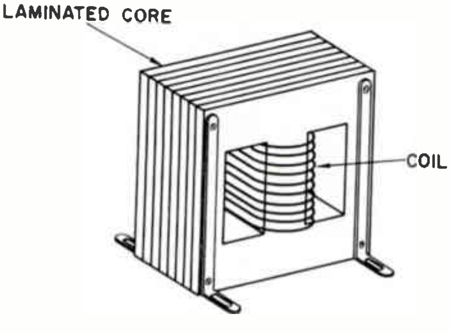

Fig. 4. Iron cores are frequently made of thin sheets of metal bolted together.

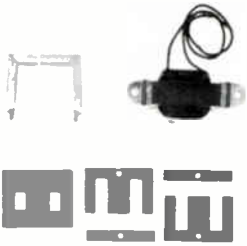

Fig. 5. Construction of an iron-core coil with laminated core.

In high-frequency circuits a powdered iron core is often used. This type of core is made by pulverizing iron filings and mixing them with a binder to hold them together and to insulate the particles from each other. A core of this type, called a slug, is often inserted in a coil by means of a screw so it can be adjusted in and out of the coil. This type of coil is shown in Fig. 6. The schematic symbol is shown beside it. Two or three lines drawn beside a coil indicate that it has an iron core, and the arrow indicates that it is movable. A coil with this type of core is called a slug-tuned coil.

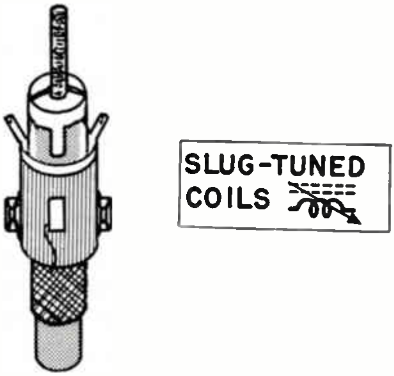

Fig. 6. A slug-tuned coil and its schematic symbol.

MAGNETOMOTIVE FORCE

The force that sends current around an electric circuit is called an electromotive force or voltage. The force that sends magnetic flux around a magnetic circuit is called magnetomotive force. It exists in every current-carrying coil.

The unit of magnetomotive force is the ampere-turn. If a coil has one turn and the current flowing through it is 1 amp, the magnetomotive force is 1 ampere-turn. If the coil has 10 turns and the current flowing is 1 amp, the magnetomotive force is the product of the two, or 10 ampere-turns. If a coil has 5 turns, and the current flowing through it is 5 amperes, the magnetomotive force is 25 ampere-turns. Thus, to find the magnetomotive force in a coil, you simply multiply the current flowing through it in amperes by the number of turns on the coil. You can increase the magnetomotive force of the coil by increasing the current flowing through the coil or by adding more turns to the coil and keeping the current constant.

As an electronics technician it is very unlikely that you will ever have to calculate the magnetomotive force produced by a coil in a circuit. However, you should know what it is. It is essential to understand magnetic circuits in order to understand magnetic devices.

RELUCTANCE

You already know that every electric circuit has resistance. Resistance is the opposition to current flow in the circuit. Just as there is opposition to current flow in an electric circuit so also is there opposition to flux in a magnetic circuit. This opposition to flux is called reluctance.

The reluctance in a magnetic circuit is distributed along the entire path taken by the flux. In other words, there is reluctance all the way around the path followed by each magnetic line of force both in the core and in the air. We can actually make a very close comparison between a magnetic circuit and an electric circuit. In Fig. 7A we have the magnetomotive force sending the flux around the magnetic circuit against the opposition offered by the reluctance of the circuit. In Fig. 7B, we have a wire connected across a battery. Here the electromotive force of the battery is forcing current around the circuit against the opposition or resistance of the wire.

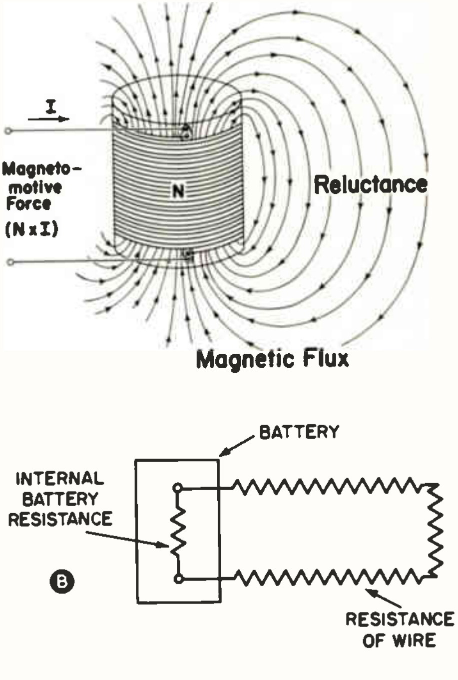

Fig. 7. Comparison between a magnetic circuit (A) and an electrical circuit (B).

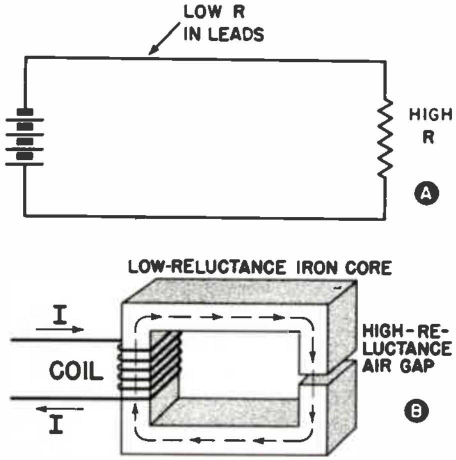

Fig. 8. In the electrical circuit at A, most of the opposition (resistance) to the current is in the resistor. The total resistance in the circuit is only slightly higher than the resistance of the resistor. In the magnetic circuit at B, most of the reluctance or opposition to the flux is in the air gap. The total reluctance in the circuit is only slightly higher than the reluctance of the air gap.

We have shown the whole length of the wire as a resistor. Here we see that the magnetomotive force is the equivalent of the electromotive force, the magnetic flux the equivalent of current, and the reluctance the equivalent of resistance.

We have a magnetic circuit that is similar to an electric circuit consisting of a resistor connected across a battery as shown in Fig. 8A. Here most of the resistance in the circuit is concentrated in the resistor; the resistance of the leads is small compared to that of the resistor. In the magnetic circuit of Fig. 8B, the iron core of the coil has an air gap. Most of the reluctance is concentrated in the air gap; the reluctance of the iron core is low in comparison to the reluctance of the air gap. One of the choke coils used in the power supply of a radio transmitter often has an air gap like this.

In an electric circuit, if we lower the resistance or opposition we can increase the current, and if we increase the resistance we reduce the current. Exactly the same situation exists in the magnetic circuit. If we lower the reluctance or opposition we increase the flux, and if we increase the reluctance we reduce the flux.

The reluctance in a magnetic circuit can be reduced by providing a better path through which the magnetic lines of force can flow. Materials such as iron and steel have a low reluctance, just as copper has a low resistance in an electric circuit. Therefore if a coil is wound on an iron core shaped like the one shown in Fig. 9, the magnetic lines will flow through the core as shown in the drawing. Because the iron has a low reluctance, there will be a much greater flux than there would

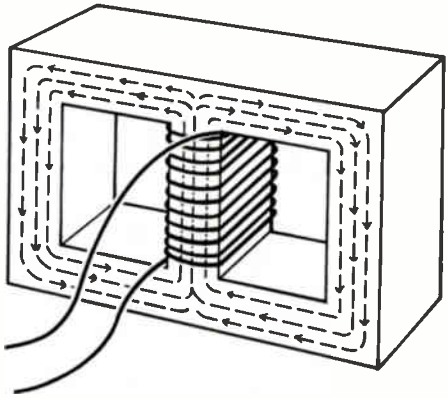

Fig. 9. There will be much greater flux if a coil is wound on an iron core like this than if the coil has an air core.

be if the same coil had an air core. Thus the flux in a magnetic circuit can be increased by providing a path of a magnetic material through which the magnetic lines of force can flow. Making a frame like the one shown in Fig. 9 of nonmagnetic material such as paper, glass, aluminum, or copper would not increase the flux, because these materials do not have a lower reluctance than air.

There are other factors that affect reluctance. Increasing the cross sectional area of the core will reduce the reluctance and increasing the length of the magnetic circuit will increase the reluctance.

PERMEABILITY

Silver, copper, and aluminum have different conductivities. Silver has the highest conductivity and is the best conductor, then copper and then aluminum. A copper wire has less resistance than an aluminum wire of the same size and length.

Similarly, different magnetic materials have different permeabilities. The permeability of the core material determines the total reluctance of the coil; when the permeability goes up, the reluctance goes down and vice versa.

The permeability of air and all other nonmagnetic materials is considered to have the numerical value of 1. Magnetic materials all have higher permeability values than 1, ranging from about 50 all the way up to 10,000 or even higher for certain special alloys. Thus if the permeability of a material is 10, we can expect 10 times the magnetic flux through this material than we would have through air for the same number of ampere turns.

MAGNETIC FLUX

You already know that magnetic flux in a magnetic circuit corresponds to current in an electric circuit. In an electric circuit, current is equal to the voltage in volts divided by the resistance in ohms. In a magnetic circuit the flux is equal to the magnetomotive force divided by the reluctance.

In practical magnetic circuits you will not have to calculate the magnetic flux. Even if you performed this calculation it would be of no value to you. However, it is important that you understand what magnetomotive force, reluctance, and magnetic flux are, and how they are related to each other.

You can increase the amount of flux in a magnetic circuit either by increasing the magnetomotive force or by decreasing the reluctance. You can decrease the amount of flux either by decreasing the magnetomotive force or by increasing the reluctance. Every change in flux is thus due to a change in either magnetomotive force or to a change in reluctance.

SUMMARY

Magnetic circuits are like electrical circuits in many ways. In a magnetic circuit there is a force which is the equivalent of voltage in an electrical circuit. We call this force a magnetomotive force. This force produces flux or magnetic lines of force which travel around the magnetic circuit. The flux or magnetic lines of force have some opposition; the opposition is known as reluctance. The magnetic lines of force are roughly the equivalent of the current in an electrical circuit and the reluctance is the equivalent of the resistance. In a circuit with a given magnetomotive force, if the reluctance is lowered, the flux in the circuit will increase. On the other hand, if the reluctance increases, the flux decreases.

Remember that the unit of magnetomotive force is an ampere-turn. A current of 1 ampere flowing through a coil of one turn produces a magnetomotive force of 1 ampere-turn. If we double the number of turns so that we have two turns and the current remains the same, the magnetomotive force produced will be two ampere-turns.

Remember the term permeability. The permeability of a material indicates the ability of the material to pass magnetic lines of force. The permeability of air is 1. Other non-magnetic materials such as paper, ceramic, glass etc. also have a permeability of 1 - in other words they act just like air insofar as a coil is concerned. However, magnetic materials such as iron and various alloys of magnetic materials have a much higher permeability than air. When we speak of a coil with a high permeability core we are talking about a coil with a core that has a much higher ability to pass magnetic lines of force than air.

Make sure that you remember these important terms used in conjunction with magnetic circuits. You will run into them many times in the future, and if you understand them now, then you'll understand the way in which they are used later. If you have any doubts about this section of this lesson be sure to review before going on. Once you are sure you have mastered the material in the lesson, do the self-test questions. Again, if you have trouble with any of the self-test questions, don't hesitate to go back to the text and restudy it. The purpose of the self-test questions is to help you be sure you have mastered the important points in the section of the lesson. If there is any self-test question you are not sure of, this indicates that you need to go back and spend some extra time on this section of the lesson before going ahead.

SELF-TEST QUESTIONS

(a) Fill in the missing word: Magnetic lines of force form ____ loops.

(b) Where will most of the lines of force produced by a coil be concentrated?

(c) What type of coil is a coil wound on a cardboard form?

(d) What are laminations?

(e) What purpose does an iron-core serve in a coil?

(f) What is magnetomotive force?

(g) What is the unit of magnetomotive force?

(h) If the current flowing through a 25-turn coil is 2 amperes, how many ampere-turns are produced?

(i) What is reluctance?

(j) Does the magnetic circuit in an air-core coil have a higher reluctance than a magnetic circuit in an iron-core coil?

(k) Which has the lowest reluctance, paper, air, aluminum or copper?

(l) What is permeability?

(m) What is the relation between flux, magnetomotive force and reluctance?

Using Coils To Produce Voltage

In most of the electronics applications of coils with which you are concerned, coils will be used to produce a voltage. An obvious example of this application is the transformer. In a transformer, a voltage is applied to one winding and this voltage causes a current to flow through this winding. This sets up a magnetic field, which in turn induces a new and completely separate voltage in another coil. Here two coils have been used to produce a voltage.

Another type of device where a coil is used to produce voltage makes use of a coil placed in the field of a permanent magnet to take a wave or signal other than an electrical signal and produce an electrical signal from it. Such a device is called a transducer. An example of a transducer using this principle is a dynamic microphone. A dynamic microphone uses coils placed in a magnetic field to convert an audio signal, which is actually a wave or vibration in air, to an electrical signal, which is the electrical equivalent of sound.

If you understand how a voltage can be produced by a coil, you will have mastered the most important point in understanding how coils work. To see how a voltage can be induced in a coil, we must first learn something about flux and flux linkages and then see how changing the flux linkages of a coil will produce a voltage in a coil.

FLUX LINKAGES

Let us see what we mean by flux linkage. Suppose we have a magnet that produces a single magnetic line of force. If the magnet is brought near a coil having one turn such as shown in Fig. 10A, we will have one magnetic line linking with or passing through a one-turn coil, and we will have one flux linkage. If we had ten turns on the coil and the one magnetic line of force passed through all ten turns, then we would have ten flux linkages as shown in Fig. 10B. However, if the single magnetic line passed through and linked only six turns of the 10-turn coil, as shown in Fig. 10C, we would have only six flux linkages. Thus the term

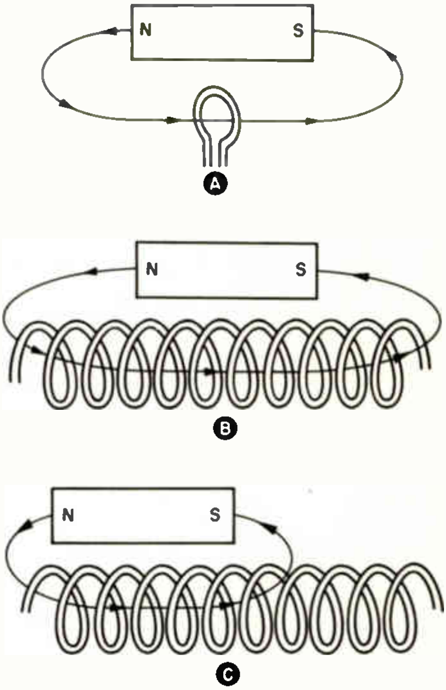

Fig. 10. How the number of flux linkages can be changed. In A there is one flux linkage; in B, ten; and in C, six.

"flux linkage" is an indication of the number of magnetic lines of force passing through and linking the turns on the coil. If we have a magnet that produces 100 magnetic lines, and the entire 100 lines linked to a coil having 80 turns, the number of flux linkages would be 80 times 100, or 8000 flux linkages.

Changing Flux Linkages.

Now let's look at Fig. 11A. Here we have a magnet with 10 magnetic lines of force, but actually only two of them are cutting through a coil with 5 turns on it, so we have a total of 10 flux linkages. As you can see, part of the flux is lost--it does not cut through the coil. This is called leakage flux or flux leakage. If we suddenly move the magnet to the position shown in Fig. 11B so that the magnet is placed inside the coil and all ten lines cut through the five turns of the coil, we have a total of 50 flux linkages. When the number of flux linkages increases from 10 to 50 there will be a voltage induced in the coil. This voltage is known as an induced voltage.

If the magnet is then moved away from the coil so that the number of flux linkages is changed from 50 back to 10, we will again have a voltage induced in the coil.

In each of the two examples given, we had a change of 40 flux linkages. If we had a stronger magnet so that the number of lines of force was greater, and therefore the change in flux linkages was greater, we would have a greater voltage induced in the coil.

In moving the magnet either towards or away from the coil, the voltage that will be induced in the coil will depend upon the speed with which the magnet is moved. If the magnet is moved slowly so that the number of flux linkages changes slowly, the voltage induced in the coil will be small. However, if the magnet is moved rapidly so that the change in flux linkage occurs very quickly, the voltage induced in the coil will be higher. If it took one second to move the magnet so that the number of flux linkages changed from 10 to 50, we would get a certain voltage induced in the coil. The exact value is not important to this discussion. However, if we were to move the magnet so that the number of flux linkages was changed from 10 to 50 in 1/100th of a second, we would get exactly 100 times as much voltage as before. The faster the rate of change in flux linkages, the greater the induced voltage will be.

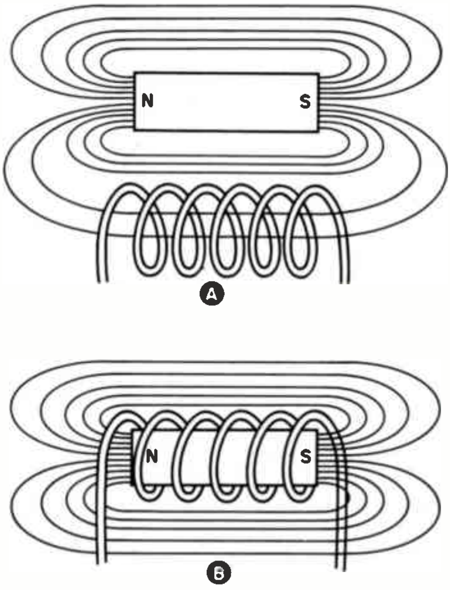

Fig. 11. In A we have 10 flux linkages; in B we have 50 when the same magnet is moved inside the coil.

LENZ'S LAW FOR COILS

The voltage induced in a coil always acts in a definite direction. In other words, the voltage has a definite polarity. This polarity at any given instant depends on just two things--on the direction of the original flux, and on whether the flux linkages are increasing or decreasing.

The exact relationship between these things is expressed by a famous electrical law known as Lenz's Law. The law is named after the man who was the first to realize that the direction in which an induced voltage will act can always be predicted before it is produced.

When the number of flux linkages cutting a coil is changed, a voltage will be induced in the coil. This induced voltage will have a polarity such that if the circuit is complete, it will send a current through the coil which opposes the change in magnetic flux. In other words, if the flux linkages are increasing, the induced voltage will tend to send a current through the coil that would produce a magnetic flux which would oppose the original coil flux to try to keep it from increasing. On the other hand, if the flux linkages are decreasing, the induced voltage will be of such a polarity that it will produce a current which in turn will produce a flux which aids the original flux and tends to prevent the flux from decreasing.

This is an extremely important law and can be better understood by referring to the circuits shown in Fig. 12. In Fig. 12A, we have a magnetic circuit with two flux lines cutting through a 5-turn coil, which gives us ten flux linkages. As the magnet is moved away from the coil, reducing the number of flux linkages as shown in Fig. 12B, a voltage will be induced in the coil, and current will flow through the coil. Current flowing through the coil will set up a magnetic field which will aid the flux linkages already existing. As long as the number of flux lines is changing, the induced voltage will be present and will cause the induced current to produce flux lines as shown.

If, as shown in Fig. 12C, the magnet is moved back into the coil, the number of flux linkages would tend to increase. However, a voltage will be induced in the coil that will cause

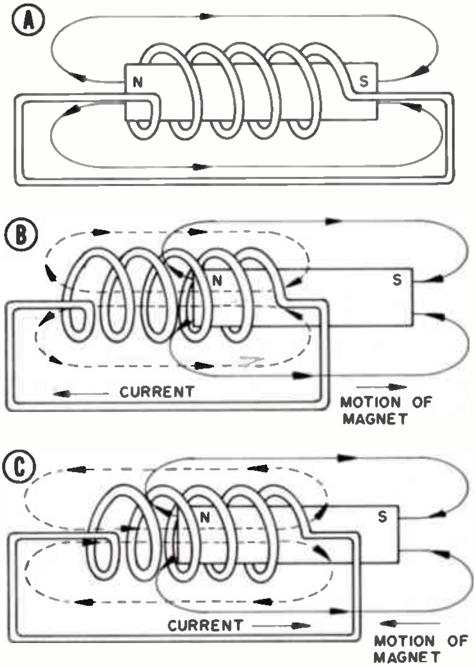

Fig. 12. Changing the number of flux linkages induces a voltage in the coil. The polarity of the voltage depends upon whether the number of flux linkages is increasing or decreasing.

a current to flow in the opposite direction and set up its own lines of force to oppose the flux lines from the magnet. In other words, if there is any change in the number of flux linkages through the coil, a voltage is induced in that coil that will cause a current to flow which in turn produces its own flux to oppose the change in flux linkages.

If the number of flux linkages is decreasing, the induced voltage will have a polarity such that it will cause a current to flow to oppose this decrease in flux linkages; and on the other hand, if the flux linkages are increasing, then the induced voltage will have a polarity that will cause a current to flow to oppose this increase in flux linkages.

METHODS OF CHANGING FLUX LINKAGES

There are three methods of producing changes in the flux linkages in a coil. They are: by cutting through magnetic lines of force; by changing the reluctance; and by changing the current flowing in the coil.

Cutting Lines of Force.

You have already seen an example of this method of producing changes in flux linkages when you studied generators in an earlier lesson. You learned that when a conductor is moved through a magnetic field it cuts the magnetic lines of force, and a voltage is induced in the conductor. We get this induced voltage because the motion of the conductor changes the flux linkages as the conductor passes through the magnetic lines of force.

In a generator, instead of moving a single wire through a magnetic field, a coil is rotated in the magnetic field. As the coil is rotated, it moves through and cuts through the magnetic lines of force produced by a permanent magnet or an electromagnet, and a voltage is induced in the coil. The voltage induced in the coil will have a polarity such that the current that will flow when the coil is connected to an external circuit will set up a magnetic field in the coil which opposes the change in flux linkages producing the voltage.

Changing the Reluctance.

Any change in the reluctance of a magnetic circuit will change the amount of flux which passes through the coil, thus changing the flux linkages through the coil and inducing a voltage. Remember, whenever there is a change in flux linkages, a voltage is induced.

An example of this method of producing a voltage is the variable reluctance phono pickup used in many record players. A simplified drawing of one is shown in Fig. 13. The needle, or stylus, is mounted on a cantilever spring, which moves between two coils. The other end of the cantilever spring is connected to the south pole of a permanent magnet. A T-shaped yoke connects the other end of the magnet to two pole

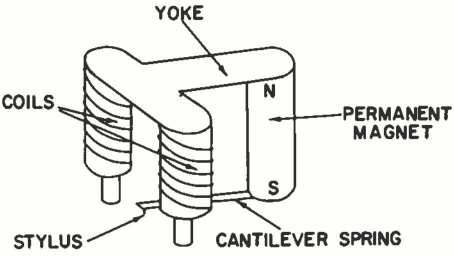

Fig. 13. A variable reluctance phono pickup.

pieces on which two coils are wound. The flux path goes from the magnet through the yoke, and the two pole pieces, across the air gap to the cantilever spring, and through it back to the magnet. As the needle follows the record grooves, it moves from side to side, nearer one or the other of the two coils. As it does so, the air gap on one side decreases, so the reluctance on that side decreases, and the flux increases. At the same time, the air gap on the other side becomes wider, increasing the reluctance and decreasing the flux. Since the flux changes are in opposite directions, the voltages induced in the two coils will be of the opposite polarity. The two coils are connected in such a way that the two voltages are added in the output. The change in flux linkages will induce a voltage in the coil.

Changing the Coil Current.

When two coils are arranged as shown in Fig. 14, the flux produced by coil L1 passes through coil L2. As long as the current through L1 remains constant, the flux produced by this coil will remain constant, and there will be no change in the flux linkages in L2. However, if the current is changed by changing the setting of the rheostat, there will be a change in the flux produced by L1 and hence a change in the number of flux linkages in L2. This will induce a voltage in L2.

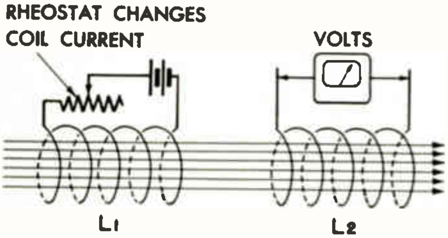

Fig. 14. When two coils are arranged as shown above, the flux produced by one passes through the other.

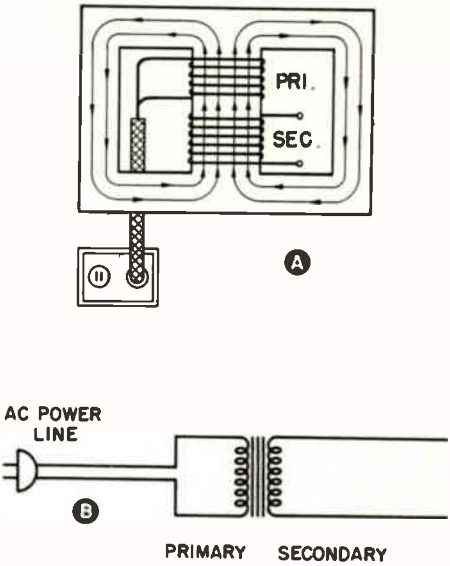

Fig. 15. A power transformer. The primary winding is connected directly to the power line. As the current through the primary working varies, the flux produced by L1 will vary, resulting in a change in flux linkages through the secondary winding, inducing a voltage in the secondary.

Of course, this is not a practical way of inducing a voltage in L2 because the rheostat setting would have to be changed continually and at a rapid rate in order to produce any appreciable voltage in L2. A more practical application would be to apply an ac voltage to L1 in place of the battery and the rheostat.

Since the ac voltage is continually changing, this means that the flux is constantly changing, which in turn will result in there being a voltage continually induced in L2.

A practical application of this principle is in the power transformer as shown in Fig. 15. We have already mentioned the transformer several times before and you are aware that a transformer is simply two coils wound on a common core. In the transformer shown in Fig. 15, the one winding called the primary is connected directly to the ac power line. The ac voltage which is a varying voltage will cause a varying current to flow through the primary winding. As the current varies, the flux produced by the primary will change, resulting in a change in the flux linkages cutting the secondary winding. This change in flux linkages will induce a voltage in the secondary winding. As we pointed out before, whether this voltage is higher or lower than the primary voltage will depend upon whether the secondary winding of the transformer has more or fewer turns than the primary winding.

SUMMARY

There are several important facts that you should remember from this section of the lesson. First, remember that a voltage is induced in a coil when the number of flux linkages changes. Either an increase in the number of flux linkages or a decrease in the number of flux linkages will induce a voltage in the coil.

Lenz's Law of coils is important. It states that the induced voltage always acts in such a direction that it tends to oppose the original change in flux linkages.

Changes in flux linkages can be produced by cutting through magnetic lines of force, by changing the reluctance in the magnetic circuit or by changing the current flowing through the circuit.

In the next section of this lesson you will learn more about coils. You will learn how the electrical characteristics of coils are expressed and also see why the opposition that a coil offers to the flow of ac through it is much higher than it is to dc. However, before going ahead with the next section of the lesson, it is important that you understand the material covered in this section. Therefore you should review this section if necessary and then answer the self-test questions. Be sure you are able to answer all of the following self-test questions before you go ahead with the next section of the lesson.

SELF-TEST QUESTIONS

(n) What is meant by flux linkages?

(o) If three magnetic lines of flux cut through four turns of a coil, how many flux linkages have we?

(p) If one hundred flux linkages cut through a coil, and this number of flux linkages does not change, what will the voltage induced in the coil be?

(q) According to Lenz's Law, if a change in the number of flux linkages cutting a coil occurs, will the voltage induced in the coil produce a current, which in turn will build up a magnetic flux that will aid or oppose the original change in flux linkages?

(r) When the number of flux linkages cutting a coil is reduced, will the field produced by the induced voltage aid or oppose the original lines of force?

(s) Name three methods of changing flux linkages.

(t) Give a practical example where changing the reluctance in a magnetic circuit is used to produce a voltage.

(u) Give a practical example of where changing the coil current produces a voltage.

Inductance

In the preceding section of this lesson you learned that if the number of flux linkages cutting the turns of a coil changes, there will be a voltage induced in the coil. The exact amount of voltage that will be induced in the coil will depend upon how great the change in flux linkages is, and how rapidly it occurs. It will also depend upon the coil itself. The property of the coil that will govern or determine the voltage induced in the coil is called inductance. The inductance of a coil will depend upon the number of turns of wire on the coil and upon the permeability of the core material. Saying that a coil has inductance is just about the same as saying a resistor has resistance. Inductance is a basic property of a coil and it indicates how much voltage will be induced in the coil for a given change in flux linkages. Before we go further with this idea of inductance, you should learn something about self-induced voltages.

SELF-INDUCED VOLTAGES

When a coil is brought near a magnetic field and the strength of the field is suddenly changed, there will be a change in the number of flux linkages through the coil. You know that this will result in a voltage being induced in the coil.

However, now let us consider a coil that is completely removed from any external magnetic field. If a voltage source is connected to the coil, current will flow through the coil and this current will set up a magnetic field. The magnetic field produced by the coil will produce lines of flux. These lines of flux will link through the turns of the coil as shown in Fig. 16.

If the current flowing through the coil is suddenly changed, the strength of the magnetic field will change and this will result in there being a change in the number of flux linkages passing through the turns of the coil. This will have exactly the same effect as changing the flux

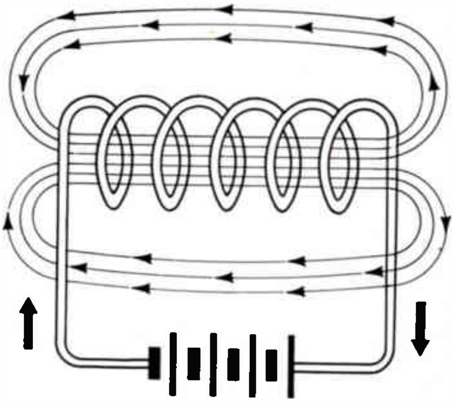

Fig. 16. If a voltage source is connected to a coil, current will flow through the coil and a magnetic field will be set up.

linkages produced by an external magnet will have. There will be a voltage induced in the coil and this voltage will be such that it will tend to oppose the change produced. In other words, the induced voltage will cause a current to flow in such a direction as to produce a magnetic field which tends to oppose the change in the magnetic field. The voltage induced in this manner is known as self-induced voltage.

It is important for you to realize that an induced voltage in a coil always opposes the change producing it. For example, in the circuit shown in Fig. 16, if the voltage is reduced to lower the current and hence the number of flux linkages, the self-induced voltage induced in the coil will have a polarity that both aids the applied voltage and tries to keep the current constant so that the number of flux linkages will not change. On the other hand, if the applied voltage is suddenly increased, then the voltage induced in the coil will oppose the applied voltage to, once again, try to keep the current flowing through the coil constant and hence the number of flux lines constant.

The induced voltage in a coil obeys Lenz's Law. Its polarity is such that it tries to oppose the change that produced it.

UNITS OF INDUCTANCE

For a given change in flux linkages, the voltage that will be induced in a coil will depend upon the inductance of the coil. The unit of inductance is the henry. It is named after Joseph Henry, an outstanding scientist who did a great deal of experimenting with coils.

There are a number of scientific ways of defining the henry, but these are of no importance to the electronics technician. One simple definition of the henry that can be used is as follows: if the voltage induced in a coil is 1 volt when the strength of the current flowing through the coil changes at a rate of 1 ampere per second, the coil has an inductance of 1 henry. In other words, if a coil has an inductance of 1 henry, a current change of 1 ampere per second will induce a voltage of 1 volt in the coil.

Large iron-core coils frequently have quite high inductances. You will find iron-core coils in electronic equipment having inductances of 20 or 30 henrys. In some cases you may find iron-core coils having inductances ranging as high as 1000 henrys.

Most air-core coils have a very small inductance. For convenience in specifying inductance values of air-core coils and some small iron-core coils, two other units are used, the millihenry and the microhenry. Just as the milliampere is one thousandth of an ampere, the millihenry is one thousandth of a henry; just as a microampere is one millionth of an ampere, the microhenry is one millionth of a henry. The unit millihenry is usually abbreviated mh and the microhenry is abbreviated μh.

To convert from henrys to millihenrys or microhenrys you use exactly the same procedure as in converting amperes to milliamperes or microamperes. To convert henrys to millihenrys, you multiply by 1000 or simply move the decimal point three places to the right. To convert henrys to microhenrys you multiply by 1,000,000 or move the decimal point six places to the right. To convert millihenrys to microhenrys, you multiply by 1000 or move the decimal point three places to the right.

To convert from microhenrys to henrys, you divide by 1,000,000, or move the decimal point six places to the left. To convert from millihenrys to henrys, you divide by 1000 or move the decimal point three places to the left. To convert from microhenrys to millihenrys you divide by 1000 which is the same as moving the decimal point three places to the left. If you have no difficulty converting from amperes to milliamperes and microamperes and back again to amperes you should have no problem converting between henrys, millihenrys and microhenrys.

FACTORS AFFECTING INDUCTANCE

There are several factors that affect the inductance of a coil. As you might expect, one of the chief factors is the number of turns on the coil. You can expect a coil having 200 turns to have a higher inductance than a coil having 100 turns would on the same type of core.

The inductance of a coil is also affected by the shape and size of the coil. As an example, an air-core coil wound on a round form six inches in diameter will have a higher inductance than a coil with the same number of turns wound on a form one inch in diameter. In the coil with the smaller diameter, many of the lines of flux will escape or cut through only a few turns of the coil; in other words there will be considerable flux leakage. On the other hand, in the larger coil more flux lines will cut through each turn of the coil, resulting in a greater number of flux linkages, which in turn will give the coil a greater inductance.

The inductance of a coil is affected by the core material. If a magnetic material is placed in the core of a coil, the magnetic path will have a much lower reluctance; there will be more flux and a much greater number of flux linkages than there would be in a similar coil without an iron-core. The exact material placed inside the coil also affects the inductance. The higher the permeability of the core material, the greater the inductance of the coil will be.

Before leaving this section of the lesson it should be pointed out that inductance is not limited to coils alone. Even a straight wire has some inductance, because when a current flows through the wire, a magnetic field is set up around the wire and the wire will be cut by magnetic lines. Of course, the inductance of a straight wire is much lower than it would be if the wire were wound into a coil, but nevertheless every piece of wire does have inductance. In most cases this inductance is so low it has no effect on the circuit performance, but in some ultra-high-frequency electronic equipment straight wires or tubing are actually used as "coils."

Because the most important property of a coil is its inductance, electronics men often call coils "inductors" or "inductances." The term inductance not only includes coils, but in the case of ultra-high-frequency equipment may include a straight piece of tubing that is to be used as the inductance in one of the circuits.

INDUCTIVE REACTANCE

You have learned that when a coil is connected to a voltage source as in Fig. 16, and the voltage is changed, there is a voltage induced in the coil that opposes the change in voltage. Now let us consider what happens when a coil is connected to an ac voltage source as in Fig. 17. Here the voltage is continually changing.

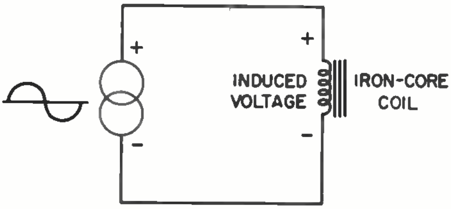

Fig. 17. A coil connected to an ac voltage source.

During the first quarter cycle when the ac voltage is increasing and has the polarity shown in Fig. 17, the polarity of the induced voltage will be as shown so it will oppose the ac voltage as it tries to increase. Thus, the induced voltage acts to oppose and limit the change in current in the coil. If there were no voltage induced in the coil, the current would increase as the voltage increased, and the actual value of current flowing at any instant would depend only on the voltage applied and the dc resistance of the coil. However, since the induced voltage is of the opposite polarity to the applied voltage, the induced voltage has the effect of opposing the applied voltage and limiting the current change in the coil. This self-induced voltage is known as "counter" or "back" emf (electromotive force). It is the induced ac voltage that appears across the coil. This ac voltage drop is just the same as the voltage drop across a resistor caused by current flowing through a resistor. In other words, the counter emf is the ac voltage drop across a coil caused by the opposition that the coil offers to the alternating current. This opposition that the coil offers is not the same as resistance because it affects only ac, and not dc. The opposition is known as inductive reactance and it is measured in ohms.

The amount of voltage induced in a coil will depend upon how rapidly the change in flux linkages occurs. When an ac voltage is applied to a coil, the speed with which the number of flux linkages changes depends upon the frequency of the ac voltage. Thus the change in flux linkages occurs more rapidly if the frequency is 100 cycles than it would if the frequency were only 10 cycles. Therefore an ac current with a frequency of 100 cycles flowing through a coil will induce more voltage than a current of the same strength but a frequency of only 10 cycles. This means that the inductive reactance depends upon the frequency.

The inductive reactance of a coil can be determined by multiplying the inductance of the coil in henrys times 6.28 times the frequency in cycles.

Electronics technicians use symbols to provide a short convenient way of expressing this relationship. The symbol used for reactance is X. A small capital letter L following the X and written X_L is used to indicate inductive reactance. The letter f is used to represent frequency, and the letter L is used to represent inductance. Thus the expression for inductive reactance of a coil in ohms can be written:

$$X_L = 6.28 \times f \times L$$

The number 6.28 is two pi. Pi is the Greek letter π (pronounced pie) which represents the number 3.14. You have probably seen this number before--it is used to find the area of a circle. Remember that the area of a circle is π times the radius squared. 2π is 6.28, which is a number that appears in many electrical formulas. Sometimes you will see the expression for inductive reactance written:

$$X_L = 2\pi fL$$

Now let's see how we use this formula to find the inductive reactance of a coil.

Example 1: Suppose we want to know the inductive reactance of a 50-henry choke at 100 cycles. The formula is:

$$X_L = 6.28 \times f \times L$$

Substituting 100 for f and 50 for L gives:

$$X_L = 6.28 \times 100 \times 50$$

Multiplying these numbers gives us 31,400 ohms. This is the inductive reactance of the coil at a frequency of 100 cycles. At a frequency of 50 cycles, the inductive reactance would be half this figure, and at a frequency of 200 cycles per second, the inductive reactance would be twice this figure. We say that the inductive reactance of a coil varies directly as the frequency varies. If the frequency increases, the reactance increases, and if the frequency decreases, the reactance also decreases.

Example 2: Suppose we want to know the inductive reactance of a 10-henry choke at a frequency of 100 cycles. Substituting 100 for f and 10 for L gives us:

$$X_L = 6.28 \times 100 \times 10$$

Multiplying this gives us:

$$X_L = 6280 \text{ ohms.}$$

Notice that this is less than in the case of the 50-henry coil. Thus the inductive reactance also varies directly as the inductance of the coil varies. Reducing the inductance reduces the reactance and increasing the inductance increases the reactance.

As an electronics technician you will seldom have to work on a problem of this type. However, it is important for you to remember that the inductive reactance of a coil varies directly both with the frequency and with the inductance of a coil.

You might wonder what the inductive reactance is of a small coil consisting of only a few turns. At low frequencies of a few hundred cycles, the reactance is so low that in most cases it can be ignored. However, when small coils are used in high-frequency circuits, their inductive reactance can be appreciable. Let's take as an example a 10-microhenry coil used at a frequency of 100 megacycles.

10 microhenrys is .000010 henry, and 100 megacycles (abbreviated mc) is 100,000,000 cycles.

$$X_L = 6.28 \times f \times L$$
$$X_L = 6.28 \times 100{,}000{,}000 \times .000010 = 6280 \text{ ohms.}$$

Thus, even though the inductance of the coil is quite small, at the frequency of 100 mc it has as high an inductive reactance as the 10-henry coil had at 100 cycles.

We mentioned previously that inductive reactance is the opposition a coil offers to the flow of ac current through it. A coil has no inductive reactance to dc. You can see that this must be true from the formula for inductive reactance. The frequency of dc is zero and so if we substitute zero in the formula for inductive reactance, then we have 6.28 × 0 × L. Whenever you multiply anything by 0, no matter how large it is, the result is 0, so the inductive reactance is 0. The only opposition a coil will offer to the flow of dc through it is due to the resistance of the wire used to wind the coil. The wire will have a certain resistance, and this resistance will oppose the flow of dc through the coil in just the same way as it would if it were one long piece of wire and we tried to pass dc through it. The ac reactance of a coil, on the other hand, is an entirely different thing; it is the opposition the coil offers to the flow of ac through it due to the inductance of the coil, and it will be much higher than the dc resistance of the coil.

MUTUAL INDUCTANCE

When two coils are placed near each other so that some of the flux produced by one coil will cut through the turns of the other coil, the coils are said to be mutually-coupled through their magnetic fields. The coils might actually be wound on the same iron core or they might simply be placed near each other. When coils are placed so they are mutually coupled, any change in the flux in one coil will induce a voltage in the other coil.

Mutual inductance is measured in henrys, just as the inductance of a single coil. The mutual inductance is usually represented in formulas by the letter M. The greater the value of mutual inductance, the greater will be the voltage in one coil when the current through the other changes.

Mutual inductance is defined in the same way as inductance - when a primary current changes at a rate of 1 ampere per second, if the voltage induced in the secondary coil is 1 volt, the mutual inductance is 1 henry.

Mutual inductance depends upon the size of both coils, the number of turns of each coil and how many flux linkages from one coil cut the turns of the other coil.

COILS IN SERIES AND PARALLEL

When we consider coils connected in series or in parallel, there are two different cases to consider. The first and simplest is if the coils are located some distance from each other so that their magnetic fields do not affect each other. When the coils are connected in series as shown in Fig. 18A, the combined inductance is the sum of the individual inductances. In other words, the total inductance is obtained simply by adding the inductances of the individual coils. This should be easy to remember because in this respect coils are like resistors.

When coils are connected in parallel as shown in Fig. 18B, the total inductance will be less than the inductance of the smallest coil in the

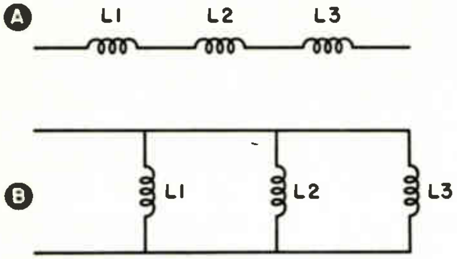

Fig. 18. Coils connected in series (A): coils connected in parallel (B).

group. Again, this is just like resistors connected in parallel - remember that when resistors are connected in parallel, the total resistance is always less than the resistance of the smallest resistor.

It is easy to see why coils connected in parallel act this way. For example, looking at Fig. 18B, if L1 has an inductive reactance of 100 ohms and is connected across a 100-volt source, an ac current of 1 amp would flow through the coil. If the second coil of equal inductance is connected in parallel with it, an ac current of 1 amp will also flow through it. Now we have a current of 2 amps flowing in the circuit and therefore, the opposition or inductive reactance must have decreased. This means that the total inductance of the two coils in parallel must have decreased. In fact, with two equal coils, the effective inductance of the two in parallel will be equal to one half the inductance of either coil.

When coils connected in series are placed close together so that some mutual inductance exists, there is interaction between the coils, and the combined inductance can no longer be figured simply by adding the inductances of the individual coils. In this situation, we must consider the mutual inductance in the circuit and also how the coils are connected together.

Let us look at the first case, where the two coils are connected in series so that the flux from one coil aids the flux from the other. In other words, the magnetic lines are flowing in the same direction. Here if the inductance of the two coils is represented by L1 and L2 and the mutual inductance by M, the total inductance (L_T) of the two coils connected in series will be equal to:

$$L_T = L1 + L2 + 2M$$

If the connections to one of the coils are reversed, its magnetic field will oppose the magnetic field of the other. Under these circumstances the total inductance of the two coils connected in series will be:

$$L_T = L1 + L2 - 2M$$

SUMMARY

You have studied a great deal of important material about coils in this section and it would be worthwhile to read the section over several times to be sure that you have understood everything covered.

You have learned that the electrical property that describes coils is called inductance, and that inductance is measured in henrys. A coil has an inductance of 1 henry when a current change of 1 amp per second induces a voltage of 1 volt in the coil.

You learned that when the current flowing through a coil changes, there is voltage induced in the coil that opposes the change that produces it. This voltage is a self-induced voltage and is called counter emf or back emf.

Coils have a property called inductive reactance. Inductive reactance is the opposition that a coil offers to the flow of ac through it. Inductive reactance is measured in ohms and is somewhat similar to resistance inasmuch as it opposes the flow of ac through the coil.

When two coils are placed near each other, the flux lines of one coil will cut through the other coil, and the coils are said to be mutually-coupled. The amount of coupling is determined by the nearness of the coils to each other and by the shape and size of the coils. This coupling is called mutual inductance. The mutual inductance of two coils is measured in henrys.

When coils are connected in series, the total inductance is equal to the sum of the individual inductances, and when they are in parallel, the total inductance is less than the inductance of the smallest coil. When mutually-coupled coils are connected in series, the total inductance is $L1 + L2 + 2M$ when the magnetic field of the two coils aid each other, and $L1 + L2 - 2M$ when the magnetic fields oppose each other.

SELF-TEST QUESTIONS

(v) What is the name given to the property of a coil which will determine the voltage induced in it?

(w) What is a self-induced voltage?

(x) If the voltage applied to a coil is suddenly increased, will the self-induced voltage produced in the coil aid or oppose the applied voltage?

(y) What is the unit of inductance?

(z) How is the unit of inductance defined?

(aa) Name three factors which affect the inductance of a coil.

(ab) What is the inductive reactance of a coil?

(ac) What is the unit in which the inductive reactance of a coil is measured?

(ad) What is the inductive reactance of a 10-henry coil at a frequency of 60 cycles?

(ae) What is meant by mutual inductance?

(af) If two coils, one having an inductance of 6 henrys and the other having an inductance of 8 henrys are placed some distance apart so that there is no mutual inductance between them, what will the total inductance of the two coils be if they are connected in series?

(ag) Two coils, one having an inductance of 4 henrys and the other having an inductance of 3 henrys have a mutual inductance of 2 henrys. If the coils are connected in series aiding, what will the total inductance be?

(ah) If an 8-henry coil and a 7-henry coil that have a mutual inductance of 3 henrys are connected in series opposing, what will the total inductance of the two coils be?

(ai) Convert 2.2 henrys to millihenrys.

(aj) Convert 100 microhenrys to henrys.

Ohm's Law for Coils

You will remember from earlier lessons that the current that will flow in a circuit depends upon the voltage applied and upon the resistance of the circuit. This rule can be applied to ac circuits as well as dc circuits, but in an ac circuit, you substitute the total opposition offered to the flow of current for the resistance. In an ac circuit, the total opposition to current flow is called impedance and is represented by the letter Z. In this section of this lesson, you will study Ohm's Law for coils, you will learn what impedance is and how to find impedance in ac circuits, and you will learn about another important thing in ac circuits which is called phase.

PHASE

Before you can understand why impedance is important in ac circuits you must understand what we mean by phase. Phase is important. It is something that you will run into all the way through your study in electronic circuits. Time and time again you will see the expressions, "in phase", "out of phase" and "phase shift." Since phase is so important, learning what it is now will simplify your studies later.

In a circuit made up only of resistance, if we increase the voltage, the current will increase immediately. Changes in current can be produced instantly by changing the voltage in the circuit. In other words, the current follows the voltage changes instantly. If the voltage increases, the current increases instantly; if the voltage decreases, the current decreases instantly. The current is in phase with the voltage. This idea simply means the change in the voltage will produce the same change in the current flowing in the circuit.

This is not true of circuits containing coils. If you have a constant dc voltage connected across a coil, the current that flows depends only on the dc resistance of the coil; in other words, the resistance of the wire used to wind the coil. If you suddenly increase the voltage applied to the coil, there is immediately a change in the number of flux linkages cutting the various turns of the coil. This induces a voltage in the coil, and the induced voltage opposes the change in applied voltage. When the current changes because of the increase in applied voltage, it will be limited by the induced voltage as well as the resistance. The inductance of the coil opposes the change in current through the coil - this effect is called inductive reactance. Gradually the current will increase from the value that it was originally if the voltage were increased. As the current increases, it finally reaches its new value; the self-induced voltage in the coil decreases until finally when the current becomes constant, the self-induced voltage in the coil will disappear.

Now let us look at the circuit shown in Fig. 19. Here we have a resistor and a coil connected in series and the two are connected across an ac generator. We are

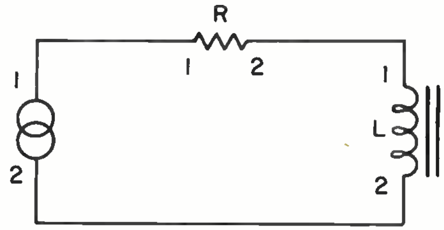

Fig. 19. A coil and resistor connected in series across an ac source.

going to examine the ac current flowing through the circuit to see what happens to the voltage across the resistor and the voltage across the coil, as the current goes through its cycle.

In Fig. 20A we have shown a single current cycle from the generator in Fig. 19. At the present, we are not worried about the voltage across the generator, we are simply concerned with the current. Remember that the ac voltages and current waveforms from the generator will be sine waves. The start of the sine wave cycle is marked point A. Let's consider that at this instant current is just starting to flow from terminal 1 of the generator around the circuit towards terminal 1 of the resistor. At the instant the cycle starts at terminal A, the current is increasing at its maximum rate of change. Notice that as the cycle moves from point A to point B, the curve is flattening out until finally at point C the current is neither decreasing or increasing, it is at a constant value for just an instant. From point C to point D the current begins to decrease. The rate at which it decreases is increasing from C to D and it continues to change at an even more rapid rate until it reaches point E at which instant the current is at 0 for just a moment. However, even though the current is at 0 for an instant at point E, the rate of change is very rapid; the instant before it reaches point E it is flowing in one direction, exactly at point E it drops to 0 and then at the instant it passes point E and starts towards point F, it begins to flow in the opposite direction. As the cycle moves from E to F, the rate at which the current is changing begins to decrease until finally at point G, once again while the current is flowing at its maximum value, the rate at which it is changing for just an instant at point G drops to 0. From point G to point H, the current again starts to drop to 0 and the rate at which it is dropping to 0 begins to

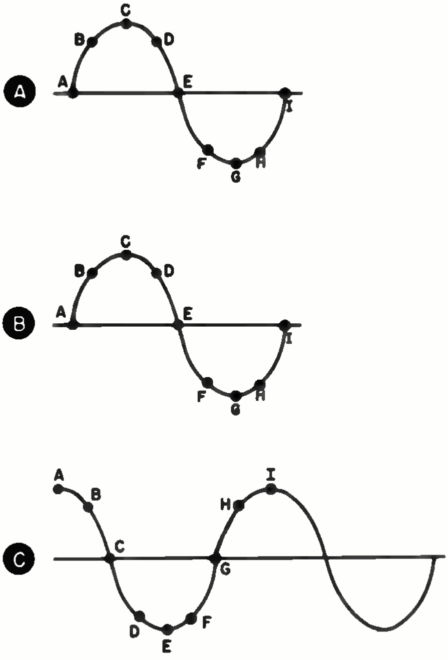

Fig. 20. Generator current is shown at A, resistor voltage at B and coil voltage at C.

increase from point G to point H and continues to increase until it reaches its maximum rate of change at point I.

Now let us see what happens as this current cycle flows around the circuit. Let us consider the voltage across the resistor R first. As the current flows from terminal 1 to terminal 2 of resistor R, the voltage that will be produced across the resistor will depend upon the current flowing through the resistor. As the current wave builds up from point A to point B and then to point C as shown in Fig. 20A, a voltage wave will be built up as shown in Fig. 20B. Point A represents 0 voltage and point C represents maximum voltage. Maximum voltage at point C on the curve B will be reached at exactly the same instant as the maximum current flow is reached at point C on curve A. As the current through the resistor begins to decrease and finally reaches 0 at point E on curve A, the voltage across the resistor will follow curve B reaching 0 at the same instant or at point E on curve B. As the current goes through the other half cycle and flows in the opposite direction, a voltage with the opposite polarity will be produced across the resistor. When the current reaches its maximum value at point G on curve A, the voltage will reach its maximum value with the opposite polarity at point G on curve B. As the last quarter of the cycle is completed and the current curve A drops from G to I, the voltage curve B will also drop from G to I.

Notice that throughout the entire cycle the voltage across the resistor was exactly in step with the current flowing through it. We say that the current and voltage are in phase.

Now let us consider what happens across the coil. We already mentioned that in curve A at point A, the current is changing at its maximum rate. Current is leaving terminal 1 of the generator and flowing around the circuit back to terminal 2. This means the current will try to flow through the coil from terminal 1 to terminal 2. The instant the current tries to build up through the coil a voltage will be induced in that coil which will oppose the change in current through it. The amplitude of the voltage will depend on the rate at which the current is trying to change. Since at point A on curve A, the change in current is at its maximum value, the maximum voltage will be built up across L. The polarity of the voltage will be such that it will oppose the current flowing in the circuit. This means that we could get the same effect by putting a battery in the circuit that would prevent the current from flowing through the coil. In order to do this we would have to connect the battery so that terminal 1 was negative and terminal 2 positive; this would oppose the current trying to flow around the circuit.

In Fig. 20C we have represented the voltage at the beginning of the current cycle as A. Notice that the voltage is at its maximum value because the rate of change of current as shown on curve A is at its maximum value at point A.

As the current in the circuit increases from A to B, the rate at which it is changing decreases. This means that the voltage induced in the coil will decrease until the current cycle has reached point B on curve A, and the voltage will have reached point B on curve C. Finally, when the current shown on curve A reaches point C where its rate of change has dropped to 0, the voltage will have dropped to point C on curve C and since the rate of change of current is 0 the voltage induced in the coil will be 0.

At point C on the current curve, the current begins to decrease in value. The rate at which it decreases begins to increase from point C to point D and reaches its maximum value at point E. Since the current is decreasing, the voltage induced in the coil will have the opposite polarity because it will try to prevent this decrease. It will reach maximum value at point E where the rate of current change is at a maximum. This is shown by the voltage waveform between points C, D and E on curve C. From point E to point G the current is still changing in the same direction, but its rate of change is decreasing from E to F until finally when it reaches G, its rate of change is 0. The voltage induced in the coil is represented by the portion of the curve between point E, F and G on curve C. Notice that once again when the current wave has reached point G where its rate of change is 0, the voltage waveform will also be at G. Notice that it is the rate of change of current which controls the voltage induced in the coil, not the actual value of the current flowing in the coil.

From point G to I on the current waveform shown in Fig. 20A, the current begins to change and the rate of change increases until it reaches its maximum value at point I. The voltage waveform is shown at C and the amplitude of the voltage increases from point G where the rate of current change is 0 to the maximum value at point I where the rate of current change is at a maximum.

From examining curves A and C, we can see that the changes in current and voltage across the coil do not occur at the same instant. As a matter of fact, since the current waveform from A to I represents one complete cycle, from A to E and from E to I represents a half cycle. We also refer to this as 180°. (There are 360° in a circle and half a circle is 180°.) From point A to C is one quarter cycle as is from C to E, from E to G and from G to I. Notice that the voltage waveform is identical to the current waveform except that it is one quarter of a cycle ahead of the current waveform. In other words, as the current starts at point A to build up to a maximum value at point C, the voltage is already at its maximum value at point A and starts to drop to its minimum value at point C. During the next quarter cycle when the current drops from its maximum value with one polarity at point C to point E, the voltage is ahead of it by one quarter of a cycle and goes from 0 to its maximum value with the opposite polarity at point E. We say that the current and voltage are out of phase. We refer to this as one quarter of a cycle or 90° phase difference. Since the voltage is ahead of the current we say that the voltage leads the current by 90° or one quarter cycle.

Summarizing what we have seen from Fig. 20, we notice that in the case of a resistance the voltage and current are in phase, but in the case of a coil the voltage leads the current by 90°. In any pure inductance, the voltage will always lead the current by 90° - this is an extremely important point; be sure that you remember it. We can also say that the current lags the voltage by 90° - this is the same thing as saying the voltage leads the current by 90°; the voltage is ahead of the current, therefore, the current must be behind or lagging the voltage.

Now what about the generator voltage - so far we have considered only the generator current. What is the phase relationship between the generator voltage and the generator current?

To simplify our problem let us assume that R has a resistance of 1000 ohms and that L has an inductive reactance of 1000 ohms. Therefore, any current flowing through R and through L will produce equal voltages across them. The voltage across the resistor will be IR and the voltage across the coil will be IX_L.

The waveforms in Fig. 20 tell us that the voltage across the coil is not in phase with the voltage across the resistance. This means that the two do not have their maximum values of voltage at the same instant nor do they have their minimum values at the same instant. Therefore, since the voltages are ac voltages and are not occurring at the same time, we can't simply add them together to find the total voltage across the two. For example, when the voltage across the resistor is at its maximum value as shown at point C and G in Fig. 20B, the voltage across the coil will be at 0. Similarly, when the voltage across the coil is at its maximum value as shown at point A, E and I in Fig. 20C, the voltage across the resistance is 0.

The relationship between the current, resistor voltage, coil voltage and generator voltages can be shown by means of a diagram called a vector diagram. The first step in drawing a vector diagram is to draw a vector to represent the current. We usually draw a horizontal line with an arrow on it and label it I to represent the current.

We know that the voltage across the resistor is in phase with the current and therefore we draw a vector E_R to represent the resistor voltage and this vector will fall on top of the current vector as shown in Fig. 21A. We can select any arbitrary length for this vector since we do not know the generator voltage or the current flowing in the circuit.

We know that the voltage across the coil will lead the current by 90°. Therefore, we draw another vector E_L which is rotated 90° counter-clockwise from the current vector as shown in Fig. 21A. Since the value of the resistance of R is equal to the inductive reactance of L, the voltage across the coil will be equal to the voltage across the resistor, therefore, we draw E_L the same length as E_R. The diagram shown in Fig. 21A represents the voltage across the resistor and the voltage across the coil.

To find the generator voltage we complete the vector diagram as shown in Fig. 21B. In this diagram we have drawn a dotted line from the end of the vector E_R parallel to vector E_L. We have drawn another dotted line from the end of vector E_L parallel to vector E_R. The point at which the two vectors intersect gives the value and phase relationship between E_G and I. Since E_L and E_R are equal, the angle between E_G and I will be a 45° angle, and the length of E_G will be 1.4 times the length of either E_L or E_R. This means that the generator voltage will be 1.4 times the voltage across either the coil or the voltage across the resistor.

Perhaps you noticed an apparent contradiction between what we have learned about the voltages in the circuit shown in Fig. 19 and Kirchhoff's Voltage Law. You will remember that Kirchhoff's Voltage Law stated that the sum of the voltage drop in a closed circuit is equal to the source voltage. If this is true for ac circuits then the voltage drop across R plus the voltage drop across L must be equal to the generator voltage. Yet in Fig. 21 we found that the generator voltage was only 1.4 times either E_R or E_L. At first glance you might think it should be twice E_R or E_L. However, remember that E_R and E_L are not in phase. This means that if you add these voltages at any instant their sum will be equal to the generator voltage.

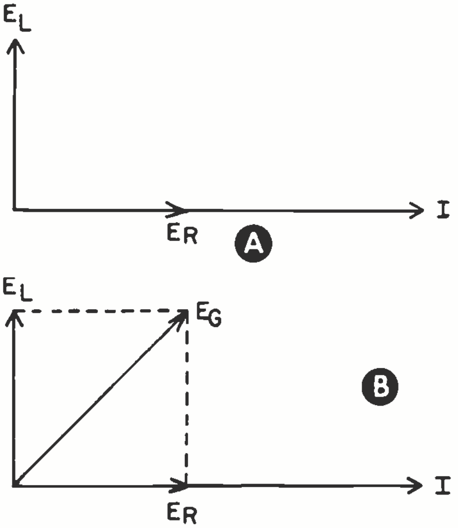

Fig. 21. Vector diagrams showing relationship between current, generator voltage, coil voltage and resistor voltage of the circuit shown in Fig. 19.

IMPEDANCE

In Fig. 19, we considered the coil as a pure inductance. We treated the resistance of the wire used to wind the coil as 0; the only opposition the coil offered was inductive reactance. Of course the wire will have resistance as well as certain other resistive effects to the ac current. The ac resistance of the coil is the sum of the resistance of the wire plus these other losses which increase the resistance. The impedance of the coil is the total opposition to current flow. It is made up of the opposition due to the inductive reactance of the coil and the opposition due to the ac resistance of the coil.

The practical way of studying how a coil behaves in an ac circuit is to consider the coil as being made up of a pure inductance with a resistor in series with it. This is essentially the type of circuit used in Fig. 19. Here you see that in the circuit the current lags behind the generator voltage. Where the resistance was equal to the inductive reactance, the phase difference was 45°. In actual practice, the resistance will usually be much smaller than the inductive reactance so that the phase difference will approach 90°. The higher the ratio of inductive reactance to resistance, the closer the phase difference will approach 90°.

In studying a complete circuit in which there is a coil and a resistance in the circuit, you can simply lump together the resistance of the resistor and the coil resistance and consider this the resistance in the circuit and then treat the inductance of the coil separately. However, if you are interested in finding the voltage across the coil, then you have to keep the resistance of the coil separated and use it with the inductive reactance of the coil since both will have an effect insofar as developing voltage across the coil is concerned.

FINDING THE CURRENT IN AN AC CIRCUIT

If you want to find the current flowing in this type of circuit when an ac voltage is applied, you must find the impedance of the circuit. The impedance is the total opposition to the ac current flow in the circuit.

There are several ways of finding the total flow of ac current in the circuit. We have already briefly started to introduce one in Fig. 21. We will go through this procedure in detail now and then show you another method. You may use whichever way is easier for you.

As an example, let us find the current flowing in the circuit shown in Fig. 22. Here we have a coil with an inductance of 2 henrys. This coil is connected in series with a 1000-ohm resistor. The two are connected across a 60-cycle generator having an output voltage of 500 volts. The resistance of the coil is so small, that compared to the 1000-ohms in the circuit, it is insignificant so we can ignore it. The problem is to find the current that will flow in the circuit.

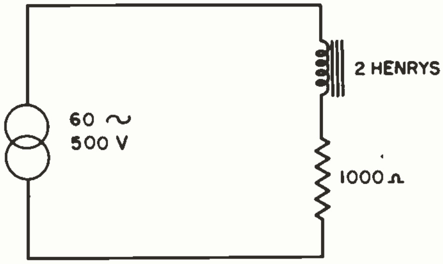

Fig. 22. There are two ways to find the current in the circuit shown above: by using vectors or by using a mathematical solution.

Vector Solution.

First, we must find the inductive reactance of the coil. To do this we use the formula:

$$X_L = 6.28 \times f \times L$$

and substituting 60 for f and 2 for L we get:

$$X_L = 6.28 \times 60 \times 2$$

which equals 753.6 ohms. Since this is a practical problem, we simply call it 750 ohms.

Now we know that the inductive reactance of the coil is 750 ohms and the resistance in the circuit is 1000 ohms. You might at first think that we can obtain the total opposition to the ac current flow simply by adding these two together. However, this is not true--you cannot simply add inductive reactance and resistance. Let us see why. We know that when voltage is applied to an inductance, the current that flows will be out of phase with the applied voltage. When voltage is applied to the resistance, the current that flows will be in phase with the applied voltage. The inductance and the resistance have different effects on current.

Adding the effect of the two together can be done by means of vectors.

You have already seen how vectors

can be used to indicate phase differences in quantities having the same frequency. Now we will see how they can be used to add similar quantities having the same frequency but a difference in phase.

As before, the angle between the vectors represents the phase difference between the quantities. The arrows are all drawn to the same scale, so that the length of the arrows indicates the amplitudes of the quantities to be added.

For example, suppose we wanted to show the relationship between two 60-cycle ac voltages A and B. A is 30 volts, and B is 40 volts, and they are 90° out of phase with each other.

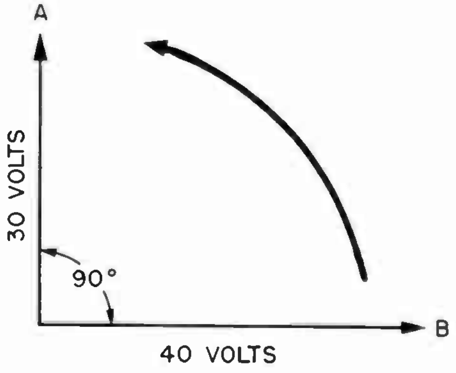

Fig. 23. In this diagram, the lengths of the arrows show the amount of voltage and the angle between them shows their phase relationship. They are considered to rotate counterclockwise.

A is leading B. Fig. 23 shows how we would draw this, using a scale of 1/2-inch equals 10 volts. We draw B 2 inches long, and we draw A, 1-1/2 inches long. Since A is leading B by 90°, we draw it 90° counterclockwise from B.

Now, suppose we wanted to find the sum of these voltages. We could not simply add 30 and 40, because of the difference in phase. This is where the vector diagrams will help us. We can add these two voltages, taking into account the phase difference as shown in Fig. 24. We say we are finding the "vector sum" of the two.

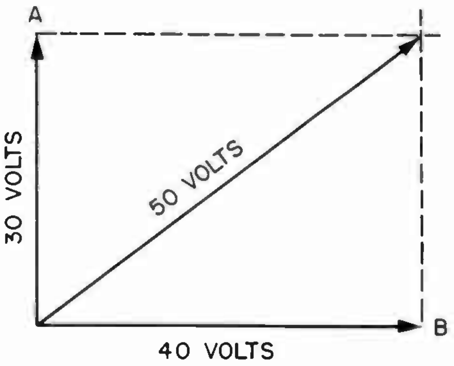

Fig. 24. How to find the vector sum of two ac voltages differing in phase.

To do this, we complete a rectangle by drawing lines parallel with the two vectors. Then we draw in a diagonal to the point where the two lines intersect. This diagonal represents the vector sum of voltages A and B. When we measure it, we see it is 2-1/2 inches long. Since we used the scale of 1/2 inch to 10 volts, we see that the vector sum is 50 volts.

Now let us see how we can apply this principle to find the total opposition or impedance in the circuit we have been studying. As we have already mentioned, when considering phase in a circuit, the phase of the current is always used as a reference. The current vector is drawn horizontally and pointing to the right, and voltage vectors are drawn in the positions corresponding to their phase relationship to the current. So the first thing we do is to draw an arrow to represent the current, as

Fig. 25. The current vector is drawn horizontally and used as a reference point for the other vectors.

shown in Fig. 25. We do not know what the current is, so its length does not matter, but we do know it should be drawn horizontally and pointing to the right. The next step in our procedure depends upon an important fact--that the voltage across the resistor will be in direct proportion to its resistance. We also know that the voltage across the resistor will be in phase with the current, and the voltage across the coil will be 90° ahead of the current. Therefore, we can draw two vectors, one on top of the current vector to represent the voltage across the resistor, and one 90° ahead of (counterclockwise from) the current vector to represent the voltage across the coil. We do not know what these voltages are, but since the voltage is in direct proportion to the resistance and reactance, we can draw the arrows using a scale that is in proportion to the ohmic values of the resistance and reactance and label the vectors R and X_L.

Fig. 26. The voltage across a resistor is in phase with the current, so the vector for the resistor voltage is drawn on top of the current vector.

First we draw a vector to represent the voltage across the resistance. If we use the scale of an inch to 500 ohms, the vector representing the voltage across the resistor will be 2 inches long. Since the current flowing through the resistor will be in phase with the voltage, we draw the resistance voltage vector and mark it R as shown in Fig. 26. Here you should notice that it is drawn right on top of the current vector. The current vector is not drawn to scale, but the resistance voltage vector is drawn 2 inches long.

Next, we draw the vector for the voltage drop across the coil. Since we have a reactance of 750 ohms, this vector should be 1-1/2 inches long. Since the coil voltage is 90 degrees out of phase with the resistor voltage, this vector is drawn as shown in Fig. 27 and labeled X_L. Now we have a vector diagram that represents the voltage across the resistance and the reactance in the circuit shown in Fig. 22. To get the impedance, we draw dotted lines as shown in Fig. 28 to complete the rectangle. The vector representing the voltage across the impedance is drawn in as shown in Fig. 28 to the point where these lines meet, and the impedance is obtained by measuring the length of this vector. On the diagram we have drawn, the impedance voltage vector is 2-1/2 inches long. Since we have used the scale of 500 ohms to the inch, the impedance in the circuit must be 2-1/2 times this value, or 1250 ohms. This is the total impedance or opposition to current flow in the circuit. Now that we have this figure, we can quickly determine the current that will flow.

To find the current we use Ohm's Law for coils. The current is equal to the voltage divided by the impedance. The letter Z is usually used to represent impedance. This can be expressed

$$I = \frac{E}{Z}$$

E=IZ

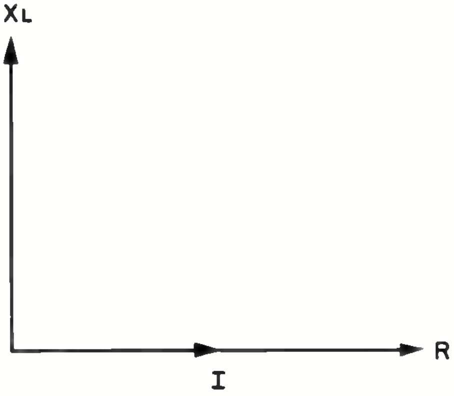

Fig. 27. The vector for the voltage across the inductance is drawn in at right angles to the resistor voltage vector.

Substituting 500 volts for E and 1250 ohms for Z we get:

$$I = \frac{500}{1250} = .4 \text{ amp}$$

Mathematical Solution.

Another method of solving for the impedance in an ac circuit is by means of the formula:

$$Z = \sqrt{R^2 + X_L^2}$$

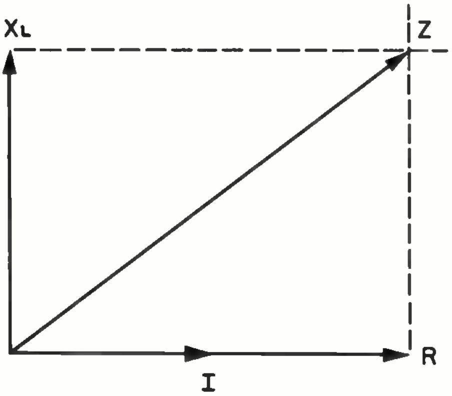

Fig. 28. The vector representing the voltage across the impedance is the vector sum of the other two.

The mathematical sign $\sqrt{}$ means to find the square root. Therefore, you square the resistance and the reactance, add the two together, and then take the square root of the sum. Once you have the impedance, proceed as before to get the current. Again, this is not the type of problem that the technician will have to solve, but it is important to remember the general method of obtaining the impedance in a circuit of this type. If you know how to do square root problems, the mathematical solution is the simpler; if you don't, the graphical solution is the one to use. It is particularly important to realize that you cannot obtain the impedance simply by adding the resistance and the reactance together. The impedance in a circuit will always be somewhat less than the sum of the two because of the difference in phase.

KIRCHHOFF'S VOLTAGE LAW

You will remember that Kirchhoff's voltage law stated that the sum of the voltage drops in a complete circuit is equal to the source voltage. Now let's see how this applies to an ac circuit consisting of inductance and resistance.

Using the same example as before, we have already calculated the reactance of the coil at 750 ohms and we know the resistance of the resistor is 1000 ohms. We can use Ohm's Law in the form:

$$E = I \times R$$

to find the voltage drop across the resistor. In the case of the coil, the voltage drop is:

$$E = I \times X_L$$

To find the voltage drop across the coil, we simply multiply 750 by the current, which we have already determined as .4 amp. 750 × .4 = 300. Therefore the voltage across the coil is 300 volts. The voltage across the resistor is 1000 ×.4 = 400 volts. Now look at Fig. 29 where we have indicated the voltages. We have 300 volts across the coil and 400 volts across the resistor, but our source voltage is only 500 volts. These are the readings we would actually obtain if we had meters connected as shown!

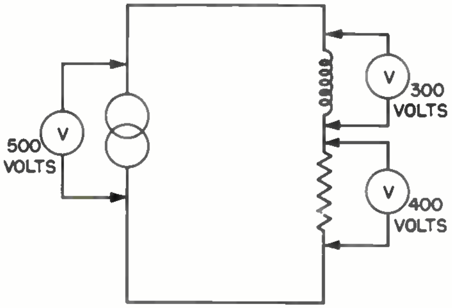

Fig. 29. With a source voltage of 500 volts, we have 300 volts across the coil, and 400 volts across the resistor, but they are not in phase.

This may appear to be a contradiction of Kirchhoff's Voltage Law, but actually it is not. You must remember that the voltage across the resistor will be in phase with the current, but the voltage across the coil will not be in phase with the current flowing through it. The voltages that we have just determined are effective voltages. At any given instant the sum of the voltage across the coil plus the voltage across the resistor will be equal to the voltage across the generator. However, the effective voltage across the coil and the resistor if they are simply added together would give us more than 500 volts.

To add these two voltages we must again resort to vectors. The vector addition of these two voltages using a scale of 200 volts equals 1 inch is shown in Fig. 30. Notice that the vector representing the voltage across the resistor is drawn 2 inches long, and the one representing the voltage across the coil is drawn 1-1/2 inches long. When we complete the vector diagram to find the sum, as before, we obtain a vector which is equal to the generator voltage of 500 volts.

The mathematical solution that we used before can also be used to obtain the source voltage. If we let the symbol E_G equal the source voltage we have:

$$E_G = \sqrt{E_R^2 + E_L^2}$$

If we substitute 400 for E_R, E_R^2 equals 160,000. Similarly E_L squared equals 90,000. Adding the two together we get 250,000; the square root of 250,000 is 500, so as before we find that $E_G = 500$ volts.

Importance of Phase.

A general knowledge of phase and vector diagrams helps you to understand the action of coils and capacitors in ac circuits and will make you a better-than-average technician. You will understand why you do certain things when making adjustments or repairs instead of just blindly following instructions. It is the men who know the "How" and the "Why" who command the highest salaries in the modern world of electronics.

Later in your course, you will learn that the opposition of a coil, which we have called inductive reactance, can be balanced or cancelled by the opposition of a capaci-

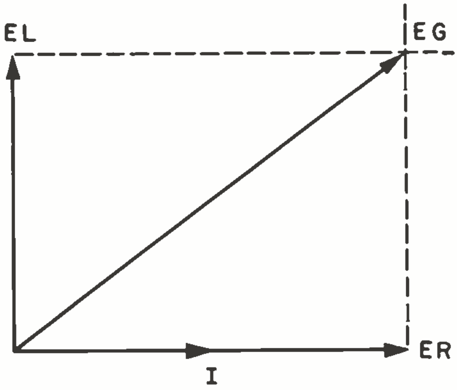

Fig. 30. Finding the vector sum of ER and EL.

tor, which is called capacitive reactance, because the two are of opposite phase. You will see the importance of phase in many other practical examples. Phase, however, is not a subject you can grasp in one lesson; you will understand it better and better with each succeeding lesson.

Q OF A COIL

We mentioned that since a coil is wound of wire and wire has resistance, there is no such thing as a perfect inductance. All coils have both inductance and resistance.

As you might expect, when manufacturers make a coil, they usually try to keep the resistance as low as possible. Generally, the lower the resistance is in proportion to the inductive reactance of a coil, the better the coil. The relationship between inductive reactance and resistance is called the Q of the coil. This is represented by the formula:

$$Q = \frac{X_L}{R}$$

A high-Q coil is a coil in which the value of the inductive reactance is much higher than that of the resistance. Coils with a Q of 100 or more are quite common.

Since the reactance of a coil increases with frequency, you might expect the Q to increase with frequency. This is true up to a certain point, but R is the ac resistance of a coil and it increases with frequency also. As long as X_L increases with frequency faster than R, the Q of the coil will increase, but if R increases faster than X_L, the Q of the coil will decrease as the frequency increases so the coil cannot be used at high frequencies.

Q is particularly important in tuned circuits when coils are used with capacitors. You will see why this is so later when you study these circuits.

SUMMARY

This section of your lesson is almost too important to try to summarize. However, to help you to review, here are the important things you should understand.

You should have a general understanding of what we mean by phase. When the current in an ac circuit is increasing exactly in step with the voltage, and reaches the maximum value at the same time as the voltage reaches the maximum value and reaches its minimum value at the same time as the voltage reaches its minimum value, we say that the current and voltage are in phase. In a circuit consisting of a pure inductance the current will lag the voltage by 90 degrees. This means that it is one-quarter of a cycle behind the voltage.

Impedance is the vector sum of resistance and reactance. The impedance in a circuit will be greater than the resistance or the reactance alone. Impedance cannot be determined simply by adding the resistance and the reactance.

The voltage across a component in an ac circuit can be found by Ohm's Law. The sum of the individual voltage drops in an ac circuit is equal to the source voltage, providing we add these voltages vectorially. We cannot add them by means of simple arithmetic and expect their sum to be equal to the source voltage. If we could measure the source voltage and the voltage across each of the parts in the circuit at any instant, we would find that the sum of the voltage drops at that instant would be equal to the source voltage.

SELF-TEST QUESTIONS

(ak) What do we mean when we say that the voltage and current in a circuit are in phase?

(al) What is the phase relationship between the voltage and current across a resistor?

(am) What is the phase relationship between the voltage and current across a coil?

(an) At what point in an ac cycle is the current changing at its maximum rate?

(ao) What is meant by impedance?

(ap) An ac generator with an output voltage of 250 volts is connected across a 1.5-henry coil and a 900-ohm resistor in series. The frequency of the generator is 100 cycles. Find the current flowing in the circuit.

(aq) In the preceding problem, find the voltage across the coil and the voltage across the resistor.

LOOKING AHEAD

You have now finished the study of the basic facts of resistors and coils. When you complete a similar study of capacitors in the next lesson, you will have a basic knowledge of these three important parts. In a later lesson you will learn more about how these three parts work together and what effect they have on ac signals. Remember that the ac supplied by the power company, audio signals, and radio frequency signals are all ac signals differing only in frequency and in some cases in wave shape. The important facts you learned about ac and coils in this lesson apply to all ac signals regardless of their frequency.

Most students are anxious to go ahead as quickly as possible with their course, particularly in the early lessons. However, do not be so anxious to go ahead with later lessons that you leave the earlier lessons without completely understanding them. The information given in these early lessons is basic and is information that you will use over and over again in more advanced lessons. If you do not understand how basic parts such as resistors, coils, and capacitors affect circuit performance, you will not be able to understand some of the later lessons.

ANSWERS TO SELF-TEST QUESTIONS

(a) Magnetic lines of force form complete loops.

(b) Near the coil.

(c) An air-core coil. The cardboard form merely supports the turns of the coil; it has no appreciable effect on the operation of the coil.

(d) Laminations are thin strips of iron or steel used to produce an iron core for a choke or transformer.

(e) An iron core provides a better path for the magnetic lines of force. We say it has a lower reluctance.

(f) Magnetomotive force is the force that sends magnetic flux around a magnetic circuit.

(g) The ampere-turn.

(h) 50 ampere - turns.

(i) Reluctance is the opposition to flux in a magnetic circuit. It is the equivalent of resistance in an electrical circuit.

(j) Yes. The reluctance in the magnetic circuit of an iron-core coil is much lower than the reluctance of the magnetic circuit in an air-core coil.

(k) They all have the same reluctance. Non-magnetic materials have the same reluctance as air.

(l) The permeability of a material indicates the ability of the material to pass the magnetic lines of force. The higher the permeability of the material, the less reluctance it will offer to magnetic lines of force.

(m) In a magnetic circuit the flux is equal to the magnetomotive force divided by the reluctance.

(n) A flux linkage is a magnetic line of flux cutting through a single turn of a coil. If the magnetic line of flux cuts through two turns then we have two flux linkages, and if it cuts through five turns then we have five flux linkages.

(o) Twelve. A magnetic line of flux cutting through a single coil produces one flux linkage. Therefore three lines cutting through four turns produces 3 × 4 = 12 flux linkages.

(p) Zero. If the number of flux linkages cutting a coil does not change, there will be no voltage induced in the coil.

(q) The induced voltage will produce a current which will in itself produce a magnetic field which will oppose any change in flux linkages.

(r) It will aid the original lines of force. If the field is reduced, the induced voltage produced in the coil will cause a current to flow in such a direction that the magnetic field produced will tend to prevent the number of flux linkages from decreasing. In order to do this it must aid the original field.

(s) (1) cutting lines of force, (2) changing the reluctance (3) changing the coil current.

(t) The variable reluctance phono pickup. In this type of pickup the needle moves between two coils. As the needle follows the record groove it moves from side to side decreasing the air gap on one side so that the reluctance on that side decreases and the flux increases.

(u) The transformer. Varying ac applied to the primary of the transformer causes a varying current to flow. This current in turn causes a varying flux; the varying flux cutting the secondary induces a voltage in the secondary of the transformer.

(v) Inductance.

(w) A self-induced voltage is a voltage induced in a coil that is caused by a change in the current flowing through the coil. The changing current causes a change in magnetic flux. The change in magnetic flux produces a self-induced voltage which tends to produce a current which in turn will produce a magnetic field opposing the original change.

(x) It will oppose the applied voltage. The self-induced voltage will try to keep the current constant so that the flux will remain constant. To do this it must oppose the applied voltage.

(y) The henry is the unit of inductance.

(z) If the voltage induced in a coil is 1 volt when the strength of the current flowing through the coil changes at a rate of 1 ampere per second, the coil has an inductance of 1 henry.

(aa) (1) the number of turns on the coil, (2) the diameter of the coil, (3) the permeability of the core material.

(ab) The inductive reactance of a coil is the opposition the coil offers to the flow of ac through it due to the inductances of the coil.

(ac) The inductive reactance of a coil is measured in ohms.

(ad) 3768 ohms. To find the inductive reactance of a coil you use the formula:

$$X_L = 6.28 \times f \times L$$

and substituting 60 for f and 10 for L we have:

$$X_L = 6.28 \times 60 \times 10$$
$$X_L = 3768 \text{ ohms.}$$

(ae) When two coils are placed near each other so that the flux from one coil cuts through turns of the other coil, any change in the flux from one coil will induce a voltage in the other coil. We call this coupling between the two coils mutual inductance.

(af) 14 henrys. When two coils that

are not mutually coupled together are connected in series, the total inductance is simply the sum of the two inductances.

(ag) 11 henrys. To find the total inductance of the two coils we use the formula:

$$L_T = L1 + L2 + 2M$$

and substituting 4 henrys for L1 and 3 henrys for L2 and 2 henrys for M we get:

$$L_T = 4 + 3 + (2 \times 2)$$
$$L_T = 11 \text{ henrys.}$$

(ah) 9 henrys. To find the inductance of the two coils we use the formula:

$$L_T = L1 + L2 - 2M$$

and substituting 8 henrys for L1, 7 henrys for L2 and 3 henrys for M we get:

$$L_T = 8 + 7 - (2 \times 3)$$
$$L_T = 9 \text{ henrys.}$$

(ai) 2200 millihenrys. To convert henrys to millihenrys you just multiply by 1000 which is the same as moving the decimal point three places to the right. 2.2 × 1000 = 2200.

(aj) .0001 henry. To convert microhenrys to henrys you divide by 1,000,000 or move the decimal point six places to the left. Moving the decimal point six places to the left requires that we add three zeros to the left of 1 and then simply move the decimal point.

(ak) When we say that the voltage and current are in phase we mean that any change in voltage produces a corresponding change in current. In other words, an increase in voltage causes an instant increase in current or a decrease in voltage causes an instant decrease in current.

(al) The voltage and current across a resistor are in phase.

(am) The voltage across a coil will lead the current by 90°. Another way of expressing the same thing is to say that the current lags the voltage by 90°.

(an) The current is changing at its maximum rate when the current wave is going through 0.

(ao) Impedance is the total opposition to current flow. It is made up of the reactive opposition and the resistive opposition to current flow.

(ap) $X_L = 6.28 \times 100 \times 1.5$
$= 942.0$ ohms

$$Z = \sqrt{R^2 + X_L^2}$$
$$= \sqrt{900^2 + 942^2}$$
$$= \sqrt{810,000 + 887,364}$$
$$= \sqrt{1,697,364}$$

$= 1303 \text{ ohms}$

$$I = \frac{E}{Z} = \frac{250}{1303} = .19 \text{ amps}$$

(aq) $E_R = IR$

$= .19 \times 900 = 171 \text{ volts}$

$E_L = IX_L$

$= .19 \times 942 = 179 \text{ volts}$

Lesson Questions

Be sure to number your Answer Sheet B106.

Place your Student Number on every Answer Sheet.

1. If the reluctance of a magnetic circuit is increased, what will happen to the flux?

2. If the number of flux linkages cutting a coil decreases, a voltage will be induced in the coil that will cause a current to flow, which will produce magnetic flux that will tend to prevent the original flux from decreasing. Is this statement true or false?

3. Explain what inductive reactance is.

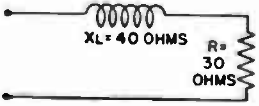
4. What is the inductive reactance of a 1-henry coil at a frequency of 100 cycles?

5. If two 15-henry coils have a mutual inductance of 5 henrys, what is the total inductance when they are connected in series if the flux of one coil aids the flux of the other?

6. Explain what is meant when we say "the voltage and current are out of phase."

7. What do we mean by the impedance of a circuit?

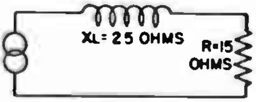
8. What is the impedance of the circuit shown?



9. If the frequency of a voltage source connected to a circuit consisting of a coil and resistor in series is increased, will the current flowing in the circuit increase, decrease, or remain the same?

10. If the current flowing in the circuit shown is 1 amp, find:

    (1) the voltage across the coil
    (2) the voltage across the resistor.



SINCERE APPRECIATION PAYS

Have you ever watched a dog respond to a friendly pat as a reward for obedience? Have you noticed how a child glows with joy when praised for good behavior? Have you ever felt your own brain cells respond with increased effort when you praise them by saying, "That's a fine piece of work, even if I did do it myself!"

Yes, everyone responds to sincere and merited praise. It is a tonic to both giver and receiver. It brings greater praise and appreciation back to you. It costs nothing more than a smile and a few sincere words, but it can truly achieve miracles in happiness and success, and put real money in your pocket.

Time spent in figuring how to give sincere and deserved praise is well worth while. Let people know that you appreciate their fine work, and watch the breaks come your way.

HOW CAPACITORS ARE USED

B107

STUDY SCHEDULE

By dividing your study into the steps given below, you can get the most out of this part of your NRI Course in the shortest possible time. Check off each step when you finish it.

☐ 1. **Introduction** .... **Pages 1 - 3**
This section gives a brief picture of what a capacitor is and the different types in use.

☐ 2. **How Capacitors Store Electricity** .... **Pages 4 - 12**
You learn about charging a capacitor, the factors affecting capacity, and the voltage rating of capacitors.

☐ 3. **Typical Capacitors** .... **Pages 13 - 23**
You study variable capacitors and paper, mica, ceramic, and electrolytic fixed capacitors.

☐ 4. **Capacitors in AC Circuits** .... **Pages 24 - 28**
You learn how ac flows in capacitive circuits, and you study the effect of connecting capacitors in series and in parallel.

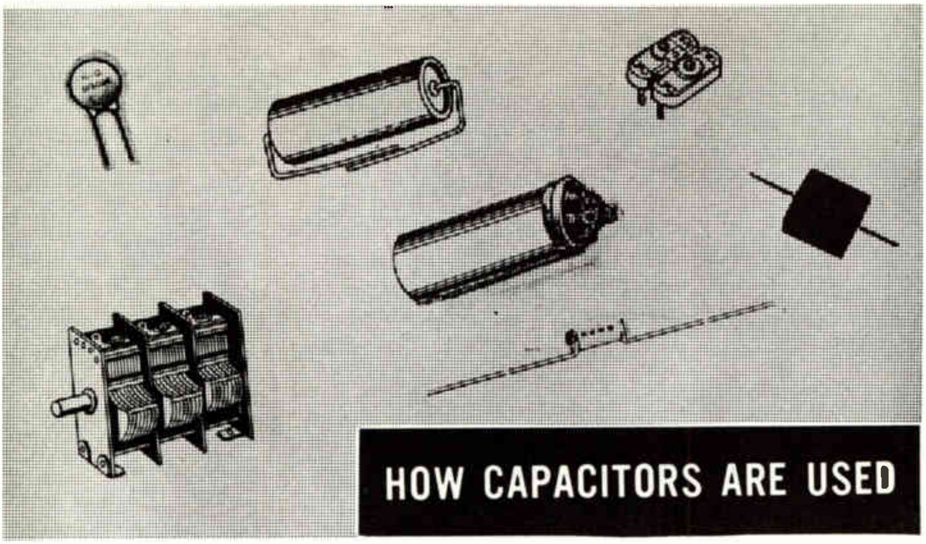
☐ 5. **Simple R-C Circuits** .... **Pages 29 - 36**
Here we take up time-constants, phase, voltage distribution, and impedance in resistor-capacitor circuits.

☐ 6. **Answers to Self-Test Questions** .... **Pages 36 - 40**

☐ 7. **Answer the Lesson Questions.**

☐ 8. **Start Studying the Next Lesson.**

PII2M375 1975 EDITION Litho in U.S.A.



HOW CAPACITORS ARE USED

Of the three major electronic circuit parts, resistors, coils and capacitors, it would be impossible to pick the one that is the most essential. All three parts are extremely important. In many circuits all three are used together; in some circuits two of the three are used together. When used in combination, these parts are able to perform jobs that one cannot do alone.

In the preceding two lessons, you studied resistors and coils. In this lesson you will study capacitors in detail. After you have completed this lesson, you should have a good understanding of how these three basic parts work. Later, you will see how they are used together.

In many respects a capacitor is the opposite of a coil. You will remember that in an ac circuit with a coil in it, the current flowing in the circuit will lag or follow the applied voltage by 90 degrees. If instead of a coil we put a capacitor in the circuit, the current would lead the voltage by 90 degrees; in other words we would have just exactly the opposite effect. You will see more of this later in this lesson and also find out exactly why it is that in a capacitive circuit the current leads the voltage. For the present, let's start this lesson by learning a little about what a capacitor is and some of the fundamentals of how it works.

WHAT IS A CAPACITOR?

In its simplest form, a capacitor, or condenser, as many old-timers call it, consists of nothing more than two pieces of metal separated either by air or by some other nonconducting material placed between them. The material between the two plates, whether it is air, a liquid, or a solid, is called the dielectric. If there is nothing between the plates but air, we say the capacitor has an air dielectric.

The electrical size of a capacitor is called its capacity. A large ca-

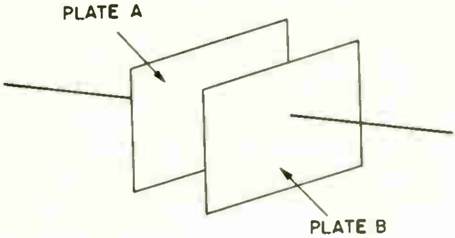


Fig. 1. A simple capacitor is nothing but two pieces of metal separated from each other.

pacitor has a large capacity. There are a number of things that affect the capacity of a capacitor, which you will study in a little while.

HOW A CAPACITOR WORKS

A simple capacitor made of two metal plates with an air dielectric between them is shown in Fig. 1. To see how a capacitor works, let's see what will happen when we connect this capacitor to a battery as shown in Fig. 2.

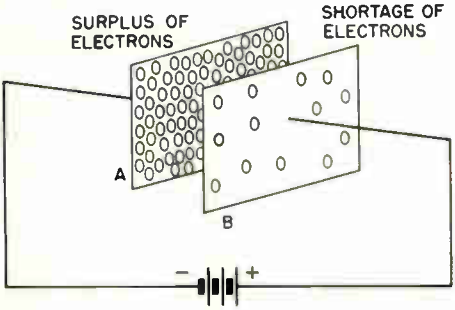

Fig. 2. When a capacitor is connected to a battery, a surplus of electrons is accumulated on one plate. This forces electrons off the other plate, leaving it with a positive charge.

When the plates of the capacitor are connected to the battery, electrons flow from the negative terminal of the battery into the plate of the capacitor connected to the negative terminal. There will be a surplus of electrons built up on this plate of the capacitor.

You know that one of the characteristics of an electron is that it repels other electrons. Remember the rule of charges, like charges repel. Therefore, the surplus electrons on the one plate of the capacitor will repel electrons from the other plate back to the positive terminal of the battery. At the same time, the positive terminal of the battery attracts electrons and pulls them from the plate connected to it, leaving a shortage of electrons on this plate, giving it a positive charge. This positive charge will attract electrons from the negative terminal of the battery to the plate connected to it. Thus, there will be a surplus of electrons on one plate and a shortage of electrons on the other. The electron flow will continue until plate A is just as negative as the negative battery terminal, and plate B is just as positive as the positive battery terminal. When this condition exists we say the capacitor is charged.

If we suddenly disconnect the capacitor from the battery, the condition of unbalance that has been set up on the capacitor plates will remain. We will have a surplus of electrons on one plate and a shortage of electrons on the other. Thus, we have electricity stored in the capacitor.

You will remember that one of the characteristics of a charged object is that it tries to give up its charge in order to become neutral as quickly as possible. Therefore, if we connect a wire from one plate of a capacitor to the other, the electrons will flow from the side having a surplus of electrons over to the side having a shortage of electrons until the number of electrons on the two plates is balanced, and there is no longer a charge on them.

This is a very brief explanation of how a capacitor works, how it is charged, and how it can store electricity. We will look into this more thoroughly in the next section of this lesson, but this is enough to give you a general idea of how a capacitor works. Keep in mind that a capacitor can store electricity. Before touching the leads of a large capacitor you should short the leads together with a screwdriver or similar object to be sure the capacitor is discharged, otherwise you may discharge the capacitor and receive an unpleasant and possibly dangerous shock!

TYPES OF CAPACITORS

Capacitors can be divided into two types, according to what type of material (called the dielectric) separates the plates. One type has an air dielectric, and the other has a solid or liquid dielectric. When we say a capacitor has an air dielectric, we simply mean that there is nothing but air between the plates of the capacitor. When we say a capacitor has a solid or liquid dielectric we mean that some insulating material other than air has been inserted between the plates.

You will see typical examples of all these types of capacitors later; you will learn more about them, what they look like, and where they are used in electronic circuits; but first let us learn more about how they work.

How Capacitors Store Electricity

In considering a capacitor, you may at first wonder how a capacitor can be used in an electronic circuit because there is no complete circuit through the capacitor. In the sketch of the simple capacitor shown in Fig. 1 you can see that the two plates of the capacitor do not touch each other. There is a space between the two plates so that the electrons on one plate cannot normally flow from one plate to the other.

When we connected a battery to a capacitor we saw that the plates of the capacitor became charged, one plate picking up a surplus of electrons and the other losing electrons so that it had a shortage.

The usefulness of a capacitor depends upon its ability to store electricity or to hold a charge. Let's learn a little more about how a capacitor is charged, so we can better understand some of its more important uses.

CHARGING A CAPACITOR

A capacitor cannot be charged instantly. It takes time for the charge to build up after the electrons start to flow from the negative terminal of the battery into one plate of the capacitor and from the other plate to the positive terminal of the battery. The length of time that it takes depends upon two things, the size of the capacitor and the amount of resistance in the circuit.

You might think that there was no resistance in the circuit we have shown in Fig. 2. However, this is not the case. There is resistance in the leads used to connect the capacitor to the battery, and in addition there is the internal resistance of the battery itself. These two resistances will limit the rate at which the capacitor can charge.

Because it does take some time to charge a capacitor, there will be a current flowing in the circuit shown in Fig. 2 when the capacitor is first connected to the battery. This current will flow as long as the battery is charging the capacitor. The longer it takes the battery to charge the capacitor the longer there will be a current flowing in the circuit. Therefore, you can see that even though the electrons cannot cross from one plate of the capacitor to the other plate there is a current flow in the circuit, at least for the short time it takes to charge the capacitor.

A question that sometimes comes up when considering a charged capacitor is whether or not the capacitor has any more electrons than it has in the discharged state. The answer to this question is no--the capacitor will have the same number of electrons whether it is charged or discharged. The only difference is that when a capacitor is discharged there is no charge on any of the atoms making up the metal on either plate. In other words, each atom has enough electrons to exactly neutralize the charge in its nucleus. However, when the capacitor is charged, some of the electrons are moved off one plate so there is a shortage of electrons on that plate, and the same number of extra electrons are forced onto the other plate, so there is a surplus of electrons on it. Thus the total number of electrons in the material making up the capacitor does not change.

The Amount of Charge.

The charge on a capacitor depends upon the battery voltage used to move electrons onto one plate and away from the other. A battery with a higher voltage can exert more force on the atoms making up the capacitor plates and thus move more electrons than a battery with a lower voltage could. However, there are other things that affect the charge we can store in a capacitor. The electrical size of the capacitor is just as important as the charging voltage. The electrical size of the capacitor is called the capacity of the capacitor. Now let's see what we mean by capacity.

CAPACITY

The term capacity is used to describe the electrical size of a capacitor. It is used in the same way as inductance is used to describe the electrical size of a coil, and resistance is used to indicate the electrical size of a resistor.

Just as the henry is the unit of inductance and the ohm is the unit of resistance, the "farad" (pronounced FAIR-ad) is the unit of capacity. It was named after the scientist Michael Faraday, who did a great deal of the early work with capacitors. The capacity of a capacitor is a measure of its ability to store electricity. A capacitor with a high capacity can store more electrons than a capacitor with a lower capacity. Thus the capacity of a capacitor indicates its electrical size to the technician just as the resistance of a resistor indicates the electrical size of the resistor.

We can express the capacity of a capacitor in terms of charge and voltage. The capacity of a capacitor is equal to the charge it will take divided by the voltage used to put that charge on the capacitor. The amount of charge is expressed in units called "coulombs." A coulomb represents a certain quantity of electrons. If a current of 1 ampere flows in a circuit for one second, the number of electrons moving past a given point in the circuit represents one coulomb of electricity. If when we connect a one-volt battery across a capacitor we can store a charge of 1 coulomb in the capacitor, its capacity is 1 farad. If the capacitor would take a charge of 2 coulombs with an applied voltage of 1 volt, the capacity would be two farads. The farad actually represents an extremely large capacity. It is so large in fact that it is never used in electronics. Let us look at the smaller units of capacity that are used.

Units of Capacity.

Since the farad is so large a unit, capacity in electronic circuits is usually expressed in smaller units, which are fractions of a farad. They are:

1. The microfarad, which is equal to one-millionth of a farad. Microfarads are abbreviated in several ways; the most common abbreviations are μf, mf, and mfd.

2. The picofarad, which is equal to 1-millionth of a microfarad. It

is abbreviated pf. In addition to the picofarad you will also run into the micro-microfarad, which is also equal to 1-millionth of a microfarad. The micro-microfarad was used for many years to designate a millionth of a microfarad, but in recent years the picofarad has replaced it. If you should be looking at a diagram of a modern radio or TV receiver the chances are you'll find that the abbreviation pf has been used to indicate picofarads but if you are working on an older set then you will find micro-microfarad used. The abbreviations used for micro-microfarad are µµf, mmf, and mmfd.

Because all seven abbreviations are frequently found in electronics, you should learn them all. The Greek letter µ is the Greek letter "mu" which is pronounced MEW.

You should have no difficulty in remembering that the prefix micro means one millionth, because you have run into this several times previously. The microfarad is simply one millionth of a farad. Actually, you will not be dealing with farads at all because this is such a large unit and for practical purposes you can consider that the unit of capacity in electronics is the microfarad. The smaller unit, which you will have to deal with, is the picofarad, which is a millionth of a microfarad.

Sometimes it is necessary to change from microfarads to picofarads and vice-versa. To change from microfarads to picofarads, you simply multiply by one million or move the decimal point six places to the right. In other words, a capacitor that has a capacity of 5 microfarads has a capacity of 5,000,000 picofarads. You simply add six zeros. A capacitor that has a capacity of .0005 microfarads has a capacity of 500 picofarads. You simply move the decimal point six places to the right.

To convert from picofarads to microfarads you divide by one million, and this can be done by moving the decimal point six places to the left. To do this, you can add zeros to the left. Thus 100 picofarads can be written 000,000,100 picofarads. All the zeros to the left of the 1 have no meaning. To convert this value to microfarads, move the decimal point six places to the left and you get 000.0001 microfarad. The zeros preceding the decimal point have no meaning, so they can be dropped, and you have .0001 microfarad or .0001 mfd.

Since the micro-microfarad is also equal to one millionth of a microfarad - in other words it is equal to a picofarad - if you should run into an older receiver where the values are given in micro-microfarads and you want to convert the value to microfarads you use exactly the same procedure as used in converting picofarads to microfarads.

No doubt as you are reading the preceding section you noticed how long the words microfarad and picofarad are. Technicians have shortened these words. The word microfarad is frequently abbreviated to "mike". Thus if you went to a wholesaler to buy a 2-microfarad capacitor you would probably simply say, "I want a 2-mike capacitor". Technicians have shortened picofarad to simply the abbreviation pf. Thus if you were ordering a 100 picofarad capacitor you would probably order it as a 100-pf capacitor rather than pronouncing the entire word.

Another abbreviation is as follows: instead of saying decimal point, 0, 0, 1 microfarad to identify a .001 mfd capacitor technicians usually say "point double oh one mike". Similarly for .00025 mfd they would say "point triple oh two five mike".

FACTORS AFFECTING CAPACITY

If you have ever looked into tne back of a radio receiver you have probably noticed what we call a variable capacitor. A variable capacitor consists of a set of fixed plates and a set of plates that can be rotated. As the receiver is tuned across the broadcast band the rotating plates will move into position and mesh between the fixed plates. The actual capacitor in the receiver might have been made of two or three separate capacitors all connected together so that the rotating plates all rotate at the same time. A capacitor with two sections is called a 2-gang capacitor and one with three sections is called a 3-gang capacitor. This type of capacitor is called a variable capacitor because its capacity is varied as you rotate the movable plates and mesh them between the stationary plates. When the plates are completely meshed the capacitor has its maximum capacity and when they are rotated so that they are separated as far as possible the capacitor has its minimum capacity.

There are a number of factors that affect the capacity of a capacitor. So you will understand how the capacity of a variable capacitor is changed and also help you to understand the other capacitors you will encounter in electronics work, we will now discuss some of the factors affecting capacity.

1. Area of Plates.

The capacity of a capacitor depends upon the area of the plates. Thus, if the area of each plate of a simple capacitor such as the one shown in Fig. 1 is doubled, the capacity would be doubled.

There are other ways in which the area can be increased in order to increase the capacity. For example, look at the capacitor shown in Fig. 3A. Notice that instead of a simple capacitor made up of two plates as we had in Fig. 1, here we have three plates. Two of the plates, marked A1 and A2, are connected together. If we start off with a capacitor having the two plates A1 and B, and then add the plate A2 to the capacitor, we would double the capacity. You can see why this is so when you consider what happens to the area of the plates when we add plate A2. Let's assume that each plate has an area of one square inch. Thus the area of plate

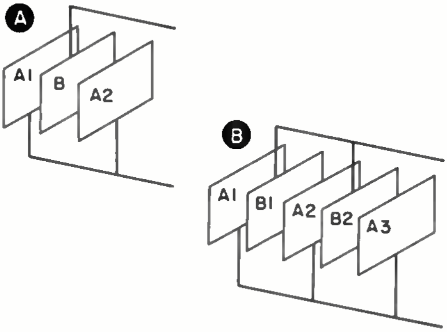

Fig. 3. Adding plates to a capacitor increases the capacity.

A1 opposite plate B is one square inch. When we add plate A2, we will have the areas of A1 and A2 exposed to both sides of B. Thus the effective area of the plates is doubled and therefore the capacity is doubled.

Additional plates can be added as shown in Fig. 3B. Adding additional plates to a capacitor actually increases the area of the plates, which in turn increases the capacity.

In considering the area of the plates, we must consider only the overlapping area. For example, if we have a capacitor made up of two plates each having an area of 1 square inch, and positioned as shown in Fig. 4A, we will have a certain capacity. However, if without changing the size of the plates we move them as shown in Fig. 4B, the capacity will be reduced, because the overlapping area of the plates is reduced. The part of plate A that is not directly opposite part of plate B will have little or no effect on the capacity. Similarly, the part of plate B that is not opposite part of plate A will have little or no effect.

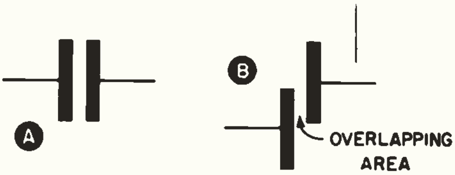

Fig. 4. Only the overlapping areas of the plates affect the capacity of a capacitor.

This is the principle that is used in variable capacitors. Here a number of plates are arranged so that one section of plates is movable and can be made to overlap more or less of the other section, thus exposing larger or smaller areas of the two sections to each other.

2. Spacing.

The distance between the plates of a capacitor will also affect the capacity. Capacity is inversely proportional to the spacing between plates. For example, if the spacing is reduced to one half, there will be twice the capacity. If it is reduced to one quarter, there will then be four times as much capacity. Also, if you double the space between the plates you will have one half of the capacity; if you triple the space you will have one third of the capacity. This is due to the fact that when the repelling effect of the electrons on one plate and the attracting force of the shortage of electrons on the other plate must act over a greater distance, they are not able to drive as many electrons out of the one plate of the capacitor and pull as many onto the other plate. As a result, the capacitor is not able to store as great a charge. You already know that the capacity of a capacitor is equal to the charge in coulombs divided by the voltage required to give that charge. Thus, if the charge a capacitor can hold is reduced, the capacity will go down. Moving the plates farther apart will reduce the charge that you can get on a capacitor for a given applied voltage. Conversely, bringing the plates closer together will increase the charge you can get on a capacitor for a given applied voltage.

3. Dielectric.

We have already mentioned that the type of dielectric used between the plates of the capacitor has an effect on the capacity. If instead of air between the plates we place a piece of mica, paper, or ceramic material, the capacity will be increased. As a matter of fact, if we slide a piece of mica between the plates of a capacitor so that the mica exactly fills up the space we will find that the capacity will increase somewhere between 6 and 8 times.

DIELECTRIC CONSTANT

In the preceding section we mentioned that inserting a piece of mica between the plates of a capacitor would increase the capacity somewhere between 6 and 8 times. The amount that a certain material will increase the capacity when used as a dielectric, compared to the capacity when air is used, is called the "dielectric constant" of the material. In other words, the dielectric constant tells us the number of times that the capacity will be increased by inserting a certain material between the plates of a capacitor. Actually, the dielectric constant is based on the number of times the capacity would be increased over the capacity we would have if the dielectric were a perfect vacuum. However, air between the plates affects the capacity very little. The capacity is practically the same with an air dielectric as it would be with a perfect vacuum between the plates so we say that the dielectric constant of air is 1; in other words it is the same as a vacuum between the two plates.

Different materials have different dielectric constants. Paper has a dielectric constant of somewhere between 1.5 and 3, depending upon the grade of paper. Mica has a dielectric constant between 6 and 8. Different types of oil have dielectric constants from about 2 up to about 10. The ceramic materials used in ceramic capacitors have a wide range of dielectric constants going up to as high as about 1500. You can see from this why it is possible to make ceramic capacitors with large capacities in small physical sizes.

We already mentioned that the effect of a dielectric is to increase the capacity of the capacitor. If there were a perfect vacuum between the plates of a capacitor, electrons flowing into one plate of the capacitor would place a negative charge on this plate and electrons flowing from the other plate would place a positive charge on it.

However when we place any dielectric material, which of course includes air, between the plates of the capacitor, the electrons on the negative plate of the capacitor distort the atoms of the material between the plates. Before the plates of the capacitor are charged, the atoms in the dielectric will be in their normal state with the electrons revolving around the nucleus as shown in Fig. 5A. However, when the electrons flow onto the negative plate of the capacitor, they will tend to repel the electrons in the dielectric. Since the dielectric is an insulator, the electrons are not free, but are bound to the atoms; however the repelling effect of the electrons on the negative plate will shift the path of the electrons in the dielectric so that the path around the nucleus will be like that shown in Fig. 5B. Notice that the electrons are pushed away from the negative plate and towards the positive plate. As these electrons move closer to the positive plate, they tend to repel the electrons

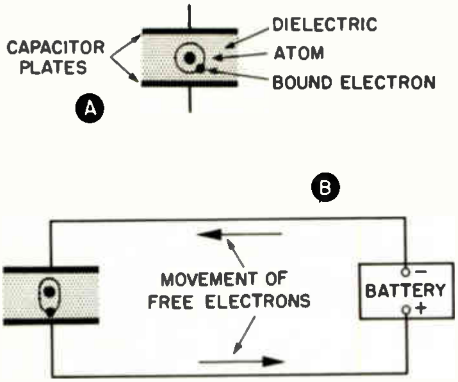

Fig. 5. Electrons in the dielectric are bound to their atoms, but their paths are shifted when a battery is connected across the capacitor, so that they come closer to the positive plate, thus transferring the effect of the extra electrons on the negative plate.

on the positive plate. Because the electrons from the atoms in the dielectric move over towards this plate of the capacitor, the dielectric has the effect of reducing the space between the plates. This places the negative charge very close to the positive plate and drives many more electrons off the positive plate of the capacitor than could be removed if the two plates were in a vacuum.

As we mentioned, air acts almost like a perfect vacuum. There is very little of this effect occurring when the dielectric is air. However, with materials of a higher dielectric constant this effect is more pronounced. This is particularly true in the case of ceramic materials where there is considerable distortion of the atoms in the dielectric so that the net effect is to get the same result as you would get by having the plates of the capacitor practically touching. Of course, in a practical case you can't have the plates practically touching, because they would probably short together and then the capacitor would be of no value. However, by using the right dielectric we get just as much capacity as we would with the plates practically touching and at the same time the dielectric between the plates holds the plates rigid and reduces the possibility of the plates accidentally shorting together.

VOLTAGE RATINGS

We mentioned previously that the charge that can be placed on a capacitor depends upon the electrical size or the capacity of the capacitor and also on the voltage used to place the charge on the capacitor. You might think from this that you could put more and more charge on a capacitor simply by increasing the voltage higher and higher. However, this is not the case because there is a limit to how much voltage can be applied to a capacitor.

Manufacturers design capacitors with a certain spacing between plates. If the plates are put very close together, you cannot put a very high voltage on the capacitor, because the electrons forced onto the one plate of the capacitor would jump right across the space between the plates to reach the other plate of the capacitor which has a shortage of electrons. Once this happens current will flow across the point where the capacitor breaks down, at least until you eliminate the short by shutting off the power. Sometimes when the electrons jump across the capacitor in this way the capacitor is permanently damaged.

Working Voltage.

When a manufacturer designs a capacitor he designs it for use in a circuit with a certain maximum operating voltage. The voltage is marked on the capacitor and is usually called the working voltage. The capacitors you will find in small pieces of electronic equipment such as radio and TV receivers will usually have a working voltage somewhere between 200 and 600 volts. Some of the capacitors in a TV receiver may have a working voltage as low as 200 volts. These capacitors are used in circuits where the operating voltage does not exceed 200 volts. Others used in higher voltage circuits may have a working voltage of 400 volts and still others used in circuits with an even higher voltage may have a working voltage of 600 volts or more.

One point to keep in mind when servicing electronic equipment is that the manufacturer of the equipment usually uses as low a working voltage as possible in order to keep the cost of the equipment low. However, there is no reason why a capacitor with a higher working voltage cannot be used providing there is room to do so.

Peak Voltage.

Sometimes you will find a capacitor with two voltage markings on it. It may be marked "working voltage 450 volts, peak voltage 525 volts". This type of marking is usually found on an electrolytic capacitor designed for use as a filter capacitor in a power supply. Here you know that the output of the rectifier in the power supply is pulsating dc. Thus the actual voltage at the output of the rectifier is not constant. If the dc output voltage from the power supply is 450 volts, during part of the time when the pulses from the rectifier tube reach their peak, the voltage will exceed this value. As long as this voltage peak does not exceed 525 volts, a capacitor marked with a 450-volt working voltage and a 525-volt peak voltage will work satisfactorily.

Some manufacturers do not mark electrolytic capacitors in this way. They simply mark them with the working voltage with the assumption that the peak voltage will not exceed a safe value.

SUMMARY

There are a number of important points that you should remember from this section of the lesson. First, remember that the basic action of a capacitor depends upon its ability to store an electric charge. Also remember that there is no complete circuit through a capacitor, but current will flow in a circuit in which a capacitor is connected while the capacitor is being charged and while it is being discharged. Remember that a capacitor is not charged instantly, but there is some time involved in charging a capacitor. The actual time it takes to charge a capacitor fully will depend upon the capacity and the resistance in the circuit.

Remember that the electrical size of a capacitor is measured in farads, but the farad is such a large unit that the practical values are the microfarad, which is a millionth of a farad, and the picofarad, which is a millionth of a microfarad.

The capacity of a capacitor depends upon the area of the plates, the spacing between the plates, and the dielectric between the plates.

The dielectric constant of the material is a number which tells you the number of times the capacity of a capacitor will be increased when this type of material is placed between the plates of the capacitor. Different materials have different dielectric constants; one of the highest is ceramic, which has a dielectric constant as high as 1500.

The voltage rating of a capacitor tells you the maximum safe voltage that you can apply to a capacitor. Capacitors having a higher voltage rating can always be used in replacing a defective capacitor in a piece of electronic equipment if there is room.

SELF-TEST QUESTIONS

(a) What do we mean when we say a capacitor is charged?
(b) What two factors affect the length of time it takes to charge a capacitor?
(c) Does a capacitor have any more electrons on its plates when it is charged than when it is discharged?
(d) What factor determines the amount of charge a capacitor can hold for a given applied voltage?
(e) What is the basic unit of capacity?
(f) What two practical units are used in electronics to indicate the capacity of a capacitor?
(g) Convert .0033 mfd to picofarads.
(h) Convert 680 pf to mfd.
(i) Name the three factors that affect the capacity of a capacitor.
(j) If you cut the spacing between the plates of a capacitor in half, will this double the capacity of the capacitor or will it cut the capacity of the capacitor in half?
(k) What is the dielectric constant of a material?
(l) What is the dielectric constant of air?
(m) What type of material has the highest dielectric constant?
(n) Why does a material with a dielectric constant greater than air have the effect of increasing the capacity of a capacitor?
(o) A capacitor is marked .02 microfarads, 400 volts; what does the marking 400 volts mean?

Typical Capacitors

Capacitors can be divided into two types, fixed capacitors and variable capacitors. A fixed capacitor is a capacitor which has a fixed capacity - in other words, the capacity of the capacitor cannot conveniently be varied. A variable capacitor, on the other hand, is a capacitor that is designed so that its capacity can be varied.

Capacitors can be further divided into types depending upon the dielectric material used. Most variable capacitors have an air dielectric and therefore are also referred to as air capacitors. Some variable capacitors have a mica dielectric and these are referred to as variable mica capacitors.

Most fixed capacitors use some dielectric other than air. Many capacitors use a paper dielectric and these are usually referred to as paper capacitors. Some capacitors of this type are dipped in a mylar coating to seal the capacitor and these are sometimes called paper mylar capacitors. Some fixed capacitors use a mica dielectric and these are called mica capacitors. Mica capacitors might also be sealed in a mylar case and these are sometimes called mylar-dipped mica capacitors.

Ceramic is widely used in capacitors as the dielectric and this type of capacitor is called a ceramic capacitor.

Large capacitors used in power supplies are called electrolytic capacitors. These capacitors use an electrolyte which forms a film that acts as the dielectric. You will study these capacitors in detail shortly and learn more about them at that time.

All capacitors, regardless of type, can store a charge. Of course, some capacitors can store more charge than others because they have a greater electrical size. In this section you will see that there is a reason for having these different types of capacitors, and also you will learn more about the common types of capacitors that you will encounter in electronics work.

VARIABLE CAPACITORS

A typical variable capacitor is shown in Fig. 6. This capacitor is actually two capacitors coupled by a common shaft, and as you know this type is called a two-gang capacitor. In some receivers you will find 3-gang capacitors, and in some old sets and in some communications

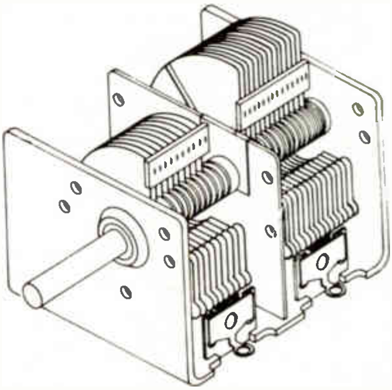

Fig. 6. A variable capacitor.

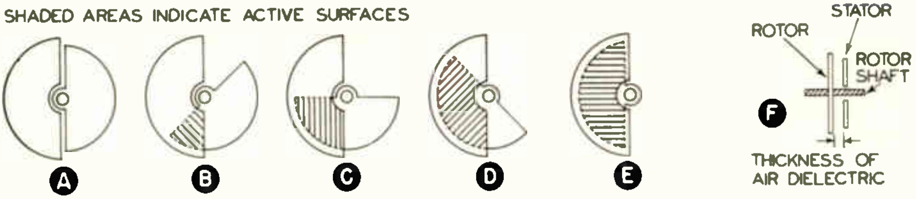

Fig. 7. How a variable capacitor with straight-line capacity plates works.

receivers you will find 4-gang capacitors. Sometimes all sections are identical; sometimes you will find that one section has smaller plates than the others.

Each section of a variable capacitor is made up of two sets of plates. The one set of plates that do not move are all connected together and insulated from the capacitor frame. These plates are called the stator plates, in other words, the stationary plates. The other set of plates are connected directly to the shaft and to the capacitor frame. These plates rotate and hence are called the rotor plates. Since these plates are connected directly to the capacitor shaft and to the frame, if you mount the capacitor on a metal chassis, the plates are automatically connected to the chassis. This does not present any problem, because in most circuits where a capacitor of this type is used, it is desirable to connect one set of plates to the chassis. The chassis acts as a ground or common connection for all rf (radio frequency) circuits.

There are two different types of plates found in variable capacitors. One type of plate is called the straight-line capacity type; the other is called the straight-line frequency type. An example of the straight-line capacity type of plate is shown in Fig. 7. Notice that in A of Fig. 7 the plates are completely separated so that the capacity is at a minimum. Actually there will be some capacity, because even though the plates are not meshed, the ends of the plates of the rotor have a certain capacity to the ends of the plates of the stator. In B the capacitor plates have been rotated through one eighth of a turn and the overlapping area of the two sets of plates is one quarter of the total area. We now have approximately one quarter of the total capacity. As the capacitor is turned another eighth of a turn, from position B to position C, so that it has completed a quarter turn, one-half of the area of the plates is overlapping and we have one half of the total capacity. Similarly, when the capacitor has been moved to three

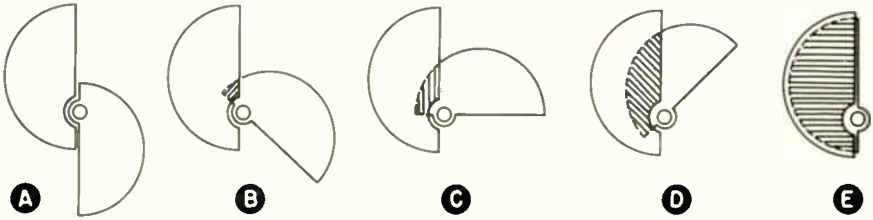

Fig. 8. How a variable capacitor with straight-line frequency plates works.

eighths of a turn, three-quarters of the area is overlapping and we have three quarters of the total capacity, and finally with a half turn the entire two areas are completely overlapping and we have maximum capacity.

There is another type of plate that is called the straight-line frequency type. Here the plates are shaped as shown in Fig. 8. Now when the plates are moved from position A to position B, less than a quarter of the area is overlapping even though the capacitor has gone through an eighth of a turn and we have less than a quarter of the total capacity.

Similarly when it is moved to position C, although the capacitor has been turned through a quarter of a turn, less than half of the two areas are overlapped and we will have less than half the total capacity. However, the increase in capacity obtained by rotating the capacitor from B to C is greater than was obtained in rotating it from A to B because the increase in overlapping area is greater. Similarly we get a still greater increase in capacity in going from C to D and an even greater increase in capacity in going from D to E.

The reason for this type of capacitor is that capacitors are used in conjunction with coils in the tuning circuits of radio and TV receivers, to select one station and reject others. For example, in a radio designed for the standard broadcast band you will find a coil and a capacitor used to select the desired station and reject the others. At the high end of the broadcast band it takes a smaller change in capacity to get a given frequency change than it does at the low end of the broadcast band. Therefore if you use the straight-line capacity type of capacitor, stations at the high-end frequency of the dial will be squeezed together and stations at the low-end frequency will be spread out. This makes it difficult to tune stations at the high frequency end of the dial. With the straight-line frequency type, however, the different frequencies are spread evenly across the dial of the receiver so that it is just as easy to tune in a station at the high end of the dial as one at the low end of the dial. Most modern broadcast receivers use the straight-line frequency type of capacitor because it is somewhat easier to tune the receiver.

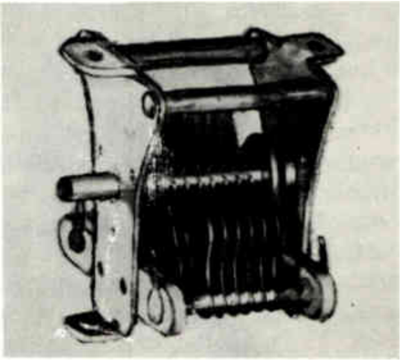

Fig. 9. A single-section variable capacitor of the transmitting type.

A single-section tuning capacitor such as might be found in a radio frequency transmitter or any other device where a variable capacitor is needed and high voltage is present is shown in Fig. 9. Notice that this capacitor is basically similar to one section of the capacitor shown in Fig. 6. The big difference is that the spacing between the plates is greater. The greater spacing is needed in high-voltage circuits to avoid arcing between the plates. Arcing is simply a flash-over that occurs where the voltage is so high that the electrons are able to jump from one plate of the capacitor to the other.

Trimmer Capacitors.

Trimmers are small variable capacitors, so called because they are used to trim or adjust resonant circuits whose main tuning capacitor is much larger.

Most ganged variable capacitors are equipped with trimmers so each ganged section can be individually adjusted. These trimmers use a mica dielectric, and the movable plate is of spring material which tends to stay away from the fixed plate, as shown in Fig. 10. A screw electrically insulated from the movable plate draws it closer to the fixed plate when tightened, thus increasing the capacity.

In some cases the trimmer is a miniature air dielectric capacitor, just like a single tuning capacitor.

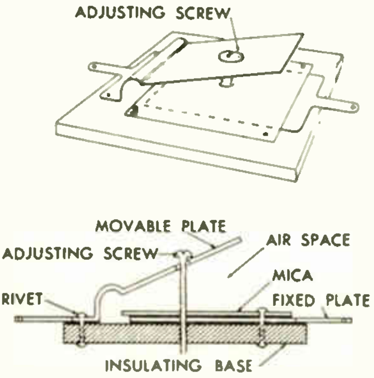

Fig. 10. A typical trimmer capacitor.

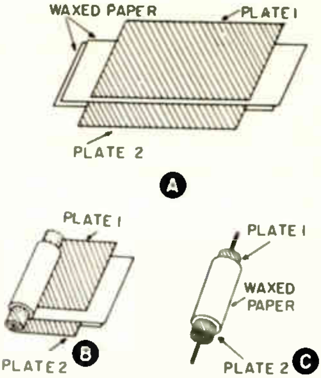

Fig. 11. How a paper capacitor is made.

PAPER CAPACITORS

A paper capacitor is made by taking two sheets of tinfoil and placing a sheet of paper between them as shown in Fig. 11A. The tinfoil and the paper are then rolled as shown in Fig. 11B until they are shaped like Fig. 11C. Wire leads are then attached to the foil sheets that protrude from each end of the capacitor.

After the leads have been attached to the capacitor it is then encased in a suitable container. In older radio and TV receivers you will find capacitors of this type that have been encased in a cardboard case with wax or some other sealing compound poured into both ends. However, this type of capacitor frequently caused trouble and is seldom used in modern electronic equipment. Modern paper capacitors are completely encased in a molded ceramic type of material or are encased in a mylar type of material. Either type completely seals the capacitor so that moisture cannot seep into it. Capacitors of this type are referred to as molded capacitors, molded paper capacitors, mylar capacitors or mylar paper capacitors.

A photo of two typical paper ca-

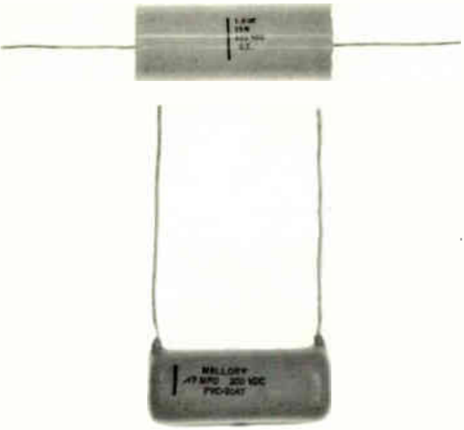

Fig. 12. Typical paper capacitors.

pacitors is shown in Fig. 12. Notice that in one capacitor the leads come out the ends. This type of lead arrangement is referred to as axial leads. In the other type of capacitor the leads come out the side and this is referred to as a radial-lead type. Capacitors with radial leads are frequently used in electronic equipment in which printed circuitry is used. This type of capacitor is very convenient for mounting in this type of construction. However, axial lead capacitors can also be used in the same application simply by bending the leads at right angles to the body of the capacitor.

Paper capacitors are made in a wide range of capacities. You will find paper capacitors as small as .0005 mfd and as large as 1 mfd or 2 mfd. Paper capacitors can be made in a larger size, but it is usually more economical to make other types when the capacity needed in a circuit exceeds about .5 mfd.

Defects.

Since you are training as an electronics technician, one of your chief concerns with capacitors will be the defects that occur in them. There are a number of different types of defects that can occur in paper capacitors. As we mentioned earlier, in older receivers you will find paper capacitors encased in a cardboard case. Moisture can seep into this type of capacitor, resulting in leakage from one plate to the other or an eventual breakdown in the paper insulation, so that for all practical purposes one plate is touching the other. Of course, when this happens the capacitor can no longer store a charge and acts as though there were a wire connected between the two leads of the capacitor.

Occasionally in a molded or a mylar type of capacitor the material encasing the capacitor will crack, particularly around the point where the leads are brought out. When this happens moisture can seep into this type of capacitor and you get exactly the same effect as moisture in the cardboard-encased capacitor.

It is usually not too difficult to identify a completely shorted capacitor, but one that has a high leakage may cause almost as much trouble as a shorted capacitor and it is much more difficult to find. There is no such thing as a perfect capacitor. There is some leakage between the plates of all capacitors. However, a good paper capacitor will usually have a leakage resistance of several thousand megohms. When the leakage resistance drops below this figure it is a sign that the capacitor is deteriorating. In some circuits a leakage resistance as low as 2 or 3 megohms can be tolerated and the circuit may work perfectly, but in other circuits a capacitor with a leakage resistance as high as 10 or 20 megohms may be totally unusable. It is too early for you to try to distinguish between these cases; the important thing for you to remember at this time is that leakage between the plates and direct shorts between the plates of capacitors are two defects that paper capacitors can develop.

Another defect found in paper capacitors is an open. The open is usually where one of the leads breaks loose from the tinfoil. Sometimes the lead will pull right out of the capacitor, and of course this is easy to spot because you can see it. But in most cases the break will be inside the capacitor so you cannot see it and you will have to rely on the way the circuit performs to give you a clue that this is a possible cause of trouble.

Another defect found in paper capacitors is an intermittent defect. Part of the time the capacitor will operate normally, but other times it may short or it may open. Again, we do not expect you to be able to find these defects at this time; the important thing is to remember that these types of defects can and do occur.

MICA CAPACITORS

Mica capacitors are somewhat larger physically than paper capacitors of equal capacity. However, mica is used in some capacitors that are to be used in high-frequency circuits. Mica capacitors are also used in the rf signal circuits of transmitters. Mica capacitors are made with capacities ranging from a few picofarads to approximately 10,000 pf. Some mica capacitors found in transmitters are designed for operation in circuits where the voltages are extremely high; capacitors with working voltages of 5000 volts are quite common.

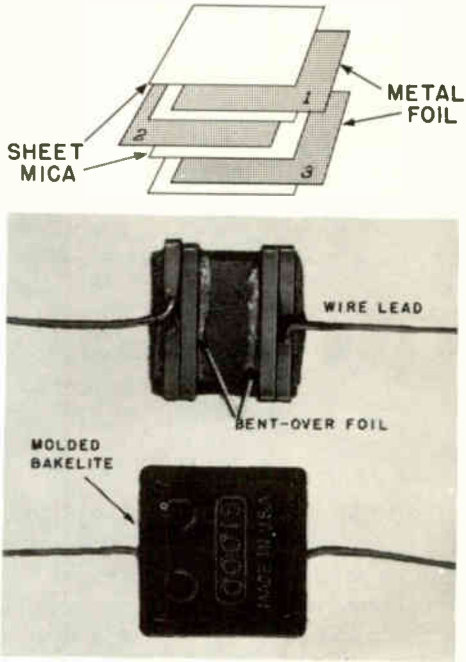

Fig. 13. How a mica capacitor is made.

The construction of a mica capacitor is shown in Fig. 13. Notice that there are simply two sets of plates, and that the plates are separated by thin sheets of mica placed between the metal plates. Because mica is brittle, this type of capacitor cannot be rolled into a tube like a paper capacitor and therefore most mica capacitors are rectangular in shape. The plates and the mica are enclosed in a ceramic or Bakelite case that is molded over the unit.

Mica capacitors seldom cause trouble. About the only defect that they ever develop is a short. Occasionally one of the leads will pull loose and the capacitor will open, but it is very rare to find any defect at all in a mica capacitor.

In spite of the fact that mica capacitors are almost trouble-free, they are not used too often in radio or TV receivers because they are more expensive than ceramic capacitors. However, in some critical circuits you will still find mica capacitors. You may find them used in the tuners of TV receivers or in critical sections of color TV receivers. They are still used almost exclusively in transmitting equipment.

As with paper capacitors, mica capacitors are available with both types of leads. Leads coming out of the end which are called axial leads are probably more common, but mica capacitors that have been dipped in mylar or some similar sealing compound are available with radial leads coming out of the side of the capacitor.

CERAMIC CAPACITORS

There are three types of ceramic capacitor found in electronic equipment. One type is the tubular, another is the disc. The third type is the feed-through. All three types are shown in Fig. 14.

Tubular ceramic capacitors are made in sizes ranging from less than 1 pf to about 1500 pf. They can be made to rather close tolerances and at one time were quite widely used in electronic equipment where small electrical size capacitors were needed. Most modern equipment, however, uses disc capacitors, because they are more economical than tubular capacitors and can also be made to quite close tolerances.

The feed-through capacitor is a special type of ceramic capacitor used exclusively as a bypass element, particularly at very high and ultra high frequencies. The unique construction of the feed-through capacitor, shown physically and schematically in Fig. 14, makes it a particularly effective bypass capacitor for filament, bias, agc and B+ leads in UHF and VHF TV tuners. One lead of the tubular feed-through capacitor connects directly to ground, whereas the fed through lead forms the other lead of the capacitor. The capacitor leads, therefore, are very short, making the capacitor extremely effective at UHF and VHF.

Disc capacitors are made with capacities from about 1 pf up to almost 1 mfd. These capacitors are made with different tolerances. Common tolerances are ±5%, or ±10% or ±20%.

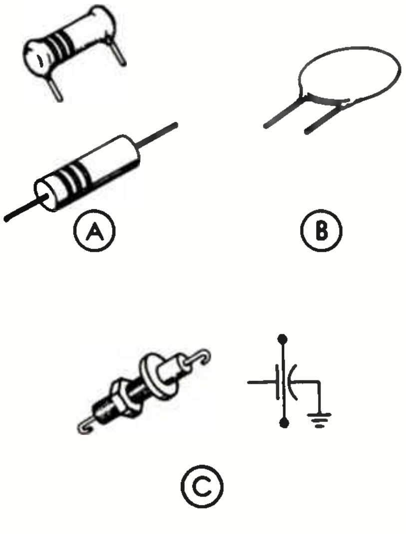

Fig. 14. Three types of ceramic capacitor. (A) Tubular; (B) Disc; (C) Feed-Through.

Sometimes the tolerance is indicated by a letter rather than by the actual tolerance figure. The letter J is used to represent a 5% tolerance, K a 10% tolerance and M a 20% tolerance. Ceramic capacitors are also made with a tolerance of +100% or -0. The letter P is used to represent this tolerance, and with a tolerance of +80%, -20% the letter Z is used.

Many types of ceramic capacitors change capacity with changes in temperature. For example, a capacitor that is labelled Z5U is a ceramic capacitor designed for operation between 10° and 85° C. The Z5 gives you this information. The letter U indicates that the capacity may change as much as +22% or -56% over that temperature range. In many circuits where ceramic capacitors are used a change in capacity is not particularly important and therefore you will find many capacitors used as bypass capacitors with the label Z5U.

Ceramic capacitors are made with lower temperature coefficients. For example, a capacitor labelled Z5F has a temperature coefficient of only ±7.5%. Z5P indicates a temperature change of 10% within the operating range.

When you have to replace a ceramic capacitor you can use one with the same temperature coefficient or one with a better temperature coefficient. The letter A indicates the smallest temperature coefficient, a change of ± 1%; the letter V is the poorest temperature coefficient. When you have to replace a ceramic capacitor, use one having the same temperature coefficient or a coefficient indicated by a letter closer to the letter A - this will be a better or closer tolerance temperature coefficient.

Ceramic capacitors normally have a voltage rating of at least 500 volts. Many have a voltage rating of 1000 volts. However, some will have a voltage rating as low as 100 volts where size is an important consideration. High-voltage ceramic capacitors having a voltage rating of 6000 volts or more are also available. Usually if the voltage rating is higher than 1000 volts or less than 500 volts, the voltage rating will be stamped on the capacitor.

Defects.

Occasionally a lead will break off a ceramic capacitor, but other than this they seldom open. Ceramic capacitors do short sometimes, but a shorted capacitor is usually not too difficult to locate. A low resistance reading across any capacitor indicates either that there is something directly across the capacitor causing the reading or else the capacitor itself is defective.

ELECTROLYTICS

There are two types of electrolytic capacitors, dry and wet. In the wet electrolytic capacitor a liquid called an electrolyte is used whereas in the dry electrolytic capacitor the electrolyte is in a paste form instead of a liquid. Wet electrolytic capacitors are no longer used. Modern electrolytic capacitors are all of the dry type.

A dry electrolytic capacitor is made of two plates with an electrolyte in paste form placed between the two plates as shown in Fig. 15. The anode plate is treated chemically before the capacitor is as-

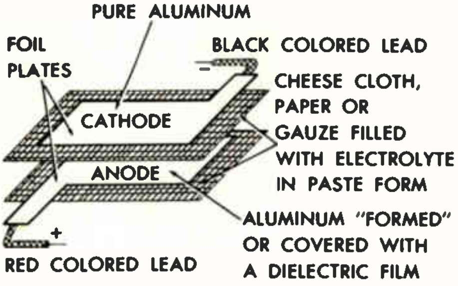

Fig. 15. How dry electrolytics are made.

sembled to produce a coating of oxide on the surface of the plate. The oxide then acts as the dielectric and the paste electrolyte acts as the other plate of the capacitor. The plate marked the cathode is the means of making contact to the paste.

Most electrolytics that you will encounter in commercial electronic equipment are made with aluminum plates. These capacitors are referred to as aluminum electrolytic capacitors. However, in some special applications, particularly where small size is important, the capacitor may be made with tantalum plates. This type of capacitor, however, is seldom found in radio or television receivers, because the tantalum plate electrolytic capacitor is much more expensive than an aluminum plate capacitor.

Polarity.

Electrolytic capacitors have polarity. This means that they can be used only in circuits having dc or pulsating dc. The plate called the anode must always be connected to the positive side of the voltage source and the plate called the cathode must always be connected to the negative side of the voltage source. If an electrolytic (technicians frequently shorten electrolytic capacitor to "electrolytic") is connected into the circuit backwards it will act as a low resistance, and a high current will flow through the capacitor, destroying it.

Dry electrolytic capacitors may be rolled into a tubular form and look very much like large paper capacitors. Flexible leads are brought out of the ends of the capacitor and the polarity of the leads is shown either by marking one end with a + sign and the other end with a - sign, or by using a wire of one color as one lead and a wire of another color as the other lead. The polarity is thus identified by the color of the lead. Usually a black wire is used to identify the negative lead and a red wire is used to identify the positive lead.

In some capacitors of this type there may actually be two electrolytic capacitors in the one container. The capacitor might be made with a common negative lead; in other words one negative lead for the two capacitors and separate positive leads so that there are only three leads coming from the capacitor or it can be made with separate positive and separate negative leads so that there are four leads brought out of the capacitor. The type with three leads, where a common negative lead is used, is found far more frequently than the type with the four separate leads.

Dry electrolytics are also sometimes placed inside a metal can. The can is the negative terminal of the capacitor and the positive terminal is brought up through an insulated wafer at the bottom of the capacitor. Sometimes there may be several separate capacitors in the one can. The can will be the common negative terminal and the separate positive leads will be brought out the bottom wafer. Symbols such as a small triangle, a half-moon or a square are cut into the wafer near the terminals to identify the various sections of the capacitor. An example of a can type electrolytic capacitor with four separate capacitors in the one container is shown in Fig. 16A. Fig. 16B shows a bottom view of the capacitor; you can see the symbols near the terminal lugs. The symbols identify the various terminals of the capacitor; the code used to identify the symbols is stamped into the metal capacitor can.

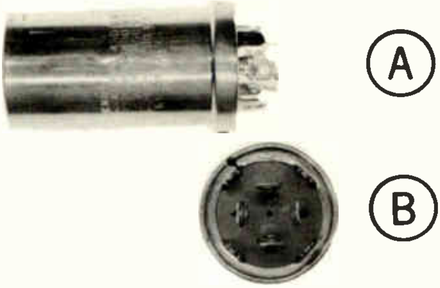

Fig. 16. A typical four-section electrolytic capacitor.

Defects.

As we mentioned previously, most electrolytic capacitors manufactured today are dry electrolytic capacitors. These capacitors deteriorate, particularly if they are not put into use. An electrolytic capacitor that has been unused for six months or more should be formed before the capacitor is put into service. An electrolytic can be formed by placing a low voltage on the capacitor and gradually increasing the voltage until it is equal to or slightly exceeds the rated working voltage of the capacitor. If a 450-volt capacitor that has been sitting around unused for six or seven months is simply installed in a circuit, and has a full 450 volts applied to it without first being formed, the chances are that it will short and the capacitor will be destroyed.

Electrolytic capacitors also deteriorate with use. The moisture in the electrolytic will slowly escape from the capacitor and when all the moisture has escaped the capacitor will really be dry and it will no longer work. Electrolytic capacitors also develop leakage. Leakage in an electrolytic capacitor can be detected quite easily; you will notice that the capacitor starts to get hot. In normal operation there is some leakage through an electrolytic capacitor and this will cause the capacitor to get warm, but if you notice that an electrolytic is getting extremely hot, it is a sign that the leakage through the capacitor is too high, and the capacitor should be replaced.

SUMMARY

In this section of the lesson you learned that there are a number of different types of capacitors. There are two types of variable capacitors, those with an air dielectric and those with a mica dielectric such as compression-type trimmers. You also learned that there are paper, mica, ceramic, and electrolytic capacitors. You are likely to run into all types, but you will probably have more to do with electrolytics than the other types because electrolytic capacitors cause more trouble than the others.

It is not important that you remember how the various types of capacitors are made; the important thing to remember is that capacitors can open, they can short, or they can develop intermittent defects. A low resistance reading across a capacitor indicates that the capacitor is shorted or has developed excessive leakage. Exactly how low a resistance can be tolerated through the capacitor depends upon the type of capacitor and the circuit in which it is used.

SELF-TEST QUESTIONS

(p) What two types of dielectrics are found in variable capacitors such as trimmer capacitors?

(q) What is the disadvantage of using a variable capacitor with straight-line capacity plates as a tuning capacitor in a radio receiver?

(r) Which type of capacitor plate is best suited for use in a tuning capacitor in a radio receiver?

(s) What is the main difference between a variable capacitor such as might be found in a radio receiver and a variable capacitor that might be found in a broadcast transmitter?

(t) What is the name given to the leads that come off the ends of a paper capacitor?

(u) Why are paper capacitors molded in a ceramic type of material or dipped in a mylar type of material?

(v) If the resistance of a paper capacitor is 100,000 ohms, would you replace the capacitor or is it satisfactory for continued use?

(w) Why are mica capacitors not more widely used in radio and television receiving equipment?

(x) In what type of circuits would you expect to find mica capacitors used?

(y) What two types of ceramic capacitors are used in electronic equipment?

(z) What does Z5F stamped on a ceramic disc capacitor indicate?

(aa) What are the two types of electrolytic capacitors, and which type is used in modern electronic equipment?

(ab) What do we mean when we say that an electrolytic capacitor has polarity?

(ac) If you notice that an electrolytic capacitor in a TV receiver is getting very hot, what should you do?

(ad) If you have a replacement electrolytic on hand that you have had for about a year, what should you do with it before installing it in a piece of equipment?

Capacitors in AC Circuits

Capacitors actually have very little use in circuits where there is nothing other than pure dc. Once a capacitor is placed in a dc circuit and charged, there will be no further current flow in the circuit. The chief importance of a capacitor comes from the way in which it works in ac circuits, and in circuits where there are ac and dc mixed together. Capacitors are used in all types of ac circuits found in electronic equipment ranging from the low frequencies found in power supplies and audio equipment up to the very high frequencies found in microwave equipment. Microwave equipment is that used at frequencies of 3000 mc (megacycles) and higher. The importance of the capacitor in ac circuits depends upon its ability to store an electrical charge. Because a capacitor can store a charge, it can be used in an ac circuit.

HOW AC FLOWS IN CIRCUITS USING CAPACITORS

In Fig. 17 a simple circuit is shown in which a capacitor is connected across an ac generator. In this type of circuit there will be a current flow. The exact amount of current flowing will depend upon the voltage of the generator, its frequency, and the capacity of the capacitor.

When the terminal of the generator marked 1 is negative and the terminal marked 2 is positive, electrons will flow from terminal 1 into the side of the capacitor marked A and force electrons out of the side marked B to terminal 2 of the generator which will attract these electrons because it is positive. During the next half cycle when the polarity of the generator reverses, electrons that have been piled up on the side of the capacitor marked A will be pulled out by terminal 1 which is positive, and electrons will be forced into side B of the capacitor by terminal 2 of the generator, which is negative. Extra electrons will be forced on this side of the capacitor so the side marked B will become negative and side marked A will become positive.

This action continues as the generator goes through first one half cycle and then the other. Electrons will flow back and forth in the circuit. They will flow first into one side of the capacitor and force electrons out of the other side and then electrons will flow out of the side on which they built up a surplus and into the side on which there was a shortage. It is important that you notice that electrons do not flow through the capacitor. You will remember that the plates of the capacitor are separated by a dielectric and the dielectric is a non-conducting material. However, because the capacitor can store a charge, we have the effect of a current flowing in the circuit.

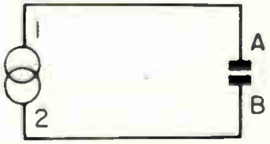

Fig. 17. A capacitor connected across a generator.

The action inside the capacitor can be seen in more detail in Fig. 18. At the start of the ac cycle when the voltage of the generator is zero, there will be a certain number of electrons on both plates of the capacitor. The electrons in each atom of the dielectric will be revolving around the nucleus as shown in Fig. 18A. However, when electrons begin to move into one plate, as shown in Fig. 18B, and out of the other plate, the electrons in the dielectric will be forced out of their normal path as shown. Thus, although the electron flowing into plate 1 does not reach plate 2, it does force another electron in the dielectric over near plate 2, and this in turn forces an electron out of plate 2.

As the ac voltage decreases and finally drops to zero, the electrons in the dielectric will return to the normal position as shown in Fig. 18C. During the next half cycle, when the polarity of the generator reverses, electrons will be forced into plate 2 and they in turn will force the electrons in the dielectric out of their normal positions and they will push electrons out of plate 1. Thus we have the effect of current flowing through the capacitor in the opposite direction, although the electrons flowing into the one plate never do get through the dielectric into the other plate of the capacitor.

You can see that there is a back and forth motion of the electrons in the conductors connected to the capacitor. The electrons in the dielectric will move back and forth and therefore we are justified in saying that ac current flows "through" a capacitor, even though the electrons never get through the dielectric into the other plate. Because of this effect, capacitors can be used in ac circuits. They are very useful in circuits where we have both ac and dc. The capacitor can be used to block dc, while at the same time allowing ac to flow through the capacitor.

The action of a capacitor in allowing electrons to flow back and forth is a good demonstration of what ac is. The actual movement of each electron is very small; however, there may be a large number of electrons moving back and forth over a very short distance. The distance of the electron's travel is unimpor-

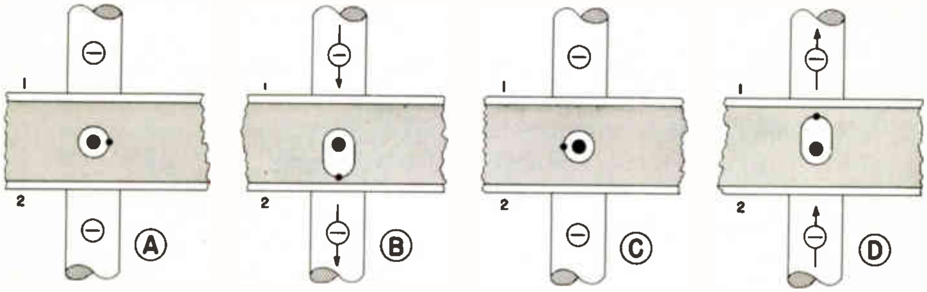

Fig. 18. When ac is applied to a capacitor, the bound electrons in the dielectric move first one way, then the other, so in effect, alternating current flows through the capacitor.

tant; the important thing is the number of electrons in motion. If we have a large number of electrons in motion, we have a large current.

The capacitor does not allow electrons to move back and forth without offering opposition. Capacitors do offer opposition to the flow of ac current through them and this opposition is called capacitive reactance.

CAPACITIVE REACTANCE

Since work must be done to move the electrons in the dielectric back and forth to permit ac current to flow, in a capacitive circuit there is opposition to the flow of current. This opposition is called capacitive reactance. This opposition is measured in ohms, just as the inductive reactance of a coil is measured in ohms. However, there is a great deal of difference between inductive reactance and capacitive reactance.

Capacitive reactance is represented by the symbol Xc. It can be expressed by the formula:

$$Xc = \frac{1}{6.28 \times f \times C}$$

In this formula the frequency f is the frequency expressed in cycles and C is the capacity in farads. We can write this formula in another way by expressing C in microfarads. To do this, we divide 6.28 into 1 and multiply this result by 1,000,000. We get:

$$Xc = \frac{159{,}000}{f \times C}$$

In this expression f is the frequency in cycles per second, and C is the capacity in microfarads.

From this formula there are several important things that you can see. First of all, let us consider the effect of a change in frequency on the reactance of a capacitor. Let us find the reactance of a 1-mfd capacitor at a frequency of 10 cycles per second. Using the formula:

$$Xc = \frac{159{,}000}{f \times C}$$

and substituting 10 for f and 1 for C we get:

$$Xc = \frac{159{,}000}{10 \times 1} = 15{,}900 \text{ ohms}$$

When the frequency is 100 cycles, we get:

$$Xc = \frac{159{,}000}{100 \times 1} = 1{,}590 \text{ ohms}$$

Notice that at the higher frequency, the capacitive reactance is lower.

As the frequency increases, the capacitive reactance decreases. In an inductive circuit we had just the opposite effect; if the frequency increased, the inductive reactance increased.

We have the same situation when the capacity is increased. If the capacity is made larger, the capacitive reactance decreases. We can see this if we find the reactance of a 1-mfd capacitor at a frequency of 100 cycles per second and then find the reactance of a 10-mfd capacitor at 100 cycles per second. We already know that the 1-mfd capacitor has a reactance of 1590 ohms. To find the reactance of the 10-mfd capacitor we use:

$$Xc = \frac{159{,}000}{100 \times 10} = 159 \text{ ohms}$$

Notice that this is one tenth the reactance of the 1-mfd capacitor at 100 cycles per second. Therefore in a capacitive circuit, we have exactly the opposite effect to what we had in an inductive circuit. We can say that the capacitive reactance varies inversely with the frequency and the capacity. This simply means that if the frequency or capacity increases, the reactance decreases, and if the frequency or capacity decreases, the capacitive reactance increases.

While we are discussing capacitive reactance it might be well to point out that the reactance of even a small capacitor becomes quite small if the frequency is made high enough. For example, a 100-pf capacitor has a reactance of 1590 ohms at a frequency of 1 megacycle. One megacycle is not a high radio frequency; as a matter of fact this frequency falls in about the middle of the standard radio broadcast band. At a frequency of 10 megacycles, which is in the short-wave bands, the reactance is only 159 ohms, and at a frequency of 100 megacycles, which is in the FM broadcast band, the reactance is only 15.9 ohms. Even a 1-mmf capacitor has a reactance of only 1590 ohms at a frequency of 100 megacycles. Thus, if the frequency is made high enough even small capacitors have a comparatively low reactance.

Capacitors in Parallel.

When two capacitors are connected in parallel we have two capacitive reactances in parallel. If the capacitive reactance of each capacitor is 100 ohms, we have the same effect as we would have with two 100-ohm resistors in parallel. The reactance would be only 50 ohms. This effect is the same as connecting a capacitor twice as large as either capacitor into the circuit.

To find the total capacity of capacitors connected in parallel you simply add the capacities. In other words, if a 4-mfd capacitor is connected in parallel with a 6-mfd capacitor, the total capacity in the circuit is 10 mfd. The reactance in the circuit would be exactly the same as you would obtain by connecting a 10-mfd capacitor in the circuit.

This is an important rule to remember--to find the total capacity of parallel-connected capacitors you simply add the capacitors together. The working voltage that can be applied to the parallel combination is the lowest working voltage of the capacitors connected in parallel.

Capacitors in Series.

When capacitors are connected in series, we have two reactances in series. The total capacitive reactance in the circuit is equal to the sum of the two reactances, just as the total resistance in a circuit made up of resistors connected in series is equal to the total resistance in the circuit. Thus connecting capacitors in series increases the total reactance in the circuit. If the reactance in the circuit increases, then the capacity must decrease.

When two capacitors are connected in series, you can find the total capacity by using the formula:

$$C_T = \frac{C1 \times C2}{C1 + C2}$$

When three or more are in series, use the formula:

$$C_T = \frac{1}{\frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} + \cdots}$$

When capacitors are connected in series, the total capacity is always less than the capacity of the smallest capacitor.

You will seldom actually have to calculate the value of series and parallel-connected capacitors. However, it is important for you to realize that connecting capacitors in series results in a lower total capacity, while connecting them in parallel results in a higher total capacity in the circuit.

SUMMARY

There are several important things that you should remember from this section of the lesson. First, remember that although current does not actually flow through a capacitor, the effect produced in the circuit is the same as though current does flow through the capacitor. Thus we say that an ac current flows through a capacitor.

Remember that we call the opposition offered to current flow in an ac circuit by a capacitor the capacitive reactance, and the capacitive reactance is measured in ohms. The capacitive reactance is equal to:

$$Xc = \frac{159{,}000}{f \times C}$$

where f is in cycles per second and C is in microfarads.

Increasing the capacity or the frequency in the circuit will result in a lower capacitive reactance and decreasing the frequency or capacity will result in a higher capacitive reactance.

When capacitors are connected in parallel, the total capacity is equal to the sum of the capacities. When capacitors are connected in series, the total capacity is always less than the capacity of the smallest capacitor.

SELF-TEST QUESTIONS

(ae) When a capacitor is connected across an ac generator, does current flow from the generator?

(af) When a capacitor is connected across a generator, does current flow through the capacitor?

(ag) What is the name given to the opposition that a capacitor offers to the flow of ac?

(ah) What is the formula used to determine the capacitive reactance of a capacitor?

(ai) What is the capacitive reactance of a .02 mfd capacitor at a frequency of 150 cycles per second?

(aj) What is the total capacitance of a .1 mfd and a .22 mfd capacitor connected in parallel?

(ak) A 27 pf capacitor and a 56 pf capacitor are connected in series. What is the total capacity of the series-connected capacitors?

(al) In what unit is capacitive reactance measured?

(am) Complete the following statement: Increasing the capacity or the frequency in a circuit will result in a ________ capacitive reactance and a decrease in frequency or capacity will result in a ________ capacitive reactance.

Simple RC Circuits

An RC circuit is a circuit containing resistance and capacity. These circuits are found in all types of electronic equipment. RC circuits are used to shape signals. We can apply a signal with one type of wave shape to an RC circuit and get a signal having a different wave shape at the output. RC circuits are used to feed signals from one stage to another in electronic equipment. There are many applications of RC circuits, but before you can understand how these circuits are used, you must learn something about the fundamentals of the circuit.

You already know that when a capacitor is connected across a voltage source it does not charge instantly, but takes a certain length of time to charge. The length of time depends upon the size of the capacitor and the resistance in the circuit. The length of time it takes to charge up to a certain value is called the time constant. Time constant is an important consideration in circuits using resistance and capacitance. Let's learn a little more about it.

TIME-CONSTANT

When a resistor is connected in series with a capacitor and the two are connected across a battery as shown in Fig. 19, current begins to flow in the circuit to charge the capacitor. At the first instant that the resistor and capacitor are connected across the battery, a rather large current flows because there is no charge on the capacitor. The size of the resistor will limit the amount of current that can flow for any given voltage source. At this instant, although the current flowing in the circuit is high, the voltage across the capacitor is zero. In other words, when the current flowing into the capacitor is at a maximum, there is no voltage across it.

Gradually the capacitor is charged and as the capacitor charges, the voltage across the capacitor builds up and the current flowing in the circuit decreases. This is due to the fact that the actual voltage driving electrons in the circuit is equal to the source voltage minus the voltage across the capacitor. As the voltage across the capacitor increases, the voltage forcing electrons through the circuit goes down. In other words the current flowing into the capacitor decreases as its voltage increases.

If we draw a graph showing the way in which a capacitor charges, it would look like Fig. 20. In this graph, time is measured along the horizontal axis. The extreme left of this axis represents the instant we connect the capacitor and resistor across the source. Notice that at this instant there is no voltage across the capacitor, but the voltage starts

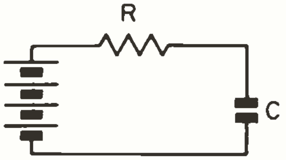

Fig. 19. A resistor and a capacitor connected in series across a battery.

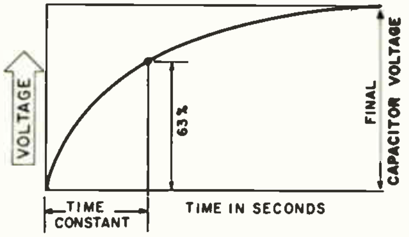

Fig. 20. How a capacitor charges. The time-constant is the time it takes for the capacitor to charge to 63% of the total voltage.

to build up rapidly. Then, as the charge on the capacitor increases, the rate of charge decreases so that when the capacitor is almost charged to a value equal to the source voltage, the rate of charge becomes very slow.

When we speak of the time-constant of an RC circuit, we mean the time it takes the capacitor to charge up to about 63% of the total source voltage. This value is shown on Fig. 20. The time-constant of any RC circuit in seconds can be found by multiplying the resistance of the resistor in megohms times the capacity of the capacitor in mfd. Thus, if a 2-mfd capacitor is connected in series with a 1-megohm resistor, the time-constant will be 2 × 1 = 2 seconds. This means that it will take two seconds for the capacitor to charge up to 63% of the source voltage.

One important thing to note is that the source voltage has nothing to do with the time-constant of the circuit. In other words, whether a resistor-capacitor combination is connected across a 10-volt battery or a 100-volt battery, the time-constant is the same. If a certain resistor and capacitor are connected across a 10-volt battery and the time-constant is one second, the capacitor will charge up to 63% of 10 volts, or 6.3 volts in one second. On the other hand, if the same resistor-capacitor combination is connected across a 100-volt battery, the capacitor will charge up to 63% of 100 volts, or 63 volts, in one second. The voltage across which the resistor-capacitor combination is connected does not determine the time-constant; the only factors that affect the time-constant are the resistor and capacitor values.

If a .05-mfd capacitor is connected in series with a 100,000-ohm resistor, the time-constant will be .05 × .1 (100,000 ohms = .1 meg) = .005 second. Thus, you can see that the time-constant of the combination using a smaller capacitor and resistor is much shorter than the time-constant of the combination of the two-mfd capacitor and the one-megohm resistor. Decreasing the size of either the resistor or the capacitor decreases the time-constant of the circuit, and increasing the size of either the resistor or the capacitor increases the time-constant of the circuit.

VOLTAGE-CURRENT PHASE

In the preceding example, you will notice that when the capacitor and resistor combination is first connected across the battery, a very high current flows in the circuit. However, at this first instant when they are connected across the bat-

$T_c = RC$

R= MEG C = MFD

tery, there's no voltage across the capacitor. Here we have a situation where the current is at a maximum, and the voltage across the capacitor is at a minimum or zero voltage.

As the voltage across the capacitor builds up, the current flowing in the circuit decreases until finally, when the capacitor is fully charged to a value equal to the battery voltage, the current drops to zero, because the source voltage is unable to force any additional electrons onto the one plate of the capacitor or pull electrons off the other plate.

Essentially the same situation exists when a capacitor is used in an ac circuit. When the ac voltage across the capacitor builds up, the current decreases until, by the time the capacitor is fully charged, the current has dropped to zero. When the voltage across the capacitor begins to decrease, then current must flow in the opposite direction in order for the electrons to remove the excess electrons from the plate of the capacitor having a surplus of electrons and to replace the missing electrons on the plate of the capacitor having a shortage of electrons. During the second half of an ac cycle, as the capacitor voltage drops from a maximum value to zero, the discharge current flowing in the circuit increases until, at the time the voltage reaches zero and begins to change polarity, the current flowing in the circuit is at maximum. As the voltage across the capacitor builds up in the opposite direction, the current begins to decrease until, at the instant when the capacitor is fully charged with the opposite polarity, the current flowing in the circuit has dropped to zero again.

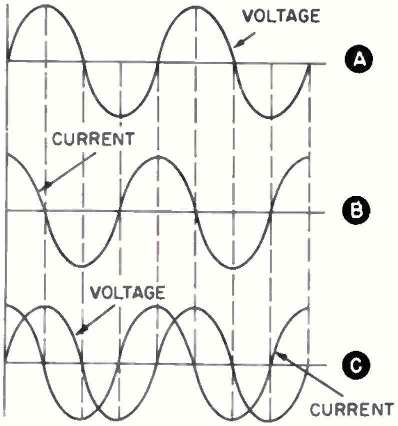

Fig. 21. The phase relationship between current and voltage in a capacitive circuit.

In Fig. 21 the relationship between the current and voltage in a capacitive ac circuit is shown. Notice that in Fig. 21A two cycles of an ac sine wave are drawn. Immediately beneath the voltage sine wave, in Fig. 21B, the current that will flow at the corresponding instant is shown. The voltage and current waves are superimposed in Fig. 21C.

In this circuit the effect is exactly opposite to that obtained when a coil is used. You will remember that in inductive circuits the current lags behind the voltage. Here, in a capacitive circuit, the current is leading the voltage. In a circuit containing only capacity, the current will lead the voltage by 90 degrees. In a circuit containing both resistance and capacity, the current will lead the voltage by a value somewhat less than 90 degrees; the actual phase difference between the voltage and current will depend upon the size of the capacitor and resistor in the circuit.

Thus, you have now seen two important examples of phase. In an inductive circuit, the current lags the voltage by 90 degrees. In a capacitive circuit, the current leads the voltage by 90 degrees.

VOLTAGE DISTRIBUTION

If we connect a capacitor in series with a resistor and connect the two across a dc voltage source, we will eventually have the situation shown in Fig. 22A. Here, all the voltage appears across the capacitor and there is no voltage across the resistor. Since there is no voltage across the resistor, we know immediately that there is no current flowing in the circuit. Of course, you know that at the instant the resistor and capacitor in series are connected across the voltage source, there will be a current flow while the capacitor is charging. However, once the capacitor is charged, there is no further current flow in the circuit and the meters would read like those shown in Fig. 22A.

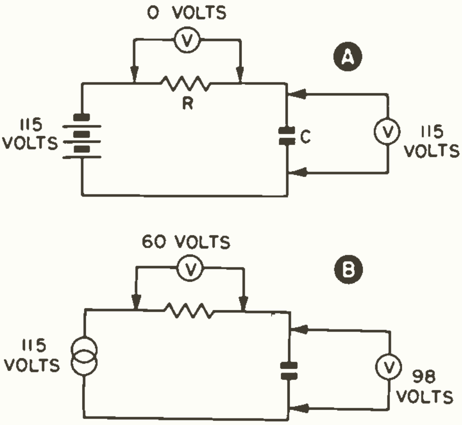

Fig. 22. When a resistor and a capacitor are connected in series across a dc source as at A, there is no current flow in the circuit. When the resistor and capacitor are connected in series across an ac generator as at B, there is current flowing, and hence there are voltage drops across R and C.

If the same resistor and capacitor are connected across a 115-volt ac source and the meters are replaced by ac voltmeters, we might encounter the situation shown in Fig. 22B. Here we have 98 volts across the capacitor and 60 volts across the resistor. 98 plus 60 adds up to 158 volts, which is more than the source voltage. It is obvious that we cannot add these two voltages in order to get the source voltage, because we know that the sum of the voltage drops in a circuit must be equal to the source voltage. The reason for the apparent contradiction is that the voltmeters indicate the RMS or effective voltage appearing across the capacitor and across the resistor. These voltages are not in phase and hence cannot be added by simple addition. You will remember that we encountered exactly the same thing when a resistor was connected in series with a coil. We found that we could not simply add the voltages appearing across the two and get the source voltage, but instead had to add the two by means of vectors. Let us see how we can do the same thing with these two voltages.

First, we start by drawing the current vector as shown in Fig. 23A. This vector is always drawn in this position since we use this as a starting point. We consider this vector as rotating in a counterclockwise direction around its starting point as the current goes through its cycle. If we use a scale of 50 volts to an

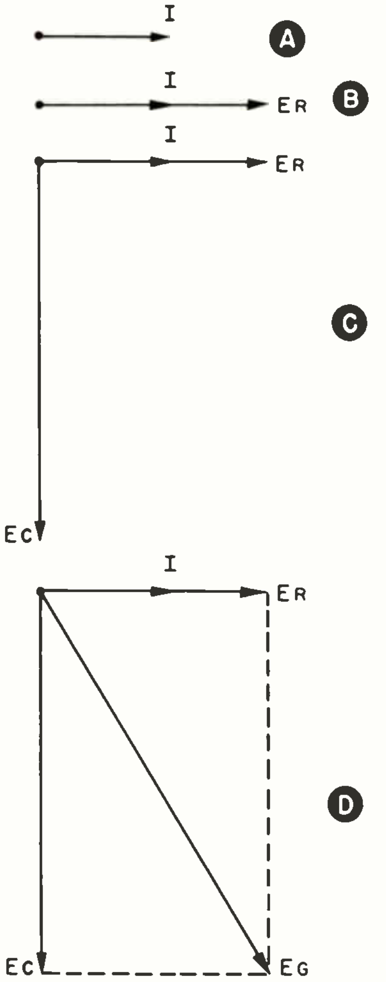

Fig. 23. Vector addition of two voltages.

inch, we can draw the vector E_R, representing the voltage across the resistor, 1-1/5 inches long as shown in Fig. 23B. We know that this vector must be drawn right on top of the current vector because the voltage across the resistor is in phase with the current flowing through it.

The next vector to draw is the vector representing the voltage appearing across the capacitor. We know that in a capacitor the current leads the voltage by 90 degrees. Another way of saying this is that the voltage lags the current by 90 degrees. Since the current vector is rotating in a counterclockwise direction, to show the voltage vector 90 degrees behind the current vector, we draw it as shown in Fig. 23C. Since the voltage across the capacitor is almost 100 volts, we can draw this vector 2 inches long as shown. Now we have only to draw in the dotted lines as shown in Fig. 23D and complete the vector diagram by drawing in the vector E_G which is the vector sum of the two voltages. If you measure this vector, you will find that it is a little more than 2-1/5 inches long, indicating a voltage of about 115 volts. In other words, when we used this scheme of adding the two voltages, we found that the voltage across the capacitor plus the voltage across the resistor, when added by means of vectors, are equal to the source voltage.

Another method of arriving at the same result is by means of the formula:

$$E_T = \sqrt{E_R^2 + E_C^2}$$

To solve this we take E_R^2, which is 60 × 60 = 3600, and add this to E_C^2 which is 98 × 98 = 9604. The sum is 13,204. $E_T = \sqrt{13{,}204}$, and the square root of 13,204 is approximately 115. Therefore the sum of the two voltages is 115 volts. As we pointed out before, if you know how to handle squares and square roots, the mathematical solution is somewhat quicker but if you do not know how to do square root, then the vector solution is entirely satisfactory.

IMPEDANCE

Because the voltage that will appear across each component in an RC circuit will depend upon the resistance or reactance of the particular part, we can draw impedance diagrams to obtain the total impedance in the circuit using the same procedure we used to add the voltage in a circuit. As an example, suppose we have a 1000-ohm resistor connected in series with a capacitor having a reactance of 1000 ohms. If we want to find the total impedance in the circuit, we proceed as follows:

First, draw the current vector as shown in Fig. 24A. Since the voltage appearing across the resistor will be in phase with the current flowing, we draw a resistance voltage vector immediately on top of the current vector. The voltage across the resistor will depend on its resistance. If we use a scale of 1000 ohms equals 1 inch, the resistance vector R is drawn, as shown in Fig. 24B, 1 inch long.

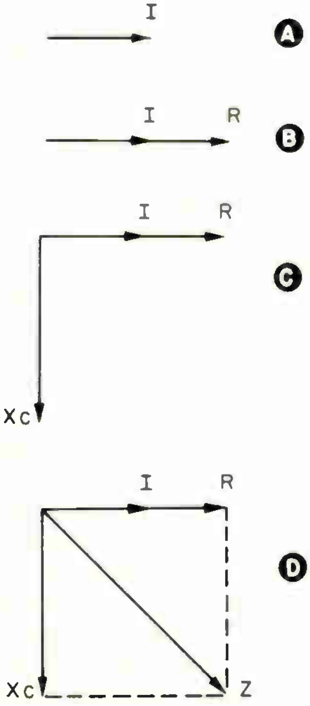

Fig. 24. Vector addition of resistance and capacitive reactance to find impedance.

Next, draw the vector shown in Fig. 24C to represent X_c. This vector also should be 1 inch long. It is drawn as shown, because the voltage appearing across the capacitive reactance will lag the current flowing in the circuit by 90 degrees.

We now complete the impedance diagram as shown in Fig. 24D, and you will find that the impedance vector Z will be 1.41 inches long. Since the scale we used was 1000 ohms per inch, the impedance of the circuit is 1410 ohms.

The same result could have been obtained mathematically by squaring the resistance and the capacitive reactance and adding the two together and taking the square root of the sum as indicated in the formula:

$$Z = \sqrt{R^2 + X_c^{\,2}}$$

It is important to notice the difference between the capacitive reactance and the inductive reactance. Notice that one is simply the opposite of the other. Notice that the impedance diagrams are drawn differently. In Fig. 25A, we see the solution of a circuit using a scale of 1000 ohms per inch where a 1000-ohm resistor is connected in series with the capacitor having a reactance of 1000 ohms. In Fig. 25B we

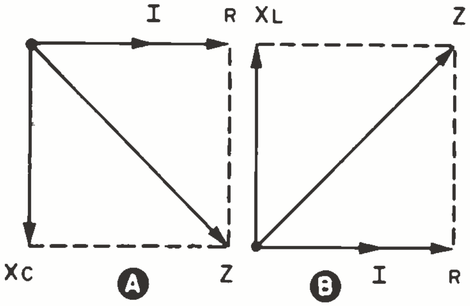

Fig. 25. When resistance and capacitive reactance are added as at A, the impedance vector lags the current; but when resistance and inductive reactance are added as at B, the impedance vector leads the current.

see an impedance diagram using the same scale, where a 1000-ohm resistor is connected in series with a coil having a reactance of 1000 ohms. Notice that we end up with the same impedance, 1410 ohms, in each case, but also notice the fact that in one case, the impedance vector leads the current vector, whereas in the other case, the impedance vector lags the current vector. In a later lesson, you will see more about these circuits and will also see the effect of having capacitive reactance and inductive reactance in the same circuit.

SUMMARY

In this section of the lesson you began the study of a very important phase of your course; you began to see what happens when resistance and capacitance are both used in the same circuit. You found that it takes a certain length of time for a capacitor to charge when the two are used in a dc circuit, and the length of time depends upon the size of the capacitor and the resistance in the circuit. The time-constant of a circuit is equal to the product of the resistance in megohms times the capacity of the capacitor in microfarads. The time-constant of the circuit is the length of time it would take to charge the capacitor to a value of 63% of the total voltage applied to the circuit.

You learned that in an ac circuit the current flowing in a capacitive circuit will lead the voltage by 90 degrees. In other words, a capacitive circuit acts exactly the opposite to an inductive circuit.

In an ac series circuit with a resistor and capacitor in series the voltage appearing across the resistance is not in phase with the voltage across the capacitor. If we have to add these voltages together, we must add them by means of vectors.

You also have learned that the impedance in an ac circuit using a resistor and a capacitor is the total opposition to current flow. The impedance can be obtained by means of the vector addition of the resistance plus the capacitive reactance in the circuit.

SELF-TEST QUESTIONS

(an) What do we mean by the time-constant of an rc circuit?

(ao) What is the time-constant of a .02 mfd capacitor charging through a 2.2 meg resistor?

(ap) If the time-constant of an rc circuit is 2 seconds when it is charged across a 10-volt battery, what will the time-constant be when it is connected across a 100-volt battery?

(aq) When a capacitor is connected across an ac generator, what is the phase relationship between the voltage and current in the circuit?

(ar) If a resistor and a capacitor are connected in series across an ac generator, what will the phase relationship between the voltage and current be?

(as) If a generator is connected across a resistor and a capacitor in series, what is the generator voltage if the voltage across the resistor is 9 volts and the voltage across the capacitor is 12 volts?

(at) What do we mean by the impedance in a series rc circuit in which a resistor is connected in series with a capacitor?

(au) If a 6-ohm resistance is connected in series with a capacitor having a capacitive reactance of 8 ohms, what will the impedance of the combination be?

LOOKING AHEAD

Up to this point in your course, you have been studying the basic action of a few important components found in electronic circuits. Other than tubes and transistors, the parts you will run into most frequently are resistors, coils, and capacitors or parts made of these three basic components. Now that you have studied each of these three parts separately, you are in a position to go ahead to see how they work together. A later lesson will discuss resonance. Resonance is perhaps one of the most important things you will study, because if it were not for resonant circuits many of the electronic miracles that we have today would not be possible.

ANSWERS TO SELF-TEST QUESTIONS

(a) When we say a capacitor is charged, we mean there is a surplus of electrons on one plate and a shortage of electrons on the other. When a capacitor is completely charged by connecting it across a voltage source, the voltage existing across the plates of the capacitor will be equal to the source voltage used to charge it.

(b) The length of time it takes to charge a capacitor is affected by the resistance in the circuit and the capacity of the capacitor.

(c) A charged capacitor does not have any more electrons on its plates than when it is discharged. Although the number of electrons on the two sets of plates is the same, some electrons have been removed from one plate and added to the other when the capacitor is charged.

(d) The capacity of the capacitor determines the amount of charge a capacitor can hold for a given applied voltage.

(e) The farad is the basic unit of capacity.

(f) The microfarad and the picofarad are the two practical units used in electronics. A microfarad is equal to one millionth of a farad, and the picofarad is equal to one millionth of a microfarad.

(g) 3300 pf. To convert microfarads to picofarads, you multiply by 1,000,000 or move the decimal point six places to the right.

(h) .00068 mfd. To convert picofarads to microfarads you divide by 1,000,000 or move the decimal point six places to the left.

(i) (1) the area of the plates (2) the spacing between the plates (3) the dielectric of the medium between the plates.

(j) The capacity will be doubled. The capacity of a capacitor is inversely proportional to the spacing between the plates. If you cut the spacing in half, the capacity will be doubled, but on the other hand if you double the spacing between the plates, the capacity will be cut in half.

(k) The dielectric constant of a material tells you how many times the capacity of the capacitor will be increased by substituting the material between the plates of the capacitor in place of air. In other words, if a material has a dielectric constant of 5, if you fill the spacing between the plates completely with that material, then the capacity will be increased five times from what it would be if the dielectric was air.

(l) The dielectric constant of air is 1.

(m) Ceramic-type materials have the highest dielectric. This is why ceramic capacitors of a given capacity will be smaller than any other type of capacitor.

(n) A material with a dielectric constant greater than air increases the capacity because it has the effect of reducing the spacing between the plates of the capacitor.

(o) The marking, 400 volts, on the capacitor means that the capacitor can be used in circuits having a dc voltage up to 400 volts. In other words, the rated maximum voltage at which the capacitor can be used is 400 volts. If you use a capacitor in a circuit where the dc voltage is 500 or 600 volts, the chances are it will break down in a short time. On the other hand a capacitor rated at 400 volts can be used in a circuit where the voltage is 300 volts or any value less than 400 volts.

(p) Air and mica.

(q) The stations on a high end of the band will be very close together and difficult to separate. On the other hand, the stations on the low end of the band will be spread out much more than they need be.

(r) A capacitor with straight-line frequency plates.

(s) The transmitter capacitor will have a much greater spacing between the plates than the receiver capacitor. The greater spacing is required to prevent arc over due to the high voltages used in the transmitter.

(t) Axial leads.

(u) To seal the capacitor so moisture can't seep into the capacitor and cause it to break.

(v) The capacitor should be replaced; a leakage resistance of 100,000 ohms is much too low for a paper capacitor.

(w) There are more economical types available which are almost as good as mica capacitors.

(x) In critical circuits where extremely stable capacitors are required.

(y) Tubular ceramic capacitors and disc type ceramic capacitors.

(z) Z5 indicates that the capacitor is designed for operation between 10° C and 85° C. The F indicates that the capacity will not change more than ±7.5% within the capacitor's normal operating range.

(aa) The two types of electrolytic capacitors are the wet and dry type. The dry type is used in modern electronic equipment; the wet type of capacitor is no longer made.

(ab) When we say a capacitor has polarity it means that it is made so that one plate must always be connected to a positive voltage and the other always to the negative voltage.

(ac) You should replace the electrolytic capacitor. The fact that it is getting very hot indicates that there is excessive current flow through it due to excessive leakage.

(ad) The capacitor should be formed. You can form it by placing a low voltage on it and gradually increasing the voltage until it is equal to or slightly exceeds the rated voltage of the capacitor. If you do not reform the capacitor and simply install it in the receiver, the chances are that it will break down.

(ae) Yes. Current flows from the generator to charge the capacitor with one polarity during one-half cycle, and then flows in the opposite direction to charge the capacitor with the opposite polarity during the next half cycle.

(af) No. Electrons flow into one plate and out of the other to charge the capacitor with one polarity during one half cycle, and then electrons flow out of the first plate and into the second to charge the capacitor with the opposite polarity during the second half cycle. Current flows back and forth in the circuit so that it has the effect of flowing through the capacitor and often we say that ac flows through a capacitor, but actually there is no electron flow across the dielectric of a capacitor unless the capacitor breaks down.

(ag) Capacitive reactance.

(ah) $X_c = \frac{1}{6.28 \times f \times C}$ where f is in cycles/second and C is in farads. Also

$$X_c = \frac{159{,}000}{f \times C}$$

where f is in cycles/second and C is in microfarads.

(ai) To find the capacitive reactance of the capacitor we use the formula:

$$Xc = \frac{159{,}000}{f \times C}$$

and substituting 150 for f and .02 for C we get:

$$Xc = \frac{159{,}000}{150 \times .02}$$

$$Xc = \frac{159{,}000}{3}$$

$$Xc = 53{,}000 \text{ ohms}$$

(aj) .32 mfd. To find the capacity of capacitors which are connected in parallel you simply add the capacities.

(ak) To find the capacity of the two capacitors connected in series we use the formula:

$$C_t = \frac{C1 \times C2}{C1 + C2}$$

and substituting 27 pf for C1 and 56 pf for C2 we get:

$$C_t = \frac{27 \times 56}{27 + 56}$$

$$C_t = \frac{1512}{83}$$

$$= 18.2 \text{ pf}$$

(al) Ohms.

(am) The complete statement should be: Increasing the capacity or the frequency in the circuit will result in a lower capacitive reactance and decreasing the frequency or capacity will result in a higher capacitive reactance.

(an) The time-constant of an rc circuit is the length of time it takes the capacitor to charge up to approximately 63% of the total source voltage.

(ao) .044 seconds. To find the time-constant you multiply the resistance in megohms by the capacity in microfarads. 2.2 × .02 = .044 seconds.

(ap) 2 seconds. The time-constant will be exactly the same because the charging voltage has no effect on the time-constant. The time-constant is determined solely by the value of the resistance and the capacitor in the circuit. In each case the capacitor will charge up to 63% of the applied voltage in 2 seconds.

(aq) The current will lead the voltage by 90°.

(ar) The current will lead the voltage by some angle less than 90°.

(as) 15 volts. You can use either a vector solution to get this answer or the mathematical solution using the formula:

$$Eg = \sqrt{E_R{}^2 + E_C{}^2}$$

$$Eg = \sqrt{9^2 + 12^2}$$

$$Eg = \sqrt{81 + 144}$$

$$Eg = \sqrt{225}$$

$$= 15 \text{ volts.}$$

(at) By impedance we mean the

total opposition to the flow of ac in the circuit. The impedance will be the vector sum of the opposition offered by the resistance plus that offered by the capacitive reactance of the capacitor.

(au) We can find the impedance using the formula:

$$Z = \sqrt{R^2 + X_C^2}$$

and substituting 6 ohms for R and 8 ohms for X_C we have:

$$Z = \sqrt{6^2 + 8^2}$$

$$Z = \sqrt{36 + 64}$$

$$Z = \sqrt{100}$$

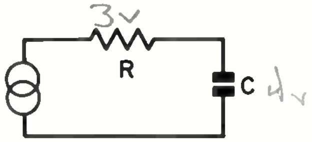
$$Z = 10 \text{ ohms.}$$

Lesson Questions

Be sure to number your Answer Sheet B107.

Place your Student Number on every Answer Sheet.

1. Name three types of solid dielectric capacitors.
2. Express .0001 mfd (microfarads) in pf (picofarads).
3. Can you use a .01-mfd, 600-volt capacitor in place of a .01-mfd, 400-volt capacitor?
4. What will happen to an electrolytic capacitor if you install it in a circuit with the wrong polarity?
5. What is the capacitive reactance of a 10-mfd capacitor at a frequency of 10 cycles?
6. What is the total capacity of a 6-mfd capacitor and an 8-mfd capacitor connected in parallel?
7. What is the total capacity of two 8-mfd capacitors connected in series?
8. What do we mean by the time-constant of an RC circuit?
9. What is the phase relationship between the voltage across a capacitor and the current flowing through the capacitor in an ac circuit?
10. If the voltage across R is 3 volts and the voltage across C is 4 volts, what is the generator voltage in the circuit shown?



THE VALUE OF COURTESY

A recent survey showed that people complain more about discourteous clerks than about any other fault a business could have. In fact, many people pay extra at higher-priced stores just to get the courtesy and respect they feel entitled to.

Regardless of whether you work for someone else or have a radio business of your own, plain ordinary courtesy can bring many extra dollars to you.

Courtesy becomes a habit if practiced long enough. Be courteous to everyone -- to members of your family, to those who don't buy from you, even to the very lowest persons who serve you -- then you can be sure you'll be courteous when it really counts.

Give your courtesy with a smile. There is an old Chinese proverb which says, "A man who doesn't smile shouldn't keep a shop." And you're keeping a "shop" even if you are selling only your ability and knowledge to an employer. A friendly smile is itself courtesy of the highest type, bringing you unexpected returns in actual money as well as friendship.

HOW RESISTORS, COILS, AND CAPACITORS ARE USED TOGETHER

B108

STUDY SCHEDULE

By dividing your study into the steps given below, you can get the most out of this part of your NRI Course in the shortest possible time. Check off each step when you finish it.

☐ 1. **Introduction** . . . . **Pages 1 - 2**

Here you get a general idea of how resistors, coils, and capacitors are used together.

☐ 2. **Series-Resonant Circuits** . . . . **Pages 3 - 16**

You study RL and RC series circuits, and learn the effects of varying inductance, capacitance, and frequency.

☐ 3. **Parallel-Resonant Circuits** . . . . **Pages 17 - 23**

You study the effect of varying resistance, capacity, inductance, and frequency in a parallel-resonant circuit.

☐ 4. **Comparison of Series-Resonant and Parallel-Resonant Circuits** . . . . **Pages 23 - 26**

You learn how to tell whether a circuit is a parallel-resonant or a series-resonant circuit, and study the important characteristics of each.

☐ 5. **How Resonant Circuits Are Used** . . . . **Pages 27 - 31**

You learn how resonant circuits are used to select desired signals and reject undesired ones.

☐ 6. **RC Circuits** . . . . **Pages 32 - 36**

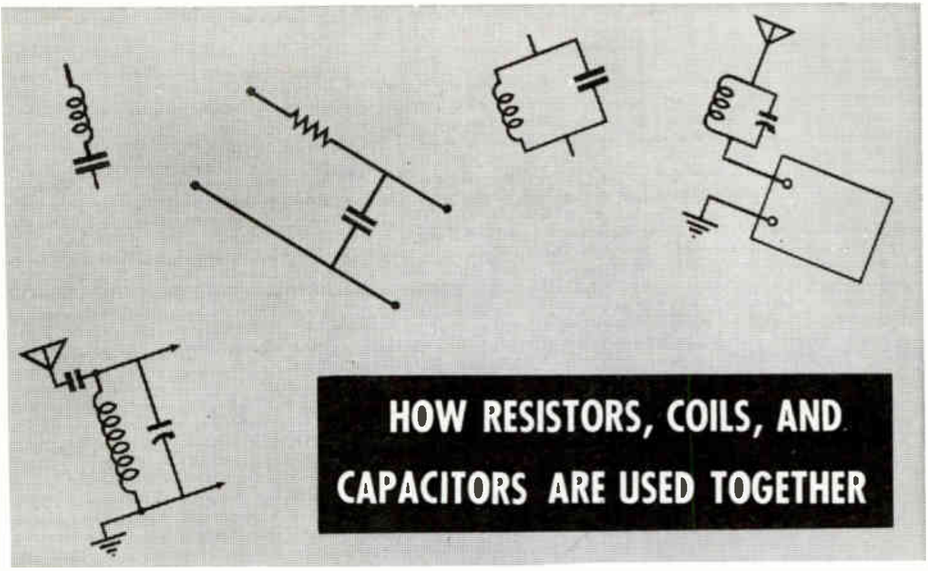
You study coupling circuits, differentiating circuits, and integrating circuits.

☐ 7. **Answers to Self-Test Questions** . . . . **Pages 37 - 40**

☐ 8. **Answer the Lesson Questions.**

☐ 9. **Start Studying the Next Lesson.**

JDL3M1174 1974 EDITION Litho in U.S.A.



HOW RESISTORS, COILS, AND CAPACITORS ARE USED TOGETHER

In the preceding lessons you have studied resistors, coils and capacitors. Other than tubes and transistors, these are the three most important parts you will run into in electronic equipment. In your studies of these parts you have been primarily concerned with the part itself, with its characteristics and briefly with how it is made. In electronic equipment these parts are seldom used alone; in most cases two or more of these parts will be used together. For example, in coupling circuits, you will often use combinations of resistors and capacitors to feed the signal from one audio stage to a second audio stage. Circuits of this type are referred to as RC coupling circuits.

You will run into circuits where coils and resistors are used together. Circuits of this type are referred to as RL circuits. You will also encounter circuits where coils and capacitors are used together. These circuits are referred to as LC circuits. In this lesson we will study all three types of circuits but will spend most of the time on LC circuits because these are perhaps the most important of the three.

From your studies of the coil and the capacitor you might remember that in many ways one is the opposite of the other. For example, in a circuit having only inductance, you will recall that the voltage leads the current by 90°. On the other hand, in a circuit having only capacitance, the voltage lags the current by 90°. In other words, we will get the exact opposite effect; with a coil we have a 90° leading voltage and with a capacitor a 90° lagging voltage.

In circuits where coils and capacitors are used together the two more or less work against each other. In some of these circuits, the circuit may act like a coil and the voltage will lead the current by some angle less than 90°. In other circuits you may find that the circuit acts like a capacitor and the voltage lags the current by some value less than 90°. In still other circuits the effect of the coil will cancel the effect of the capacitor so that the voltage and the current will be in phase. Circuits of this type are called resonant circuits. Resonant circuits are extremely important. They are used in radio and TV receivers to separate the various stations. In other words, a resonant circuit is used in a broadcast-band receiver to select the station you want to listen to and at the same time reject the unwanted stations. Resonant circuits are used in TV receivers to tune the set to the channel you want. Without resonant circuits there would be no way to separate the stations.

There are two types of resonant circuits. One is called a series-resonant circuit, and the other is called a parallel-resonant circuit. Whether a circuit is series-resonant or parallel-resonant depends upon how the voltage is applied to the coil and the capacitor in the circuit. Both types are important; we will study both and you will soon see how to distinguish one type from the other. Since it is a little easier to see exactly what is happening in a series-resonant circuit than it is in a parallel-resonant circuit, we will study the series-resonant circuit first.

Series-Resonant Circuits

A resonant circuit is a circuit in which the inductive reactance of the coil is equal to the capacitive reactance of the capacitor. When the voltage is applied to the coil and the capacitor in series we call the circuit a series-resonant circuit. To help you get a clear understanding of what a series-resonant circuit is, let us start with a simple series circuit and review some of the things you already know.

A SERIES CIRCUIT

Let's begin with the circuit shown in Fig. 1, consisting of a 500-cycle ac generator that is generating a voltage of 120 volts. Across this generator we will connect a variable resistor, which is set so that it has a resistance of 120 ohms. If we have a voltmeter connected across the resistor, the voltage reading will be close to 120 volts. This is true because the resistor is connected directly across the generator, and the voltage being supplied by the generator is 120 volts. An ammeter connected in series with the resistor will indicate that the current flowing in the circuit is 1 ampere. Actually, we do not need the ammeter to tell us this, because we know that we can determine the current by dividing the voltage by the resistance. Remember this formula for Ohm's Law:

$$I = \frac{E}{R}$$

Therefore

$$I = \frac{120}{120} = 1 \text{ amp}$$

In this simple circuit we know that the current will be in phase with the voltage, because the only element connected in the circuit is resistance. This means that the voltage across the resistor will reach its peak at the same time that the current flowing in the circuit is at a maximum.

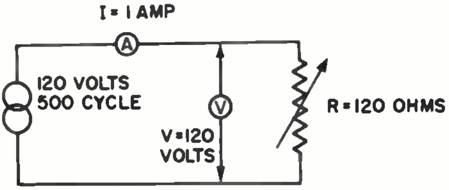


Fig. 1. A simple series circuit.

Remember that the voltmeter and the ammeter are measuring the effective value (or the rms value) of the ac voltage and current and that during part of the cycle, the generator voltage actually exceeds 120 volts. You will recall that the peak voltage of an ac sine wave will be 1.41 times the effective voltage. Therefore, even though the meter is reading 120 volts, the voltage will be greater than this value during part of the cycle and less than this value during the other part of the cycle. The voltage will actually be zero twice each cycle. Likewise, the current is the effective current and its actual value will be greater than 1 amp twice each cycle and less than 1 amp the remainder of the time. The current will reach a peak value of 1.41 amps twice each cycle and will actually drop to 0 twice each cycle.

AN RL CIRCUIT

Now let us see what happens when we modify the simple circuit of Fig. 1 by adding a 100-mh (millihenry) coil in series with the resistor as shown in Fig. 2. In Fig. 1 we showed the resistor as a variable resistor. We did this deliberately because you know that any coil will have some resistance. If the 100-millihenry coil has a resistance of 10 ohms, we can adjust the variable resistor so that its resistance is only 110 ohms. Now we will still have a total of 120 ohms resistance in the circuit: the 110 ohms from the resistor and the 10 ohms from the coil. In Fig. 2, we have represented the total resistance made up of the coil resistance and the resistance of the variable resistor as only one 120-ohm resistor. Notice that in Fig. 2 we have the ammeter in series with both the coil and resistor and have added a second voltmeter across the coil. But look at the readings on the meters! The ammeter shows that the current flowing is .35 amp. The voltmeters show that the voltage across the resistor is 43 volts, and the voltage across the coil is 112 volts. You have already seen this type of circuit, and probably know why we have obtained these readings, but let's go through this again to be sure you understand why such voltage readings are obtained. You may at first think this looks complicated, but actually it is not nearly as difficult as it might appear.

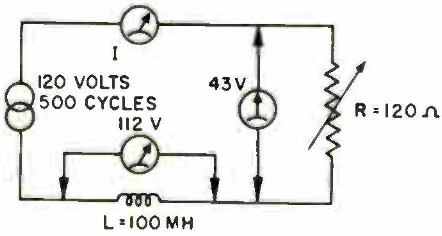

Fig. 2. A simple RL series circuit.

First, we have a series circuit. We know that the total opposition to the current flowing in the circuit will be the impedance of the circuit, which in turn is made up of the 120-ohm resistance plus the inductive reactance of the coil. We can find the inductive reactance of the coil from the formula:

$$X_L = 6.28 \times F \times L$$

Since 100-mh is .1 henry, L = .1 and F = 500 cycles, we have:

$$X_L = 6.28 \times 500 \times .1$$
$$= 314 \text{ ohms}$$

As you might expect, it is extremely difficult to make a coil with an inductance of exactly 100 millihenrys. Furthermore, we are not interested in exact calculations in most electronic circuits. To simplify things, we are going to call the inductive reactance of the coil 315 ohms. The impedance of the circuit is therefore equal to 120 ohms plus the reactance of 315 ohms. To show this by means of symbols, electronics men write this as

$$Z = 120 + j315$$

The letter j is used to indicate that 315 ohms is a reactive component which cannot be added directly to 120 ohms to get the total impedance of the circuit. If we simply wrote the impedance as 120 + 315, it would be very easy to forget that 120 was resistance and 315 was reactance and simply add the two and get 435 ohms, which of course, is incorrect.

The value of Z can be determined either by vectors as shown in Fig. 3 or from the formula

$$Z = \sqrt{R^2 + X^2}$$

In this case R is 120 ohms, and X is the inductive reactance, which is 315 ohms. So we have:

$$Z = \sqrt{120^2 + 315^2}$$

Remember that the small 2 to the right of 120 and 315 means that the number is to be squared, and that 120 squared is equal to 120 times 120. If you want to go through the arithmetic, the actual operations of squaring these numbers are as follows

$$\begin{array}{r} 120 \\ \times\ 120 \\ \hline 2400 \\ 120 \\ \hline 14400 \end{array} \qquad \begin{array}{r} 315 \\ \times\ 315 \\ \hline 1575 \\ 315 \\ 945 \\ \hline 99225 \end{array}$$

Now that we have the value of 120 and 315 squared, we have

$$Z = \sqrt{14{,}400 + 99{,}225}$$

and by adding these we will get

$$\begin{array}{r} 14400 \\ +\ 99225 \\ \hline 113625 \end{array}$$

Therefore $Z = \sqrt{113{,}625}$

To get the value of Z we have to take the square root of 113,625. This is done by first writing the number down and then marking it off in groups of two numbers working from the decimal point to the left. The steps in getting this square root are as follows:

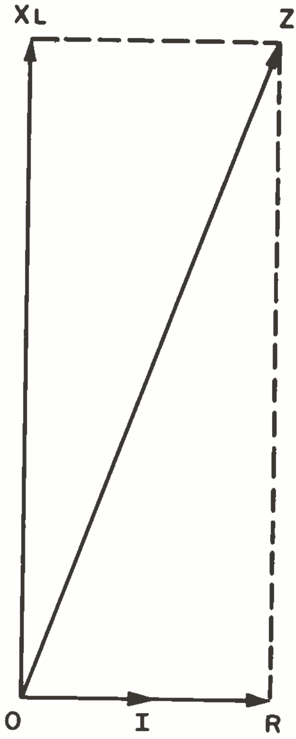

Fig. 3. Vector addition of R and X_L using a scale of 100 ohms = 1 inch, when R = 120 ohms, and X_L = 315 ohms. R is drawn 1.2 inches long, and X_L is drawn slightly less than 3.2 inches long. The impedance vector Z is then found by completing the rectangle and drawing Z from zero to the junction of the dotted lines. Z will measure between 3.25 and 3.5 inches, giving a Z of about 340 ohms.

$$\begin{array}{r|l} & \sqrt{11'\,36'\,25'} \quad \underline{|337} \\ & 9 \\ \underline{63} & \overline{2\,36} \\ & 1\,89 \\ \underline{667} & \overline{47\,25} \\ & 46\,69 \\ & \overline{56} \end{array}$$

Therefore, the impedance of the circuit is 337 ohms. We need not be concerned if there is a slight remainder when we work out the square root because electronic parts have considerable tolerance, and 337 ohms is close enough. As a matter of fact, in many practical problems you could probably round this off either to 335 or 340 ohms. However, we'll use 337 ohms.

Now that we know the total impedance in the circuit, we can determine what the current flowing in the circuit would be in this manner:

$$I = \frac{E}{Z} = \frac{120}{337} = .356 \text{ amp}$$

The ammeter we have connected in the circuit should and does read about .35 amp.

Now that we know the current flowing in the circuit, we can determine the voltage that will appear across the coil by multiplying the reactance of the coil by the current flowing in the circuit. In other words:

$$E_L = I \times X_L$$

Multiplying .356 × 315 we get 112.14 volts. We do not have to be concerned with such accuracy as this; we will simply call the voltage 112 volts. As a matter of fact this is the voltage indicated by the voltmeter connected across the coil; you cannot get a more accurate reading. Similarly, the voltage across the resistor is

$$E_R = I \times R$$

which is equal to .356 × 120, or 42.72 volts. We will round this off to 43 volts, which is what the meter will indicate.

Each of the steps that we have shown in the preceding example is important. It is not particularly necessary that you sit down and follow through the multiplication and division unless you want to do so. If you expect to go into radio and TV servicing you will have no occasion to do this type of work, but if you intend to go into industry as an electronics technician, you should be sure you understand the various steps in this circuit explanation.

Whether you go through the mathematics or not, there are several important points you should see. The current flowing in the circuit is limited by the impedance of the circuit. The impedance, as you know, is the total opposition to current flow in the circuit. The voltage that will appear across each part in the circuit will depend upon the resistance or reactance of that part and upon the current flowing in the circuit. Also, you should remember that in this example, although it may appear that the sum of the voltage across the coil plus the voltage across the resistance is greater than the source voltage, the meters are measuring the effective value of the voltage and that these voltages are not in phase. These voltages are ac voltages and hence continually changing, but the voltage across the resistor plus the voltage across the coil at any given instant is exactly equal to the source voltage at that instant.

THE RC CIRCUIT

Now, let's remove the 100-mh coil from the circuit and put a 1-mfd capacitor in its place. We will readjust the variable resistance so that the total resistance of the circuit is 120 ohms. We will then have the circuit shown in Fig. 4. Notice that

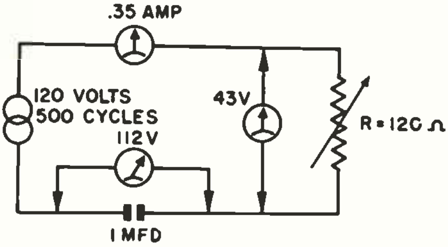

Fig. 4. A simple RC series circuit.

the voltage across the resistance is the same as in Fig. 2, and also notice that the voltage across the capacitor in Fig. 4 is the same as the voltage across the coil in Fig. 2.

We can verify all the meter readings shown in Fig. 4 as we did for the circuit shown in Fig. 2. To do this, we start by finding the reactance of the 1-mfd capacitor at 500 cycles from the formula:

$$X_C = \frac{1}{6.28 \times F \times C}$$

The capacitive reactance of the capacitor turns out to be 318 ohms. We will round this off to 315 ohms, because it is unlikely that the capacitor will have a capacity of exactly 1 microfarad. You do not have to go through the solution of this formula unless you want to, but for the benefit of those who want to work it out step by step we'll go through it.

First, remember that in the formula the frequency must be in cycles and the capacity must be in farads. Therefore, F = 500 cycles and C = 1 mfd = .000001 farad. Substituting these values in the formula we have

$$X_C = \frac{1}{6.28 \times 500 \times .000001}$$

Now we can start by multiplying 6.28 × 500 and we will get

$$\begin{array}{r} 6.28 \\ \times\ \ 500 \\ \hline 3140.00 \end{array}$$

Next, multiplying 3140 by .000001, we will get

$$\begin{array}{r} 3140 \\ \times\ .000001 \\ \hline .003140 \end{array}$$

The next step in our problem is to divide 1 by .003140. To perform the division we must get rid of the decimal point; to do this we move the decimal point six places in the divisor and six places in the dividend so that our problem becomes 1000000 divided by 3140:

$$.003140\overline{)1.000000}$$

$$\begin{array}{r} 318 \\ 3140\overline{)1000000} \\ \underline{9420} \\ 5800 \\ \underline{3140} \\ 26600 \\ \underline{25120} \\ 1480 \end{array}$$

As we mentioned we will round off the value of the capacitive reactance to 315 ohms. The difference is so small that whether it is 315 or 318 you won't be able to detect any difference in the meter readings in Fig. 4. Using 315 ohms as the capacitive reactance makes the total impedance of the circuit

$$Z = 120 - j315$$

Notice that in this case we have used -j to indicate that 315 ohms is a capacitive reactance. Actually, whether the sign is minus or plus will make no difference in determining the value of the impedance. We still use the formula:

$$Z = \sqrt{R^2 + X^2}$$

In this case, X is the capacitive reactance. Even though it is shown as -j315, it will still be + when squared, because any number squared is positive. Our formula is therefore the same as before:

$$Z = \sqrt{120^2 + 315^2}$$

The impedance works out again to be 337 ohms. The current flowing in the circuit can then be found by dividing the voltage by the impedance; this is 120 ÷ 337, or .356 amp. We can find the voltage across the resistor by multiplying the current, .356 amp, by the resistance, 120 ohms. Thus, .356 × 120 = 43 volts. Similarly, the voltage across the capacitor is .356 × 315, or 112 volts.

It is worthwhile to notice that since the circuit shown in Fig. 2 contains inductance and resistance the current will be lagging the voltage. In the circuit shown in Fig. 4 the current will be leading the voltage since we have capacitance and resistance. Nevertheless, the total impedance is the same in the two circuits; therefore, the currents flowing in the circuits are equal, which accounts for the equal voltage appearing across the resistors in each circuit.

Now let us see what happens when we go one step further and put the 100-mh coil in series with the 120-ohm resistor and the 1-mfd capacitor.

THE RESONANT CIRCUIT

In the circuit shown in Fig. 5, we have 120-ohm resistance in series with the 100-mh coil and the 1-mfd capacitor, and the series combination connected across the 120-volt, 500-cycle generator. The inductive reactance of the coil and the capacitive reactance of the capacitor will each be approximately 315 ohms as before, because the frequency in the circuit has not changed. Therefore, the total impedance in the circuit will be

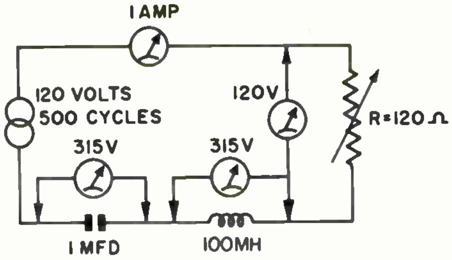

Fig. 5. A series-resonant circuit.

$$Z = 120 + j315 - j315$$

We have already pointed out that capacitive reactance is essentially the opposite of inductive reactance. We have indicated this by using +j to represent inductive reactance and -j to represent capacitive reactance.

In the expression for the impedance of the circuit you see +j315 and -j315, and, as you might expect, these two cancel so that the total impedance of the circuit is equal to the resistance of the resistor alone, or 120 ohms.

Now let's see what happens to the voltages and current throughout the circuit. First, look at the current flowing; it is 1 amp. It is higher than it was in Fig. 2 and Fig. 4. The reason for this is that the current is equal to

$$I = \frac{E}{Z}$$

Z in Fig. 5 is 120 + j315 - j315, or 120 ohms. Therefore I = 120 + 120, or 1 amp.

The voltage across the coil is 315 volts. This is equal to the current times the inductive reactance: 1 amp × 315 ohms = 315 volts. Similarly, the voltage across the capacitor will be equal to 315 volts. The voltage across the resistor is 120 volts. Notice what we now have across the capacitator and across the inductance: a voltage several times the source voltage. This is referred to as a "resonant voltage step-up." In other words, the voltage across the coil and the voltage across the capacitor in a series-resonant circuit may be several times the source voltage.

In the preceding example we saw that the impedance of the circuit at resonance is equal to the resistance in the circuit. Now you might wonder what happens when you change the resistance in the circuit. If you reduce the value of the resistance in the circuit, you will reduce the impedance. If we cut the resistance in half so that the total resistance in the circuit is only 60 ohms, the current flowing in the circuit will be doubled. We will then have the situation shown in Fig. 6. Here the voltage drop across the capacitor is equal to 2 amps × 315 ohms, or 630 volts. Similarly, the voltage appearing across the coil will be 630 volts and the voltage across the resistor will be 2 amps × 60 ohms, which is equal to 120 volts as before. Now we have an even greater resonant voltage step-up than we had previously. Reducing the resistance still further will result in an even greater voltage appearing across the coil and across the capacitor.

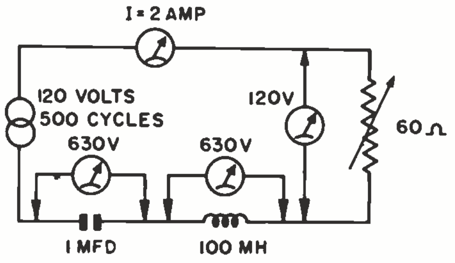

Fig. 6. Reducing the resistance in the series-resonant circuit results in a greater current flow and a higher resonant voltage step-up.

In a practical resonant circuit, we will have only a capacitor and a coil in series. However, there will always be resistance in the circuit because the coil is made by winding turns of copper wire on a coil form, and the copper wire has resistance. However, the lower that resistance can be made, the lower the impedance of the circuit and the greater the resonant voltage step-up will be.

This can be expressed in another way. The Q of a coil is equal to the inductive reactance divided by the resistance of the coil. In other words:

$$Q = \frac{X_L}{R}$$

In a coil where the resistance is low, the value of Q will be high. Since the lower the resistance we have, the greater the resonant step-up voltage will be, we say that there will be more resonant voltage step-up in a high-Q circuit than in a low-Q circuit.

Series-Resonant Facts.

Before going ahead with our study of series-resonant circuits, we should review several of the things that we have already discussed.

First, in a series-resonant circuit at resonance the inductive reactance is exactly equal to and cancels the capacitive reactance in the circuit so that the impedance of the circuit is equal to the resistance in the circuit. The impedance in the circuit will therefore be low, and the current flowing in the circuit will be high. Second, there is a resonant voltage step-up in a series-resonant circuit.

Remember these two facts -- they are important: in a series-resonant circuit you will have low impedance and high current and the voltage appearing across either the capacitor or inductance may be several times the source voltage.

Resonance occurs when the inductive reactance of the coil exactly equals the capacitive reactance of the capacitor. In other words,

$$X_L = X_C$$

$$6.28 \times F \times L = \frac{1}{6.28 \times F \times C}$$

and from this we can get:

$$F = \frac{1}{6.28 \times \sqrt{L \times C}}$$

This is the frequency at which a coil and a capacitor will be resonant.

VOLTAGE AND CURRENT WAVEFORMS IN THE SERIES-RESONANT CIRCUIT

In any series circuit, the current is always the same in all parts of the circuit. This is true whether it is a resonant circuit or a simple series circuit consisting of a number of resistors. Therefore, in a circuit such as the one shown in Fig. 7A the current flowing through the generator will be equal to the current flowing through the coil at all times, whether the circuit is resonant or not. This current is also equal to the current flowing through the resistor and to the current flowing through the capacitor.

If the circuit shown in Fig. 7A is a resonant circuit, we can make use of the fact that the current is the same at all times in all parts of the circuit to get a better idea of what is happening. We can do this by studying the voltage and current waveforms throughout the circuit. For example, we have shown two cycles and have identified a number of points on these cycles by numbers in Fig. 7B. This waveform represents the entire current flowing in the series-resonant circuit.

Look at the current waveform at point 1 and notice that the current begins swinging in a positive direction. Let's assume that at this instant the voltage at terminal a of

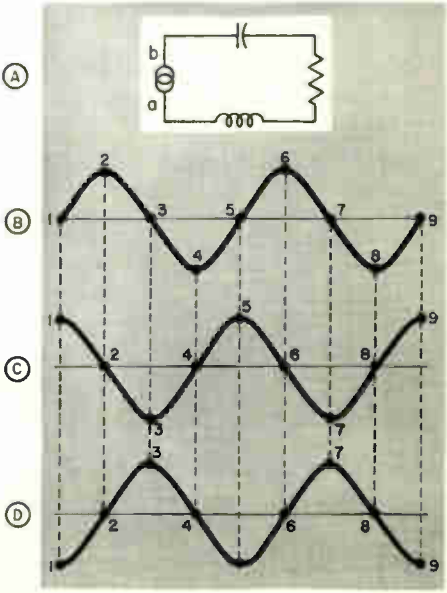

Fig. 7. Series-resonant circuit waveforms.

the generator begins to swing in a negative direction so that current starts flowing at terminal a through the coil and around the circuit back to terminal b of the generator. As the waveform increases in amplitude from point 1 to point 2, current increases in the circuit going from 0 at point 1 to its maximum value at point 2.

Although we have started the waveform shown in 7B at point 1, we are actually representing what happens in a series-resonant circuit in which the current has been flowing for some time. In other words, the circuit has been connected to the generator (which is producing the current) and we simply started to analyze what is happening in the circuit at the given instant designated at point 1 on the curve B. At this instant the current flowing in the circuit has just reached 0 and has begun to increase towards point 2 as electrons move from terminal a of the generator around the circuit towards terminal b of the generator.

Fig. 7B is a sine wave. A sine wave changes value at a maximum rate at the instant it is going through 0. In other words, at point 1 the rate at which the value of the current (represented by the sine wave) changes is at a maximum. As the actual current amplitude increases towards point 2, the rate of change decreases until for an instant at point 2 there is no change in current. The current has reached its maximum value, it remains constant for just an instant at point 2, and then begins to decrease. The rate at which it decreases increases until it is changing at its maximum rate when it reaches point 3. For just an instant the current drops to 0 at point 3. Thus, the current goes through a complete change - the instant before it reaches point 3 it is flowing in one direction, it drops to 0 exactly at point 3 and then an instant later it is flowing in the opposite direction.

Now let us consider what effect this changing current has on the voltage across the coil. Remember that the self-induced voltage in a coil depends upon the rate at which the current flowing through the coil changes. Therefore, at point 1, since the current is changing at its maximum rate, the self-induced voltage induced in the coil will be at maximum. As the current increases in amplitude towards point 2, the rate at which it is changing decreases so the voltage induced in the coil decreases. At point 2, where the current is not changing at all, the voltage induced in the coil will be 0. This is shown by the portion of curve C between points 1 and 2. Now, as the current begins to decrease from point 2 to point 3 the rate at which the current is changing increases. Since the current is decreasing, a voltage is induced in the coil which tends to oppose the direction in which the current is changing. Therefore, as the current goes from point 2 to point 3 (as shown in the curve at B), the voltage across the coil will increase from 0 at point 2 to its maximum value at point 3 (as shown in the curve at C).

Notice that the voltage across the coil is leading the current by 90°. If you remember your earlier studies, this is exactly what you might expect. As the current goes through the remainder of its cycle (as shown from point 3 on over to point 9), the voltage across the coil will at all times be 90° ahead of this current.

Now let us consider what must be happening across the resistor and capacitor in the circuit. At point 1 on curve B the actual value of the current flowing is 0. Therefore, the voltage across the resistor must be 0 because it will be in phase with the current. We have not drawn a wave shape to represent the voltage across the resistor because it will be in phase with the current waveform shown at B at all times.

Since the voltage across the generator is 0 at point 1 and the voltage across the resistor is also 0 at point 1, we immediately see that the voltage across the capacitor must be exactly equal to and opposite to the voltage across the coil. We know this must be true because in any closed circuit of this type the algebraic sum of the voltage drops around the circuit must be equal to 0. Indeed, if the circuit has been in operation the capacitor would be charged with a polarity equal to and opposite to the voltage across the coil at the instant that the current was at 0, as at point 1. As the current increases from point 1 to point 2, electrons will flow into the capacitor to reduce the charge until at point 2 the charge on the capacitor will be exactly equal to 0. As current continues to flow in the same direction (as shown from point 2 to point 3 on curve B) electrons will continue to flow into one plate of the capacitor and charge it (as shown between points 2 and 3 on curve D).

Notice what has happened. At each instant, the voltage across the capacitor is equal to and opposite to the voltage across the coil. Also notice that the voltage across the capacitor is lagging the current flowing in the circuit by 90°. This is as we should expect; when you studied capacitors in earlier lessons, you learned that the voltage lags the current in a capacitor by 90°.

The curves in Fig. 7 show what happens in a series-resonant circuit and why the voltages around the circuit (if they are measured separately, then added together) will be equal to a value greater than the source voltage. If you measure the capacitor voltage you'll be measuring the rms value of the waveform shown at D. If you measure the coil voltage you will be measuring the rms value of the curve shown at C. While these voltages do exist across the components, they are always 180° out of phase and therefore as far as the total voltage across the two is concerned they cancel each other.

In a series-resonant circuit that has a pure inductance and a pure capacitance in series with a resistor, the voltage across the inductance is exactly cancelled by the voltage across the capacitance. In this case, the applied voltage is developed across the resistor. However, pure inductors and capacitors do not exist. All coils have some resistance and all capacitors have some leakage. Therefore, the voltages across the coil and capacitor do not exactly cancel. Thus, a small voltage can be measured across the coil-capacitor combination.

Before going on to the next section of the lesson it would be worthwhile to study carefully the waveforms shown in Fig. 7 to be sure you understand what is happening. It might make it easier for you if you can redraw the circuit and place a resistor next to the generator instead of between the coil and the capacitor. Actually, insofar as the current flow in the circuit and the voltage across the individual parts in the circuit are concerned, it makes no difference where the parts are placed. However, to see how the voltages across the coil and capacitor are cancelling, it might be easier to see this if you move the resistor so that it is not between the two.

VARYING L, C, F, AND R

When the inductive reactance in a series circuit is equal to the capacitive reactance, the circuit is at resonance, the two cancel each other, and we will have a low-impedance circuit in which we will get a high current flow. Let us see what happens if we use other values of C and L and if we vary the frequency of the voltage applied to the circuit. Let's start by seeing what will happen when we vary the value of the capacitor.

Varying C.

We can vary the value of C by inserting capacitors of different sizes in the circuit in place of the 1-mfd capacitor, while leaving the source frequency at 500 cycles and the coil inductance at 100 millihenrys. The current in the circuit will vary as shown in Fig. 8. Notice that we have the highest current flowing exactly at resonance. As the capacity is reduced, the current drops off rather sharply. It is important for you to realize that as the capacity is made smaller than it should be for resonance, the capacitive reactance in the circuit increases so that it is greater than the inductive reactance. Therefore, the inductive reactance does not completely cancel out all the capacitive reactance in the circuit, and the resonant circuit begins to act like a circuit having only capacity. In other words, the current flowing in the circuit will lead the voltage.

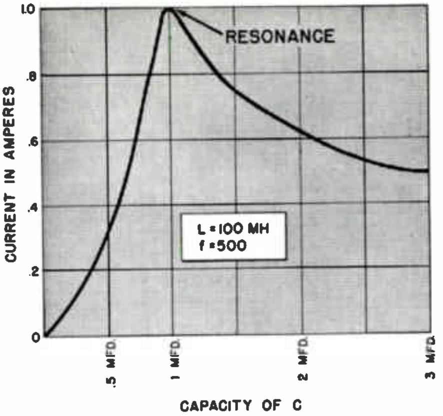

Fig. 8. How current varies in a series-resonant circuit when L is 100 mh, F is 500 cycles, and C is varied from 0 to 3 mfd.

As the capacity is increased above 1-mfd, the capacitive reactance decreases so that the inductive reactance in the circuit is greater than the capacitive reactance. Therefore, the inductive reactance cancels out all of the capacitive reactance and there is still some inductive reactance left over. The circuit begins to act like a circuit having only inductance in it and the current will lag the voltage.

In either case, when the capacity is too small or too high for resonance, the impedance of the circuit is greater than it is at resonance; this accounts for the reduction in current flow in the circuit.

Varying L.

If the inductance in the circuit is varied instead of the capacity, the current will vary as shown in Fig. 9. Here, when the size of the inductor or coil is reduced, the inductive reactance is decreased, and it will not completely cancel out the capacitive reactance in the circuit. The circuit will act like a capacitor, and the current will lead the voltage.

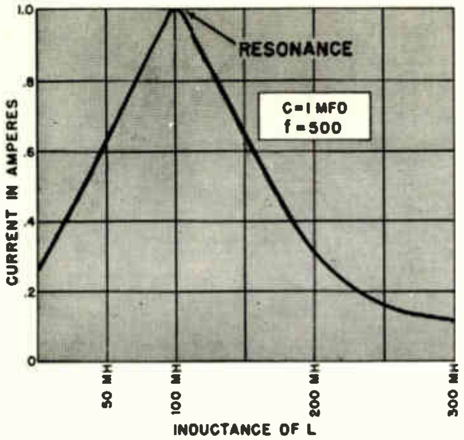

Fig. 9. How current varies in a series-resonant circuit when C = 1 mfd, F = 500 cycles, and L is varied from 0 to 300 mh.

When the inductance is made greater than 100-mh, then the inductive reactance is greater than the capacitive reactance and the circuit will act as an inductance. This means that the current will lag the voltage. Again, the current will be lower than at resonance when the inductance is made either too large or too small because the impedance in the circuit increases. Lowest impedance is obtained in a series-resonant circuit at resonance, when the inductive reactance cancels the capacitive reactance. Current will always be at maximum at this point.

Varying Both L and C.

The combination of a 100-mh coil and a 1-mfd capacitor is not the only combination that will give resonance at 500 cycles. If we double the inductance of the coil by using a 200-mh coil in the circuit, the inductive reactance of the coil will be doubled. It will be twice 315 ohms, or 630 ohms. If we reduce the size of the capacitor from 1-mfd to .5-mfd, we will also double the reactance of the capacitor so that its reactance will now be 630 ohms at 500 cycles. This means that with a 200-mh coil and a .5-mfd capacity, we will again have a situation where the inductive reactance will be equal to the capacitive reactance; therefore, these components will be resonant at 500 cycles.

You can see that many values of coil and capacitor may be used to obtain resonance at 500 cycles. Once we select a coil, it will have a certain inductive reactance at a frequency of 500 cycles. All we need is to obtain a capacitor that will have a capacitive reactance equal to the inductive reactance of the coil at this frequency, and we will have a resonant circuit at 500 cycles.

Varying F.

If we go back to the 100-mh coil and the 1-mfd capacitor and then vary the frequency of the voltage applied to this combination, we will obtain a curve like the one shown in Fig. 10. Notice that in this case we have maximum current flow at resonance, because at resonance the impedance of the circuit is lowest. When the frequency applied to the coil and capacitor combination is less than 500 cycles, the capacitive reactance of the capacitor is greater than the inductive reactance of the coil, so the combination acts like a capacitor and the current will lead the voltage.

When the frequency applied to the combination is above 500 cycles, then the inductive reactance of the coil is greater than the capacitive reactance of the capacitor, and the circuit will act like a coil. In either case, the impedance of the circuit will be minimal at resonance and higher either above or below the resonant frequency. The fact that the impedance reaches its minimum at the resonant frequency of 500 cycles is the reason the current is at maximum.

Varying R.

Under certain circumstances, the total resistance in the circuit may be varied. As the resistance in the circuit is changed, the Q of the circuit changes and the current that will flow in this circuit changes. In Fig. 11, we have shown three resonance curves. The curve marked A is the one we had in Fig. 10 with a 100-mh coil, a 1-mfd capacitor, and a series resistance of 120 ohms. In the curve marked B, the inductance and capacity are the same, but the series resistance is 100 ohms.

Changing the resistance has an important effect on the shape of a resonant curve, as shown in Fig. 11.

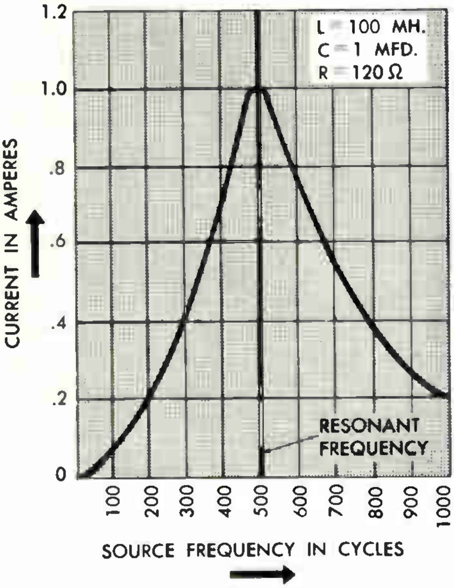

Fig. 10. How current varies in a series-resonant circuit when C = 1 mfd, L = 100 mh, R = 120 ohms, and F is varied from 0 to 1000 cycles.

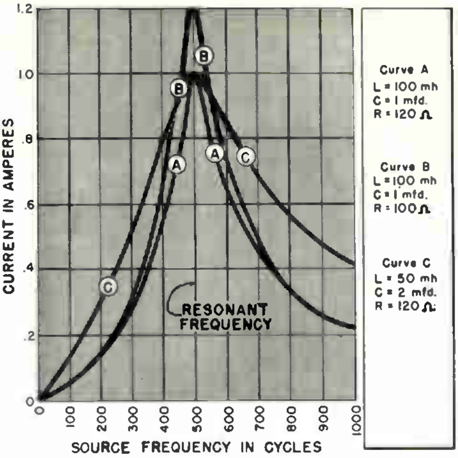

Fig. 11. How the current varies in a series-resonant circuit when F is varied, and (A) C = 1 mfd, L = 100 mh, and R = 120 ohms; (B) C = 1 mfd, L = 100 mh, and R = 100 ohms; (C) C = 2 mfd, L = 50 mh, and R = 120 ohms. In each case the product of L and C is the same, and resonance occurs at 500 cycles.

With a high-Q circuit, which is obtained when the resistance of the circuit is low, we have a very sharp curve. This means that we will get a much higher current flow at the resonant frequency of the circuit than we will get at a frequency either slightly above or slightly below the resonant frequency. However, with a low-Q circuit, we have a broad curve. This means that we can vary the frequency quite a bit either above or below the resonant frequency without causing a very great change in the current that will flow in the circuit.

The effect of resistance on a series-resonant circuit is important. Sometimes a series-resonant circuit may be used to select one frequency and reject all others. Obviously, if we have a high-Q circuit it will do a much better job of selecting one frequency and rejecting others than a low-Q circuit will. However, there are other instances when we are interested in selecting a band of frequencies rather than one particular frequency. In this case, a low-Q series-resonant circuit is used rather than a high-Q circuit which might not select the entire band or group of frequencies in which we are interested.

The curve marked C in Fig. 11 is the one we would obtain with a 50-mh coil, a 2-mfd capacitor and a series resistance of 120 ohms. Compare this curve with curve A. Notice that curve A is considerably sharper than curve C. The ratio of the inductance to the capacity is called the L to C ratio. In a series-resonant circuit a high L to C ratio will give you a sharper resonance curve than a low L to C ratio.

SELF-TEST QUESTIONS

(a) What is a resonant circuit?

(b) What do we mean when we say that the current flowing in the circuit in Fig. 1 is 1 amp?

(c) In a circuit such as the one shown in Fig. 2, why can we not simply add the voltage across the coil and the voltage across the resistor to find the total circuit voltage?

(d) The impedance of a circuit is given as $Z = 50 + j50$; what does the j mean?

(e) In an RC circuit, which part will have the greater voltage across it?

(f) In a series-resonant circuit, how will the phase of the voltage across the various components compare with the phase of the current flowing in the circuit?

(g) What do we mean by the Q of a coil?

(h) When a coil and a capacitor are connected in series, and the frequency of the voltage applied to them is varied, at what point will the current flowing in the circuit reach its maximum value?

(i) What effect on the current flowing in a series-resonant circuit will reducing the resistance in a circuit have?

Parallel-Resonant Circuits

When the source voltage for a resonant circuit is supplied across the coil and capacitor (that is, in parallel with them), as in Fig. 12, we have a parallel-resonant circuit. In a parallel-resonant circuit, as in a series-resonant circuit, the inductive reactance of the coil is exactly equal to and cancels the capacitive reactance of the capacitor. This is essentially where the similarity between the two types of resonant circuits ends. In most respects, a parallel-resonant circuit acts in the opposite way to a series-resonant circuit. Let's investigate the characteristics of this type of resonant circuit and see why it performs as it does.

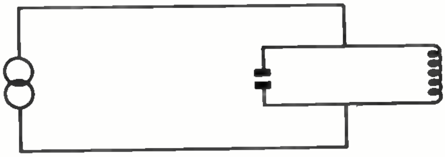

Fig. 12. A parallel-resonant circuit.

CIRCUIT CURRENT AND IMPEDANCE

In Fig. 13 we have shown a parallel-resonant circuit connected in series with a 120-ohm resistor across a 120-volt, 500-cycle generator. The coil has an inductance of 100 mh and the capacitor has a capacity of 1 mfd. All the conditions are as they were when we studied the series-resonant circuit. We have connected an ammeter in series with the resistor and the parallel-resonant circuit, a voltmeter across the coil and capacitor combination, and another voltmeter across the resistor.

In this type of circuit you can notice immediately that the current being supplied by the generator is very low. In addition, the voltage across the resistor is very low and nearly the entire source voltage appears across the resonant circuit.

The fact that the current flowing in the circuit is low immediately points out one important fact -- if the current flowing in the circuit is low, the impedance of the circuit must be high. In fact, this is the case; one of the most important characteristics of a parallel-resonant circuit is that at the resonant frequency it acts as a high-value resistance. Notice that this is just the opposite of a series-resonant circuit: at resonance a series-resonant circuit acts as a low resistance.

The fact that the parallel-resonant circuit acts like a high resistance explains why most of the source voltage appears across the resonant circuit and very little voltage appears across the 120-ohm resistor. The

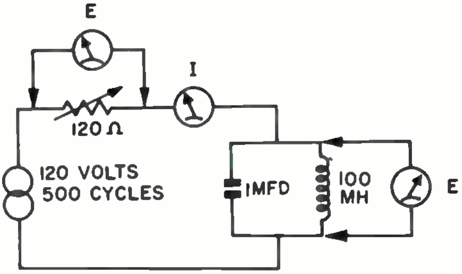

Fig. 13. In a parallel-resonant circuit, the current supplied by the generator is low, and most of the generator voltage appears across the resonant circuit.

120 volts supplied by the generator is simply divided between the resistor and the resonant circuit, with most of the voltage appearing across the higher resistance. Now let's study the parallel-resonant circuit in detail to see why it acts like a high value resistance.

Since the coil and capacitor in the parallel-resonant circuit are connected in parallel, there are two paths or branches through which current can flow. We call the path with the capacitor in it the capacitive branch, and the one with the inductance in it the inductive branch. If we connect an ac ammeter in each branch of the parallel-resonant circuit as shown in Fig. 14, we will discover that although we have a very low current being supplied by the generator, we have a very high current in each branch of the resonant circuit. You might wonder how this could be, but if we consider each branch separately we can see what is happening.

First, in a capacitive circuit we know that the current leads the voltage by 90°; in an inductive circuit the current lags the voltage by 90°. Therefore, the current flowing in the capacitive branch will be 180° out of phase with the current flowing in the inductive branch. The fact that the currents I_1 and I_2 are 180° out of phase means that the capacitor is discharging during one half cycle while the coil stores up electrical energy. During the next half cycle when the coil is releasing the electrical energy it has stored, the capacitor is charging. When the reactance of the coil is equal to that of the capacitor, as it will be at resonance, the energy stored by the capacitor equals the energy released by the coil; and during the other half of the cycle, the energy stored by the coil equals the energy released by the capacitor.

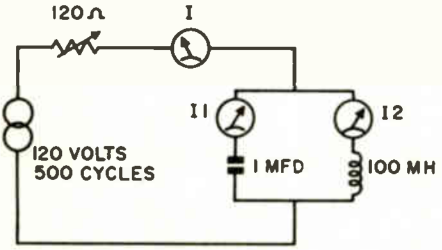

Fig. 14. Although the current supplied by the generator is low, the current flowing in each branch of a parallel-resonant circuit is high.

Thus the coil and the capacitor pass current back and forth to each other inside the resonant circuit. The actual amplitude of the current will depend upon the amount of resistance in the circuit. You know that the coil will have some resistance, and in addition, the leads connecting the coil and capacitor together have some resistance. However, because the resistance is usually kept quite low there can be a very high current flowing back and forth between the coil and the capacitor.

The fact that there is resistance in the circuit means that there will be some energy lost during each cycle. The very low current being supplied by the generator actually replaces the energy lost as heat because of the resistance in the resonant circuit.

The situation in the parallel-resonant circuit may be compared to the pendulum of a clock. The pendulum swings back and forth, and the current does essentially the same thing; it flows out of the coil into the capacitor and then back from the capacitor into the coil. If the pendulum in a clock were swinging freely, it would lose energy each oscillation due to friction and each arc would be smaller than the previous one; finally, it would come to rest. In a parallel-resonant circuit the current will flow back and forth and get smaller each cycle and eventually drop to zero unless some outside energy is supplied to it. The mechanical drive in the clock supplies the energy to the pendulum to keep it swinging; in the resonant circuit, the generator across the circuit supplies the energy to make up the losses in the circuit. Once the action of the current flowing back and forth in a parallel-resonant circuit has started, it will continue for a number of cycles until all the energy is used up in the resistance in the circuit. Similiarly, the pendulum of a clock will swing back and forth for a number of cycles once it is started in motion even if no additional energy is supplied to it.

The situation we have found in the parallel-resonant circuit exists at all times when a coil and capacitor are connected in parallel in an ac circuit. One feeds energy or current back into the circuit while the other draws current. Therefore, the current supplied by the generator at any instant will be the difference between the two currents. When the reactances are equal, as they are at resonance, then this current becomes the minimum current needed to make up the losses in the parallel-resonant circuit. Because the current does drop to a minimum value at resonance, the parallel-resonant circuit acts like a resistor of high ohmic value and reduces the line current supplied by the generator to a very low value.

At resonance, the inductive and capacitive currents are equal to each other and opposite in phase. The net result is zero current. Since the current is zero, the circuit acts as a high resistance. The current supplied to a parallel-resonant circuit by the generator will be in phase with the generator voltage. The actual resistance of the parallel-resonant circuit can be obtained by measuring the voltage across it and dividing it by the current supplied by the generator. This effective resistance is known as the resonant resistance of the circuit.

There is a resonant voltage step-up in a series-resonant circuit. This is not the case, however, in a parallel-resonant circuit since the coil and the capacitor are connected in parallel. The current flowing between the coil and the capacitor is much higher than the current supplied by the generator. Therefore, we have a resonant current step-up in a parallel-resonant circuit. In a high-Q circuit of the latter type, the current flowing back and forth may be many times the line current.

VARYING R, L, C, AND F

Varying R.

You will remember that all coils have a certain amount of resistance which gives the effect of a resistor connected in series with the coil. This resistance can be changed by changing the size of the wire used to wind the coil while at the same time keeping the inductance of the coil constant.

If we use a circuit like the one shown in Fig. 15 to study the effect of varying the resistance in series with the coil, we will find that with the resistance set at a minimum, the coil current is equal to the capa-

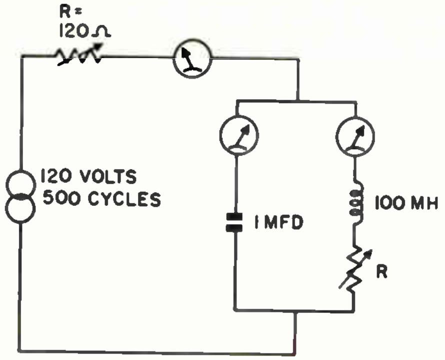

Fig. 15. Increasing R will increase the line current, which means that the resonant resistance of the resonant circuit has decreased.

citor current, and that the line current is very low. If we increase the value of the resistance R, the coil current will decrease slightly and the capacitor current will remain the same, but the line current will increase. This means that the resonant resistance of the parallel-resonant circuit must decrease in order for the line current to increase. From this we can see that the lower the coil resistance in a parallel-resonant circuit, the higher the resonant resistance and the lower the line current will be.

We mentioned earlier that once the current starts flowing back and forth in a parallel-resonant circuit, it will continue for a number of cycles even though the generator voltage may be removed. How quickly the current flowing in the circuit drops to zero depends upon the resistance in the circuit. If the resistance in the circuit is high, the energy in the circuit will be dissipated quickly in the resistor and the current will drop to zero in a few cycles. On the other hand, if the resistance in the circuit is very low, there will be very little energy lost each cycle and the back and forth action of the current may continue for a large number of cycles.

Varying C.

In the parallel-resonant circuit with a 100-millihenry coil, we will obtain resonance at 500 cycles when the capacity in parallel with the coil is 1 mfd. The line current will be minimal at this point.

If we set R to zero and try different values of capacitors in parallel with the coil, recording the line current for each capacitor, we could obtain the data to plot a curve like the one shown in Fig. 16. Notice that at resonance the line current drops to a low value. When the capacity is less than 1 mfd, the current rises until it is about .35 amp at zero capacity. Under these circumstances, with no capacity in parallel with the coil, the current flowing in the circuit will be limited by the inductive reactance of the coil and the amount of resistance in the circuit.

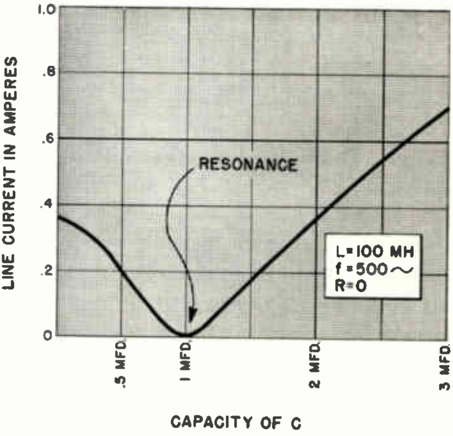

Fig. 16. How the line current varies when the capacity of the capacitor in a parallel-resonant circuit is varied.

When the capacity is reduced to zero, we have a circuit like the one in Fig. 2. However, as capacity is placed in parallel with the coil, the line current begins to drop until finally at resonance it is practically zero.

As the capacity is increased beyond 1 mfd, its reactance decreases, so you will find that the capacitor current will start to increase, the line current will increase, and the coil current will remain essentially unchanged. Here the increase in line current is due to the fact that the capacitor current becomes greater than the coil current and hence part of the capacitor current must be drawn from the line.

When the capacity is less than that required for resonance, the increase in line current is due to the fact that the coil current is greater than the capacitor current and part of the coil current must be drawn from the line.

It is interesting to note that when the capacity in the circuit is .5 mfd, the current is considerably higher than it was when the circuit was at resonance. This is because the capacitive reactance in the circuit is considerably higher than the inductive reactance. If the frequency applied to the circuit were increased, the inductive reactance would increase, and the capacitive reactance would decrease. By increasing the frequency by the correct amount, we could eventually reach the point where the inductive reactance would be equal to the capacitive reactance of the .5 mfd capacitor; once again we would have resonance.

Varying L.

If we put different coils in the circuit, while at the same time keeping the source frequency at 500 cycles, we will find that we have an effect somewhat similar to the effect of changing the value of the capacitor. The line current will be increased when the inductance is made either too large or too small for resonance. If the inductance is below the value needed for resonance, the circuit will act exactly as it did when too low a capacity was used; when the inductance is too high for resonance, the circuit will act as it did when the capacity was too high.

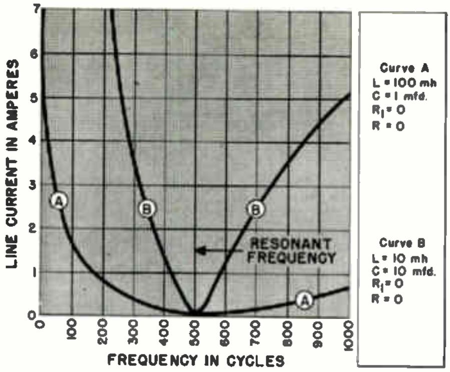

Fig. 17. How the line current varies when the frequency is varied in a parallel-resonant circuit.

Varying F.

In Fig. 17 we have a graph that shows how the line current will vary as the frequency applied to the resonant circuit is changed, if both resistors are set at zero. If we started with 0 cycles, which is dc, we would have a very high current. At this frequency there would be no current through the capacitor, and the inductive reactance of the coil would be zero. The only thing limiting the current flow in the circuit would be the resistance of the coil and of the leads used to connect it to the voltage source. However, as the frequency applied to the circuit increases, the line current drops until at 500 cycles the current is practically zero. As the frequency is increased beyond resonant frequency, the current will increase slowly. The increase in line current is due to the drop-off in the capacitive reactance of the capacitor. Current flowing through the coil will continue to decrease as the frequency is increased, because the inductive reactance of the coil will increase with the frequency.

At a frequency below the resonant frequency of the circuit, most of the current flows through the coil, and hence the parallel-resonant circuit acts as a coil. Right at resonance the circuit acts as a very high resistance, and above the resonant frequency the current flowing through the capacitor will be greater than the current flowing through the coil; hence, the resonant circuit will act as a capacitor.

The curve marked A in Fig. 17 represents an inductance of 100 mh and a capacity of 1 mfd. This circuit is resonant at 500 cycles, because the inductive reactance of the coil is equal to the capacitive reactance of the capacitor at this frequency. However, if we reduce the inductance to 10 mh and increase the capacity to 10 mfd, we will again have a situation where the inductive reactance is equal to the capacitive reactance at 500 cycles. In other words, a 10-mh coil will form a parallel-resonant circuit with a 10 mfd capacitor at a frequency of 500 cycles. The curve we would obtain by varying the frequency of the voltage applied to the parallel-resonant circuit made up of the 10-mh coil and the 10-mfd capacitor is represented by curve B in Fig. 17. Notice that the current rises much faster on both sides of resonance and drops to zero much more sharply than the curve for the 100 mh coil and the 1 mfd capacitor. We say that curve B is sharper than curve A. Curve A was obtained with one LC ratio: a 100 mh coil and a 1 mfd capacitor. Curve B was obtained with another LC ratio: a 10-mh coil and a 10-mfd capacitor. The LC ratio for curve A is higher than the LC ratio for curve B. A low LC ratio gives a sharp curve. This is an important thing to remember.

A low LC ratio is essential if a parallel-resonant circuit is to be used to separate signals having nearly the same frequency (for example, in radio receivers where stations operating on frequencies close together must be separated). If the resonant curve is sharp, we can tune in the desired signal and reject the undesired signals. However, if the resonant curve is broad, as the curve marked A in Fig. 17, it will be difficult to separate the undesired signals from the desired one.

The Q of a coil is another factor that will effect the sharpness of the resonance curves. A high-Q coil will yield a much sharper response curve than a low-Q coil.

In a series-resonant circuit, we obtain a sharp response curve with a high LC ratio. We have the opposite situation in a parallel-resonant circuit, however: we obtain a sharp curve with a low LC ratio.

SELF-TEST QUESTIONS

(j) How do you distinguish between a series-resonant and a parallel-resonant circuit?

(k) What does a parallel-resonant circuit act like at resonance?

(l) Does the generator supply a current of high value or of low value to a parallel-resonant circuit?

(m) In circuits such as the one shown in Fig. 13, why will the voltage across a 120-ohm resistor be small?

(n) Does a current of high value or low value flow in the coil and capacitor in a parallel-resonant circuit?

(o) Will increasing the resistance of the coil in a parallel-resonant circuit cause the generator current to increase or to decrease?

(p) If a parallel-resonant circuit is used in a radio receiver to select one signal and reject others, do you want a high LC ratio or a low LC ratio?

Comparison of Series-Resonant And Parallel-Resonant Circuits

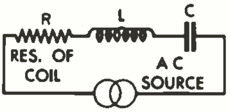
Series-resonant and parallel-resonant circuits are found in every radio and TV receiver and in many other pieces of electronic equipment. Resonant circuits are used in receiving equipment to separate the stations operating on different frequencies and in transmitting equipment in conjunction with vacuum tubes and/or transistors to generate radio frequency signals.

The chart shown in Fig. 18 compares and summarizes the important characteristics of series-resonant and parallel-resonant circuits. Notice that in many cases a series-resonant circuit is the exact opposite of a parallel-resonant circuit. Perhaps the most important characteristics of the two types are the resistance at resonance and the current at resonance. A series-resonant circuit acts as a low resistance at resonance and the current flowing through it will be at its maximum value. On the other hand the parallel-resonant circuit is exactly the opposite, so that at resonance it acts as a very high resistance and the line current flowing through it will be at its lowest value.

RESONANCE CURVES

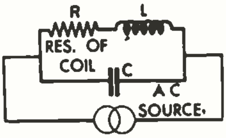
In Fig. 17 you saw that we used a small inductance and a large capacity to obtain a sharp resonance curve with a parallel-resonant circuit. This gave us a low LC ratio. For a sharp resonant curve in a series-resonant circuit you should use a high LC ratio; in other words, you should use a large inductance and a small capacity. This is simply another example of the difference between series-resonant and parallel-resonant circuits. As a technician you will not be called upon to design a series-resonant or a parallel-resonant circuit, but the more you understand about the circuits the better you will be able to maintain the equipment for which you may be responsible.

SERIES-RESONANT CIRCUITS



1. The coil, the capacitor and the AC voltage source are all in series.
2. Resonance occurs when the reactance of L is equal to the reactance of C.
3. At resonance, source current is a *maximum* (very high).
4. At resonance, a series resonant circuit acts like *a resistor of low ohmic value.*
5. At resonance, the voltages across L and C are equal in magnitude but 180 degrees out of phase with each other.
6. At resonance, the same current flows through the entire circuit.
7. At resonance, the voltage across either L or C may be greater than that of the source, giving resonant voltage step-up.
8. At resonance, increasing the value of coil resistance R lowers the circuit current, thereby *lowering* the resonant voltage step-up.
9. Off resonance, the circuit acts like that part which has the *higher* reactance.
   - a. Increasing C above its at-resonance value makes the circuit act like a coil.
   - b. Reducing C below its at-resonance value makes the circuit act like a capacitor.
   - c. Increasing L above its at-resonance value makes the circuit act like a coil.
   - d. Reducing L below its at-resonance value makes the circuit act like a capacitor.
   - e. Applying a *higher* frequency than the resonant one makes the circuit act like a coil.
   - f. Applying a *lower* frequency than the resonant one makes the circuit act like a capacitor.
10. The product LC is constant for any given resonant frequency.
11. Increasing L or increasing C lowers the resonant frequency.
12. Decreasing L or decreasing C raises the resonant frequency.
13. The Q factor of the circuit is essentially equal to the coil reactance divided by the AC resistance of the coil.

PARALLEL-RESONANT CIRCUITS



1. The coil, the capacitor and the AC voltage source are all in parallel.
2. Resonance occurs when the reactance of L is equal to the reactance of C.
3. At resonance, source current is a *minimum* (very low).
4. At resonance, a parallel resonant circuit acts like *a resistor of high ohmic value.*
5. At resonance, the voltages across L, C and the source are all the same in magnitude and phase.
6. At resonance, the currents through L and C are essentially equal in magnitude but are 180 degrees out of phase.
7. At resonance, the current through either L or C is greater than the source current, giving resonant current step-up.
8. At resonance, increasing the value of coil resistance R increases line current, thereby *lowering* the resonant current step-up.
9. Off resonance, the circuit acts like that part which has the *lower* reactance.
   - a. Increasing C above its at-resonance value makes the circuit act like a capacitor.
   - b. Reducing C below its at-resonance value makes the circuit act like a coil.
   - c. Increasing L above its at-resonance value makes the circuit act like a capacitor.
   - d. Reducing L below its at-resonance value makes the circuit act like a coil.
   - e. Applying a *higher* frequency than the resonant one makes the circuit act like a capacitor.
   - f. Applying a *lower* frequency than the resonant one makes the circuit act like a coil.
10. The product LC is constant in any given resonant frequency.
11. Increasing L or increasing C lowers the resonant frequency.
12. Decreasing L or decreasing C raises the resonant frequency.
13. The Q factor of the circuit is essentially equal to the coil reactance divided by the AC resistance of the coil.

Fig. 18. Comparison of series-resonant and parallel-resonant circuits.

DISTINGUISHING BETWEEN SERIES AND PARALLEL-RESONANT CIRCUITS

Sometimes, it is not easy to distinguish between a series-resonant and a parallel-resonant circuit. In Fig. 19A we have shown a series-resonant circuit. A series-resonant circuit is a resonant circuit in which the source voltage has been applied to the coil and capacitor in series. There is no doubt that this is a series-resonant circuit.

In Fig. 19B we have shown a parallel-resonant circuit. The parallel-resonant circuit is a resonant circuit in which the source voltage has been applied to the coil and capacitor in parallel. Again, it is easy to see that this is a parallel-resonant circuit.

Fig. 19C shows two resonant circuits that again look like two parallel-resonant circuits. Here, the secondary is inductively coupled to the primary. Let's look at the primary first. The voltage source is applied to the coil and capacitor in parallel; there is no doubt that the primary is in a parallel-resonant circuit. But how about the secondary? Since the coil and capacitor are connected in parallel you might jump to the conclusion that this is a parallel-resonant circuit, too. Actually, this has no bearing--how the voltage is applied to the circuit determines whether the circuit is a series-resonant or parallel-resonant circuit.

The voltage is induced in the secondary. Actually, some voltages are being induced in each turn of the coil and they act as if they are connected in series, so that the total voltage induced in the secondary is the sum of the voltages induced in each turn. We can compare this to a number of small generators connected in series with the various turns of the coil, and the coil might look like Fig. 19E.

Thus, the voltage induced in the coil is actually applied in series with the turns of the coil rather than in parallel with the coil and the capacitor and could be represented by Fig. 19D (which is the same as Fig. 19A). Therefore, the secondary of the transformer shown in Fig. 19C is a series-resonant circuit and not a parallel-resonant circuit.

You will run into this type of double-tuned circuit in many pieces of electronic equipment. It is often used between two stages in a radio receiver or a television receiver as shown in Fig. 20. Here the primary is connected between the plate of one tube and B+. The secondary is connected between the grid and the cath-

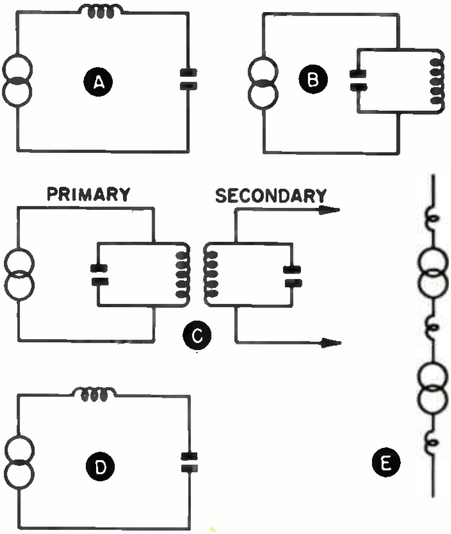


Fig. 19. A series-resonant circuit is shown at A, and a parallel-resonant circuit is shown at B. In C, the primary of the transformer and the capacitor across it form a parallel-resonant circuit, and the secondary of the transformer and its capacitor form a series-resonant circuit.

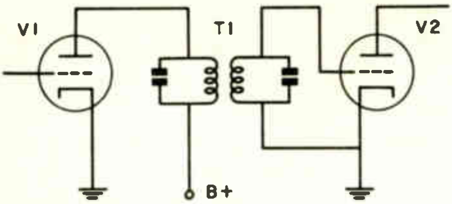

Fig. 20. The primary of T1 is a parallel-resonant circuit, but the secondary is a series-resonant circuit.

ode of the second tube. The tube marked V1 really acts as a generator and supplies the ac signal across the primary of the transformer. A signal is induced in series with the secondary winding, because the secondary is inductively coupled to the primary. Because the coil and capacitor in the secondary form a series-resonant circuit, there is a high current flow with resulting resonant voltage step-up so that this stepped up voltage is applied between the grid and the cathode of V2.

The resonant voltage step-up that occurs in the secondary winding of T1 is quite important. Actually, the primary and secondary windings of T1 will have the same number of turns in most cases. Therefore, you would expect the voltage induced in the secondary to be approximately equal to the voltage across the primary. This is what would happen if we simply had a transformer in the circuit. However, since there are capacitors across each coil and since each circuit is a resonant circuit we have the resonant voltage step-up which occurs in the secondary winding due to the high current flowing in the series-resonant circuit. Thus, there is actually a step-up in voltage occurring in the transformer even though the turns-ratio may be one to one. This means that the signal voltage available between the grid and cathode of V2 will be considerably greater than the voltage between the plate and ground of V1.

SELF-TEST QUESTIONS

(q) Explain the difference between the current flowing in the coil and capacitor in a series-resonant circuit and the current flowing in the coil and capacitor in a parallel-resonant circuit.

(r) Explain the difference between the voltage across the coil and capacitor in a series-resonant circuit and the voltage across the coil and capacitor in a parallel-resonant circuit.

(s) What is the difference between the generator current in a series-resonant circuit and in a parallel-resonant circuit?

(t) How can the voltage across the coil or capacitor in a series-resonant circuit be greater than the source voltage?

(u) What happens if we increase the value of inductance or capacitance in a resonant circuit?

(v) Will the voltage across the coil or the capacitor in a high-Q series-resonant circuit be greater than the voltage across the coil or capacitor in a low-Q series-resonant circuit?

(w) Reducing L below its at-resonance value in a series-resonant circuit makes the circuit act as a capacitor; reducing L below its at-resonance value in a parallel-resonant circuit makes the circuit act as a coil. Explain why this happens.

How Resonant Circuits Are Used

Resonant circuits have many applications. In this section of the lesson we will look into some of the more common uses of resonant circuits in radio and TV. These uses are important because they demonstrate how resonant circuits are used to select one signal from a number of signals of different frequencies.

SELECTING A DESIRED SIGNAL

The antenna connected to a radio or a TV receiver picks up signals from a large number of radio and TV stations. Even the antennas installed especially for television receivers will pick up a certain amount of signal from radio broadcast-band stations. This happens even though the antenna is designed for operation on a much higher frequency than that of the broadcast-band station. Therefore, some means must be provided inside the receiver to select the desired signal and reject the unimportant one. Resonant circuits are used for this purpose.

In Fig. 21 we have shown the input circuit of a radio receiver. The signals picked up by the antenna cause a current to flow through the primary winding L1 of T1. T1 is called an antenna coil or transformer because the signals from the antenna are applied to this coil. The secondary L2 of T1 is inductively coupled to the primary so that the current flowing in L1 sets up a magnetic field which cuts L2 and induces a voltage in it. Remember that when a voltage is induced in a coil in this way, there is a certain amount of voltage induced in each turn of the coil. The voltage induced in the coil acts like a number of generators connected in series with the coil. Thus L2 and capacitor C1 form a series-resonant circuit at some frequency within the broadcast band.

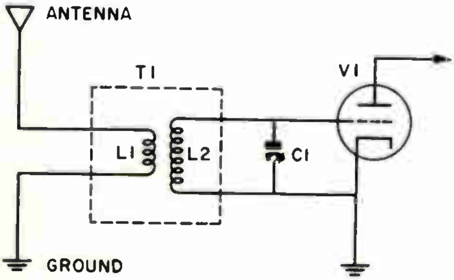

Fig. 21. The input circuit of a typical radio receiver.

Notice the symbol used for the capacitor C1. This symbol indicates that the capacitor is variable. Thus, by changing the setting of C1, the frequency at which the combination of L2 and C1 is resonant can be changed.

Let us suppose that the antenna is picking up two signals of equal amplitude or strength, one having a frequency of 500 kc and the other having a frequency of 800 kc. If the combination of C1 and L2 is resonant at 800 kc (C1 and L2 thus forming a series-resonant circuit), there will be a high 800-kc current through L2 and C1, with resultant step-up voltages appearing across L2 and C1. These voltages are applied between the grid and the cathode of V1 to be amplified by this tube.

At the same time there is a 500-kc signal being picked up by the antenna. This will flow through the primary of transformer T1 and will induce a certain voltage in L2. Since the combination of L2-C1 is not resonant at 500 kc, the impedance of this series circuit will be much higher at 500 kc than it was at 800 kc. This means that the 500-kc current flowing through the series circuit will be low so that voltage developed across L2 and across C1 by this current will be low. Therefore, the 500-kc signal applied between the grid and the cathode of V1 will be much lower in amplitude than the 800-kc signal. Thus, although one resonant circuit is not able to reject the 500-kc signal completely, the amplitude of this signal (when applied between the grid and the cathode of V1) is lower than the amplitude of the desired 800-kc signal that is applied to this tube.

Better selectivity can be obtained in a receiver by using several resonant circuits. If each circuit is tuned to the desired frequency, the difference in signal strength between the desired and the undesired signals will become greater. If enough resonant circuits are used the only signal actually heard in the output of the receiver will be the signal from the desired station.

I-F Transformers.

Most modern radio and television receivers use the superheterodyne principle. In the superheterodyne receiver the signal is picked up by the antenna and fed to a stage called a mixer or first detector. Here, the signal is mixed with a signal generated by the oscillator stage. The two signals mixed together produce two new signals, one equal to the sum of the two frequencies and the other equal to the difference of the two. Both new signals contain the modulation on the original signal. In a superheterodyne receiver we use the difference-frequency signal. In the output circuit of the mixer stage we use a transformer called an intermediate frequency transformer (usually abbreviated as an i-f transformer). This transformer is tuned to resonance at the difference frequency. One or more amplifier stages (called i-f amplifiers) are used to amplify the difference signal. I-F transformers are used between the mixer and the various stages in the i-f amplifier and between the last i-f amplifier stage and the stage called the second detector. The latter separates the audio or picture signals from the rf carrier. Resonant circuits are used in i-f transformers.

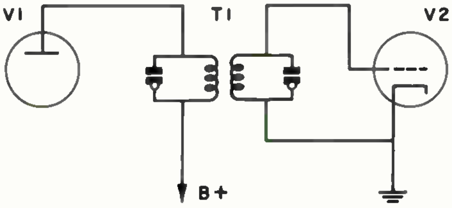

Fig. 22. Coupling between the mixer and the i-f tube in a superheterodyne receiver.

The schematic of a circuit used between the mixer and first i-f stage in a superheterodyne receiver is shown in Fig. 22. The tube marked V1 is the mixer; the tube marked V2, the i-f tube.

You have already seen this type of circuit earlier in the lesson. You know that the primary of T1 is a parallel-resonant circuit because the tube acts as a generator and applies the signal in parallel with the resonant circuit. This parallel-resonant circuit acts as a high resistance at the resonant frequency and the voltage developed by the tube will be high. At frequencies

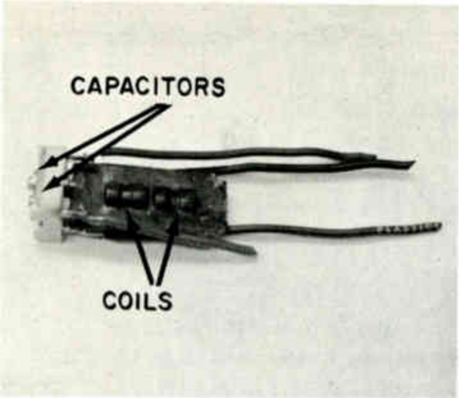

Fig. 23. The inside of an i-f transformer.

other than the resonant frequency, the primary circuit of T1 does not act as a high resistance; as a matter of fact, it acts as a fairly low impedance, so the voltage developed at these frequencies by V1 is low.

The primary of T1 is inductively coupled to the secondary winding so that the secondary circuit is a series-resonant circuit. Again at the resonant frequency, a high current flows and there is considerable resonant voltage step-up across the coil and across the capacitor. These stepped-up voltages are applied between the grid and the cathode of the i-f stage.

A typical i-f transformer is shown in Fig. 23. Notice that the two coils are placed near each other so that the primary and secondary are inductively coupled together. At the top of the transformer are two trimmer capacitors. The adjusting screws on these capacitors can be reached through holes in the top of the i-f transformer can or shield and can be adjusted for exact resonance after they have been installed in the circuit.

A modern superheterodyne receiver uses at least two i-f transformers like the one shown in Fig. 23. The selectivity of two transformers in conjunction with the selectivity obtained in other circuits will make the receiver selective enough so that it will pick up the desired signal even in the crowded broadcast band and in most cases reject the signals from undesired stations.

High-Frequency Circuits.

In some high frequency applications you might find a circuit like the one shown in Fig. 24. The symbol beside the coil indicates that the coil has a slug which can be adjusted in and out of the coil. This will change the inductance of the coil.

Although no capacitor is shown in the circuit, the circuit is actually a parallel-resonant circuit. The tube has a certain capacity between plate and ground, and this capacity will be in parallel with the coil. At high frequencies this capacity, along with the coil, is all that is needed to form a resonant circuit. Circuits of this type are frequently found in television receivers.

In some applications the coil may consist of less than one turn of a flat ribbon-type material such as

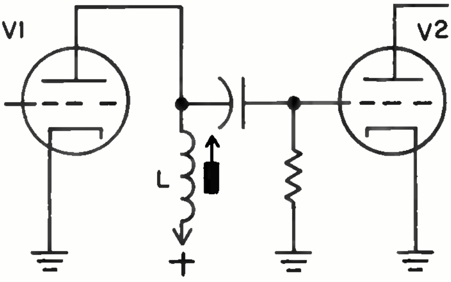

Fig. 24. Coil L in the plate circuit of V1 along with the circuit capacities form a parallel-resonant circuit.

shown in Fig. 25. This type of coil is used in UHF TV circuits and although the inductance in the circuit is extremely small, due to the fact that the circuit must operate at several hundred megacycles, this inductance is all that is required. As a matter of fact, in resonant circuits designed for UHF operation, the problem is not in getting the needed inductance and capacitance, but rather in keeping the inductance and capacitance low enough to produce resonance at the ultra-high frequency desired.

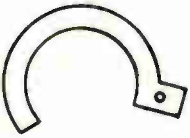

Fig. 25. A single turn of flat ribbon is all the coil that is needed in UHF circuits.

HOW DIFFERENT TYPES OF FILTERS ARE USED

Another important use of resonant circuits is in the design of filters. There are three different types of filters that you are likely to encounter as a technician. The explanation of exactly how each type works is rather complex, and since you need not know how each type of filter operates, we will not go into an explanation here. However, it is important that you know how the different types of filters are used.

Low-Pass Filters.

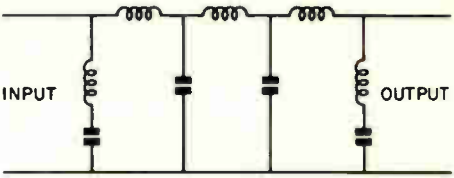

Fig. 26. A low-pass filter.

In Fig. 26 we have shown a schematic diagram of a low-pass filter, which is a filter that will allow signals below a certain frequency to pass through it with little or no attenuation, which means weakening of signals above this specific frequency. For example, if a low-pass filter is designed to pass frequencies below 10 megacycles, it will pass all frequencies from zero cycles per second, which is dc, up to 10 mc with little or no opposition. However, a signal with a frequency of 15 mc, or 25 mc, or in fact any frequency above 10 mc, will encounter a great deal of opposition in going through the filter.

High-Pass Filters.

A high-pass filter is designed to cut off all frequencies below a certain frequency and allow signals above this frequency to pass through with little or no attenuation. A schematic of a typical high-pass filter is shown in Fig. 27.

High-pass filters are often used on TV receivers to eliminate interference from stations operating on frequencies below the television channel. High-pass filters designed for this purpose are available commercially.

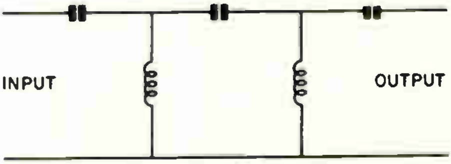

Fig. 27. A high-pass filter.

Band-Pass Filters.

Another type of filter is shown in Fig. 28. This type of filter, called a band pass filter, allows a certain band of frequencies to pass through it with little or no attenuation but offers considerable opposition to signals above and below the frequency of the band to be passed.

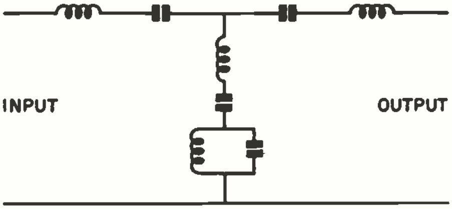

Fig. 28. A band pass filter.

For example, if a band pass filter is designed to have a band width of 2 megacycles, and the center of the pass band is 10 megacycles, then the band pass filter will pass frequencies from 9 mc to 11 mc with little or no attenuation. However, a signal having a frequency of 7 mc, which is below the pass band, or a signal having a frequency of 15 mc, which is above the pass band, will encounter considerable opposition going through the band pass filter.

SUMMARY

In this section of the lesson we have covered a few of the most important uses of resonant circuits. Resonant circuits are used in radio and TV receivers to select one desired signal and reject others. Both series-resonant and parallel-resonant circuits are used in the input stages of a receiver. They are also used between the mixer and i-f stages and between the i-f stage and the second detector.

Resonant circuits are used in filters. A low-pass filter is a filter which will pass frequencies below a certain frequency with little or no attenuation but offers high attenuation to signals above this frequency. A high-pass filter is a filter that will offer little or no attenuation to signals above a certain frequency, but offers high opposition or attenuation to signals below this frequency. A band pass filter will pass a certain band of frequencies, but attenuate signals either above or below the band of frequencies which it is designed to pass.

SELF-TEST QUESTIONS

(x) Is the resonant circuit made up of C1 and L2 in Fig. 21 a series-resonant circuit or a parallel-resonant circuit?
(y) What is a low-pass filter?
(z) What is a high-pass filter?
(aa) What is a band pass filter?
(ab) What type of circuit is used in making up filters?

RC Circuits

Another type of circuit that is extremely important in electronics work is the RC circuit, so called because it contains resistance and capacity. There are several types of RC circuits.

An RC circuit is used as a coupling circuit. This type of circuit is designed to pass a signal through it without changing the shape of the signal. Circuits of this type are used where an ac signal is mixed with dc. RC coupling circuits are widely used in the audio sections of radio and television receivers between the various stages. An RC coupling circuit used between two tubes is shown in Fig. 29A and an RC coupling circuit used between two transistor stages is shown in Fig. 29B. The purpose of the coupling circuit in each case is to pass the signal from one stage to the other without changing the shape of it; at the same time the circuit keeps the operating voltages from one stage out of the following stage.

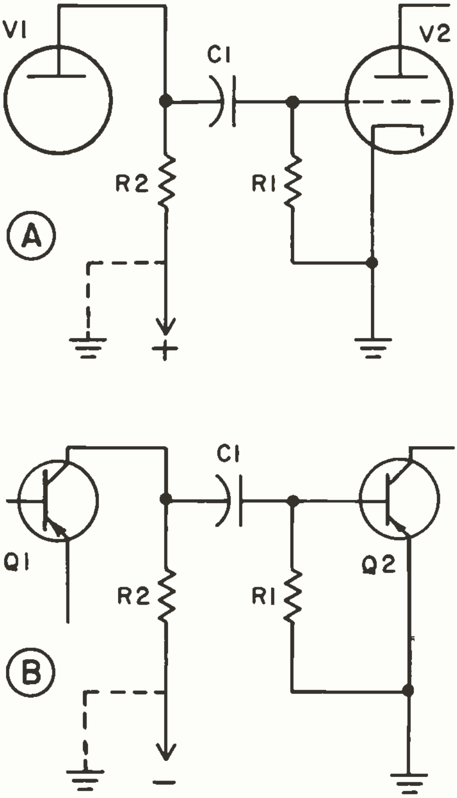

Fig. 29. RC coupling circuits used between tube and transistor stages.

Another type of RC circuit is designed specifically to change the shape of the signal applied to it. This type of circuit is used because the signal being fed through the RC circuit may be used to control the following stage. The shape of the signal may not be the best possible shape to control the stage; by means of a suitable RC circuit, the shape of the wave can be altered. In this section we will study both coupling and wave-shaping circuits, and you will see what they look like, how they work, and where each type is found.

RC COUPLING CIRCUITS

You will run into RC circuits most frequently between stages where they are used to feed the signal from one stage to the next. Typical RC coupling circuits are shown in Fig. 29. The RC coupling circuit in both cases consists of C1 and R1. These are the two components that you will be most concerned with in determining the characteristics of this type of circuit.

The tube V1 in Fig. 29A and the transistor Q1 in Fig. 29B act essentially like an ac generator in RC coupling circuits. One end of resistor R2 is connected to the tube in A and to the transistor in B. The other end is connected to the power supply. However, as far as the ac signal is concerned the end of R2 which is connected to the power supply is in effect connected to ground, because there is a large capacity in the power supply output connected between B+ and ground. This capacitor is so large that it has a very low reactance at all signal frequencies. Therefore the first stage, which is V1 in Fig. 29A and Q1 in Fig. 29B, supplies the voltage to resistor R2. The resistor acts like it is connected between the tube or transistor and ground.

An equivalent circuit of the coupling network is shown in Fig. 30. Here we have represented the tube or transistor as a generator with R2 connected across it. Notice that C1 and R1 are connected in series with each other and this combination is connected in parallel with the resistor R2. The purpose of the coupling network C1-R1 is to feed the signal that is across R2 to the following stage, V2 in Fig. 29A and Q2 in Fig. 29B. If the reactance of C1 is low enough, it will act as a short circuit at signal frequencies so R1 will in effect be connected in parallel with R2. When this situation exists, all the voltage available at the generator output will appear across R1. In other words the voltage appears between the grid and cathode of V2 in Fig. 29A and between the base and emitter of the transistor in Fig. 29B.

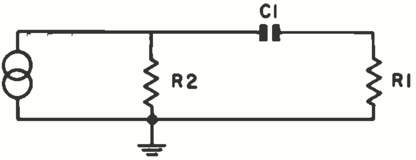

Fig. 30. The equivalent circuit of the RC coupling network shown in Fig. 29.

Capacitor C1 and resistor R1 are in series and they form a voltage divider network. Part of the voltage developed across R2 will be dropped across C1 and part of it across R1. The more voltage there is across R1 the more voltage we have available to drive the second stage. It is therefore important that the reactance of C1 be kept as low as possible in comparison with the resistance of R1. However, regardless of how large the capacitor C1 is, its reactance will eventually become high enough at some low frequency so that an appreciable part of the voltage developed across R1 is lost across C1. At some frequency the reactance of C1 will be equal to the resistance of R1. When this situation occurs 70.7% of the voltage appearing across R2 will be present across R1. You might expect only 50% of the voltage to appear across R1. However, 70.7% is correct because the voltage across R1 is not in phase with the voltage across C1. If the frequency is made still lower, then the percentage of voltage appearing across R1 will be lower.

When the voltage across R1 drops to 70.7% of the generator output, the current flowing through R1 will be only 70.7% of the maximum it would be with the full voltage across R1. When the voltage and current across R1 drop to 70.7%, the power across R1 will decrease to 50%. This point is called the "half-power" point. The amplifier is considered satisfactory in most cases as long as the output does not drop below this point.

Since C1 and R1 form a voltage divider network, we can keep the frequency at which the reactance of

C1 becomes a problem to a fairly low value by making R1 as large as possible. In the tube circuit shown in Fig. 29A, R1 is called a grid leak. Its value is relatively unimportant and a comparatively large resistor can be used. Therefore, even with a fairly small capacitor for C1, the resistance of R1 does not have much importance except at very low frequencies. On the other hand, making R1 too large will upset the operating voltages in the transistor in the circuit shown in Fig. 29B. In fact, the transistor itself affects the circuit so that there is a maximum value resistor that can be used; it is much lower than that used in the tube stage. The capacitor C1 must be of a much higher capacity in the transistor circuit than in the tube circuit to keep its reactance from becoming high enough to drop an appreciable percentage of the voltage.

Capacitor values from .01 mfd to .05 mfd are typical in tube circuits such as in Fig. 29A. In transistor circuits the value of C1 will often be 10 mfd or more.

The importance of avoiding this voltage division can be seen if you consider what happens to signals of different frequencies when they are amplified by the amplifier. If a signal voltage of 1 volt and a frequency of 1000 cycles appears across R2, almost the full 1 volt will appear across R1. But, at a frequency of 100 cycles, somewhat less than 1 volt will appear across R1; at a frequency of 10 cycles, even less will appear across R1. This means that the amplifier will not amplify signals of different frequencies equally. When this situation exists, we say we have frequency distortion. In the average radio receiver, a small amount of frequency distortion is not objectionable, but in high-fidelity equipment and in TV equipment, this type of distortion must be kept at a minimum if satisfactory results are to be obtained.

For the present the important thing you should remember is that an RC coupling circuit has a long time constant. Remember that capacitor C1 and resistor R1 are in series, but that at most frequencies the reactance of C1 is so low compared to the resistance of R1 that it acts as a short circuit and can be ignored. However, at very low frequencies the reactance of this capacitor is appreciable. We will discuss this situation in more detail when you study vacuum tubes and amplifiers.

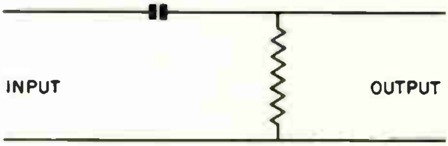

Fig. 31. An RC differentiating circuit.

RC DIFFERENTIATING CIRCUITS

Differentiating circuits are found in TV receivers and in many other pieces of electronic equipment. Fig. 31 shows a circuit of this type -- notice that it looks like a coupling circuit. However, the latter has a long time constant, whereas a differentiating circuit has a short time constant. Because differentiating circuits are normally used with pulses, you should know that a pulse is a variation of a quantity whose value is normally constant.

Fig. 32A illustrates a typical sine wave. Remember that the voltage starts at zero, builds up to a maximum and drops back to zero.

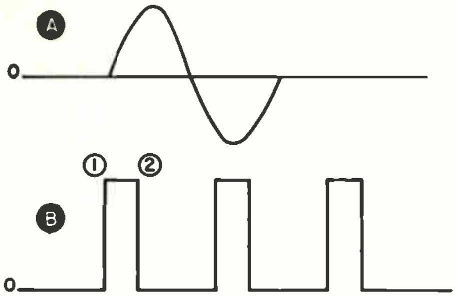

Fig. 32. A single cycle of a sine wave is shown at A, and a group of three pulses is shown at B.

A series of three positive-going pulses is shown in Fig. 32B. Notice that the signal voltage is zero, jumps instantly to its maximum value at point 1, remains constant from point 1 to point 2, and finally drops to zero again at point 2. Let's see what will happen if a pulse of this type is fed to a differentiating circuit such as the one in Fig. 31.

The value of R and of C in the differentiating circuit are chosen with a short time constant so that the capacitor charges and discharges quickly. As the leading edge of the pulse (which we have marked as 1) hits the capacitor there is an immediate current flow through the resistor to charge the capacitor. Since the capacitor has no charge on it at this instant, the current flow as well as the voltage developed across the resistor will be high. As the pulse maintains its constant value, the capacitor charges rapidly, the current flowing in the capacitor decreases and the voltage developed across the resistor falls off. Finally, the capacitor is fully charged, no additional current is flowing and the voltage across the resistor drops to zero.

The capacitor must discharge when the pulse drops from its peak amplitude at point 2 to zero. At the instant the applied voltage pulse disappears the capacitor is charged, although there is no longer a pulse across it. Then it starts to discharge through the resistor and a high current flows through the resistor. Instantly, there is a high voltage across it. The current flows in the opposite direction from that in which it flowed while the capacitor was charging, so the pulse appears in the opposite direction. As the capacitor becomes discharged, the current flowing drops gradually to zero so that the voltage appearing across the resistor also drops to zero.

The reaction of a differentiating circuit to a series of pulses is shown in Fig. 33. At A we have shown the pulse and below it at B the output voltage that will be obtained across the resistor as the pulse varies to a maximum and drops back to zero again.

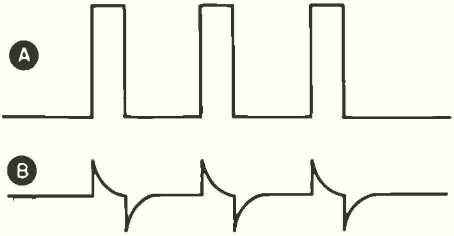

Fig. 33. Input and output signals applied to a differentiating circuit.

Differentiating circuits work in this way because they have a short time constant. The capacitor is able to charge and discharge rapidly, and therefore a double-pointed pulse as shown in Fig. 33 is obtained when a pulse is applied to the input of this type of circuit.

RC INTEGRATING CIRCUITS

A typical RC integrating circuit is shown in Fig. 34. Notice that the parts are connected in a way opposite from that in which they were connected in the differentiating circuit, and that a long time constant rather than a short time constant is used.

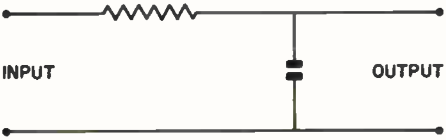

Fig. 34. An integrating circuit.

Fig. 35 illustrates the action of an integrating circuit. The capacitor begins to charge as the first pulse strikes the circuit; it starts to discharge after the first pulse passes but does not discharge completely before the second pulse arrives due to the long time constant. After the second pulse the capacitor starts to discharge again until the third pulse arrives -- then it charges still further. An integrating circuit is thus able to sum up or add a series of pulses to give one pulse in the output. Integrating as well as differentiating circuits are used in TV receivers and in many other pieces of electronic equipment.

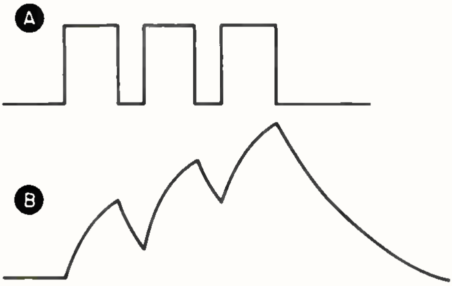

Fig. 35. Integrating circuit action on a series of pulses.

SUMMARY

In this section of the lesson you found that RC circuits can be used in several ways. They can be used as coupling circuits to feed a signal from the plate of one tube to the grid of the next tube. When they are used in this way the purpose is to pass the signal from one tube to the other without distorting or changing it in any way.

RC circuits are also used as differentiating circuits. A differentiating circuit is a circuit that develops a sharp positive and negative pulse from a single pulse. If the pulse supplied to the circuit is a positive-going pulse, which is what we call the pulse shown in Fig. 32B, then the output will be a positive pulse followed by a negative pulse. If the input signal is a negative-going pulse, then the output will be a sharp negative pulse followed by a sharp positive pulse.

An integrating circuit is a circuit that has a long time constant and adds together a number of separate pulses to produce one large pulse in the output.

SELF-TEST QUESTIONS

(ac) What is the purpose of an RC coupling circuit?

(ad) Is the reactance of the coupling capacitor likely to become a problem at high, low, or medium frequencies?

(ae) What do we mean by the half-power point?

(af) What do we mean by frequency distortion?

(ag) What is a differentiating circuit?

(ah) What is an integrating circuit?

LOOKING AHEAD

In this lesson you have seen how resistors, coils, and capacitors are used together to form a number of different types of circuits. By this time you have probably realized the importance of these three components. Before leaving this lesson it is worthwhile to stop and consider the fact that we have all three of these quantities in every circuit.

Even a piece of straight wire has a certain amount of resistance, a certain amount of capacity between it and nearby objects, and also a small amount of inductance. If the frequency of the signal running through the wire is high enough, even these small amounts of resistance, capacity, and inductance may be large enough to merit consideration.

We have brought up this point now because you will soon be working on, repairing, and replacing circuits in equipment which operates at very high frequencies. Because the resistance, capacity, and inductance in circuits operating at these high frequencies is so important, replacement parts should be put as closely as possible in the position occupied by the original part.

In the following lesson you will study additional components that will be important in your electronics career: vacuum tubes, transistors, complete stages and signals. You will also learn how the value of parts used in a circuit affects the performance of the stage.

There are a number of schematic diagrams in this lesson. If you study carefully the diagrams which appear in earlier lessons, complex diagrams in later lessons will not present a problem for you. Difficulties will occur if you wait until later lessons to trace circuits on complex diagrams.

ANSWERS TO SELF-TEST QUESTIONS

(a) A resonant circuit is one in which the inductive reactance cancels the capacitive reactance.

(b) We mean that the rms value or the effective value of the ac current flowing in the circuit is 1 amp. The ac current would have the same heating effect as 1 amp of dc. Remember that an ac current actually drops to 0 twice each cycle and reaches peak values approximately 1.4 times the effective or rms value.

(c) We cannot add the voltages because they are not in phase. The voltage across the resistor will be in phase with the current, whereas the voltage across the coil will lead the current by 90°. We must add these two voltages by means of vectors.

(d) In the expression "j50", the j indicates a reactive component; the 50 (for ohms) represents a reactance rather than a resistance. The plus sign in front of the j means that the reactance is inductive. A minus sign in front of the j indicates capacitive reactance.

(e) The voltage across the parts in an RC circuit will depend upon the parts themselves. If the reactance of the capacitor is greater than the resistance of the resistor then the voltage across the capacitor will be greater than the voltage across the resistor. On the other hand, if the resistance of the resistor is higher than the reactance of the capacitor, the voltage across the resistor will be greater than the voltage across the capacitor.

(f) Across the resistor the voltage will be in phase with the current; across the coil it will lead the current by 90°; across the capacitor it will lag the current by 90°.

(g) The Q of a coil is equal to the inductive reactance of the coil divided by the resistance of the coil. It is indicative of the worth of the coil, which is supposed to have inductive reactance with little or no resistance. Since the coil is wound with wire, however, it will have some resistance. The coil will act more like a resistor as this resistance increases. Therefore, a high-Q coil is better than a low-Q coil.

(h) The current will reach its maximum value when the inductive reactance of the coil cancels the capacitive reactance of the capacitor. When this happens we have a series-resonant circuit.

(i) Reducing the resistance in a series-resonant circuit will cause the current flowing in the circuit to increase. A higher resonant voltage will appear in turn across the coil and the capacitor. The voltage which appears across the resistor will remain the same because the increase in current will be counteracted by the reduction in resistance. Thus, the entire generator voltage will appear across the resistor.

(j) The distinction between a series-resonant circuit and a parallel-resonant circuit lies in the way in which the voltage is applied to the coil and the capacitor. If it is applied to the coil and the capacitor in series, the circuit is series-resonant; if it is applied to the coil and the capacitor in parallel, the circuit is parallel-resonant.

(k) A high value resistance.

(l) The generator connected across a parallel-resonant circuit will supply a current of low value because the high resistance of this type of circuit limits the current which can flow.

(m) The voltage across the resistor will be small because the resistor is in series with the parallel-resonant circuit. Most of the voltage will be dropped across the higher resistor. A parallel-resonant circuit has a very high resistance at resonance and most of the voltage will be dropped across it. Consequently, there will be very little voltage across the 120-ohm resistor.

(n) In a parallel-resonant circuit, a high value current flows in the coil and in the capacitor. These two currents are 180° out of phase. Energy stored in the capacitor flows out of the capacitor into the coil, where it is stored, and then flows from the coil back into the capacitor. This back-and-forth flow of current reaches a very high value. Even though the current actually supplied by the generator is low, it is enough to make up for losses in the resonant circuit due to resistance in the coil and in the wires connecting the coil and the capacitor together.

(o) Increasing the resistance of the coil in a parallel-resonant circuit causes the generator current to increase. More losses occur as a result of increased resistance, and the generator supplies more current to make up for these losses.

(p) A low LC ratio gives a sharper curve such as curve B in Fig. 17. This type of curve is required in order to select one station and reject another. A broad curve such as curve A of Fig. 17 would be unsuitable because stations operating close to the desired station would not be rejected.

(q) In a series-resonant circuit the same current flows in the coil and in the capacitor. As a matter of fact, since the generator, resistance, coil and capacitor are all in series in a series-resonant circuit, the same current must flow through all these components. On the other hand, in a parallel-resonant circuit the current through the coil and capacitor are essentially equal in magnitude, but they are 180° out of phase.

(r) In a series-resonant circuit, the voltage across the coil will be equal to but 180° out of phase with the voltage across the capacitor. In a parallel-resonant circuit the coil and capacitor are connected in parallel and the voltage across the two will therefore be the same.

(s) The generator current in a series-resonant circuit will be very high because this circuit acts as a low resistance. The generator current in a parallel-resonant circuit will be very low because this circuit acts as a high resistance.

(t) The inductive reactance of the coil in a series-resonant circuit cancels the capacitive reactance of the capacitor. Therefore the only factor that limits current flow in the circuit is the resistance in the circuit. This results in a very high current flow. The current flowing through the coil and through the capacitor produces a voltage drop across these components which will be equal to the product of the current times the reactance of the particular part. This product may be greater than the source voltage. The voltage across the coil and across the capacitor are 180° out of phase so that they cancel each other and the entire generator voltage will appear across the resistance in the circuit.

(u) Increasing the value of L or C in a resonant circuit will reduce the resonant frequency.

(v) Yes, the voltage across the coil and capacitor in a high-Q series-resonant circuit will be greater than the voltage across the coil and capacitor in a low-Q series-resonant circuit. This is due to the fact that a higher current will flow in a high-Q circuit which, all other factors being equal, will produce a greater voltage across the coil and across the capacitor.

(w) When we reduce L below its at-resonance value in a series-resonant circuit, the inductive reactance will be less than the capacitive reactance. Therefore the net reactance in the circuit will be capacitive - in other words the inductive reactance cannot completely cancel out the capacitive reactance. It will subtract from it but there will still be capacitive reactance left over, and the circuit will act as a capacitor. The current flowing through the circuit will lead the voltage. On the other hand, when we reduce L below its at-resonance value in a parallel-resonant circuit, the inductive reactance will be less than the capacitive reactance and more current will flow through the lower reactive branch. The net result will be that the capacitive current cannot completely cancel out the inductive current. Therefore, the circuit will act as inductance and the voltage will lead the current.

(x) The resonant circuit is a series-resonant circuit because the voltage is induced in series with the turns of L2. Therefore, the voltage is applied in series with the coil and the capacitor.

(y) A low-pass filter is a filter designed to pass signals below a certain frequency and reject all signals above that frequency.

(z) A high-pass filter is a filter designed to pass all signals above a certain frequency and reject signals below that frequency.

(aa) A bandpass filter is a filter designed to pass a certain band of frequencies with little or no attenuation. It will reject or offer considerable opposition to frequencies above and below the band it is designed to pass.

(ab) Various combinations of series-resonant and/or parallel-resonant circuits are used in making up filters.

(ac) An RC coupling circuit is used to transfer a signal from one stage to another without changing the shape of the signal.

(ad) At low frequencies.

(ae) The half-power point is the frequency at which 70.7% of the voltage appears across the resistor in an RC coupling circuit. At this frequency the current will also have dropped to 70.7% of its maximum value so that the power will be down 50% of its maximum value.

(af) Frequency distortion occurs when the amplifier does not amplify equal signals of different frequencies.

(ag) A differentiating circuit is an RC coupling circuit with a short time constant. A circuit of this type will produce sharp spikes in the output which can be used for controlling stages in a TV receiver.

(ah) An integrating circuit is a circuit with a long time constant that will build a series of pulses up into a single pulse.

Lesson Questions

Be sure to number your Answer Sheet B108.

Place your Student Number on every Answer Sheet.

Most students want to know their grade as soon as possible, so they mail their set of answers immediately. Others, knowing they will finish the next lesson within a few days, send in two sets of answers at a time. Either practice is acceptable to us. However, don't hold your answers too long; you may lose them. Don't hold answers to send in more than two sets at a time, or you may run out of lessons before new ones can reach you.

1. What determines whether a resonant circuit is a series-resonant or a parallel-resonant circuit?

2. What is the impedance of a series-resonant circuit having the following component values: $R = 25$ ohms, $X_L = 200$ ohms, $X_C \doteq 200$ ohms?

3. What do we mean by the resonant voltage step-up in a series-resonant circuit?

4. In which type of series-resonant circuit will the resonant voltage step-up be the greatest: (a) a high-Q circuit, (b) a low-Q circuit? Why?

5. What part does a parallel-resonant circuit act like at resonance?

6. What is meant by the resonant current step-up in a parallel-resonant circuit?

7. Which one of the following parts does a parallel-resonant circuit act like below the resonant frequency: (a) a resistor (b) a coil (c) a capacitor?

8. Compare the following characteristics of series and parallel circuits at resonance: (a) resistance at resonance, (b) current at resonance.

9. What is the difference between an RC coupling circuit and an RC differentiating circuit?

10. What is the purpose of an integrating circuit?

YOU HAVE AN AIM IN LIFE

When you enrolled as a student member of the National Radio Institute, you took the first step on your road to success and happiness. You now have a goal for yourself -- you have an aim in life -- you are looking forward to the sort of work you like, the sort of income you want, and the respect and admiration of your friends.

Keep your goal in mind. Never forget it for a moment. Of course you will have your moments of discouragement -- we all have. But if you make a thorough search for the cause of your discouragement, you will most likely find that you ate something which did not agree with you, or were kept awake last night by the neighbor's dog.

Whenever you are tempted to neglect your studies, say to yourself: "I have a goal to reach and I'm going to reach it." Think how unhappy you would be if you did not have this goal. There is nothing as pathetic as a rudderless ship or a man without an aim in life.

Here's to success and happiness -- your goal.

TRANSFORMERS, IRON-CORE CHOKES, AND RELAYS

B109

STUDY SCHEDULE

By dividing your study into the steps given below, you can get the most out of this part of your NRI Course in the shortest possible time. Check off each step when you finish it.

☐ 1. **Introduction** .... **Pages 1 - 2**
A brief picture of the three magnetic devices you will study in this lesson is given here.

☐ 2. **Magnetic Circuits** .... **Pages 3 - 9**
Here you learn how magnetic quantities are measured, and you study magnetic saturation and iron-core losses.

☐ 3. **Iron-Core Power Transformers** .... **Pages 10 - 17**
In this section you study losses in transformers, turns-ratios of transformers, and power losses.

☐ 4. **Transformers for Specific Application** .... **Pages 18 - 26**
You study audio, rf, i-f, and autotransformers.

☐ 5. **Iron-Core Chokes** .... **Pages 27 - 31**
You study the electrical and physical characteristics of chokes, and learn how they are used.

☐ 6. **Relays** .... **Pages 31 - 36**
The relay is an electric switch. You study several different types.

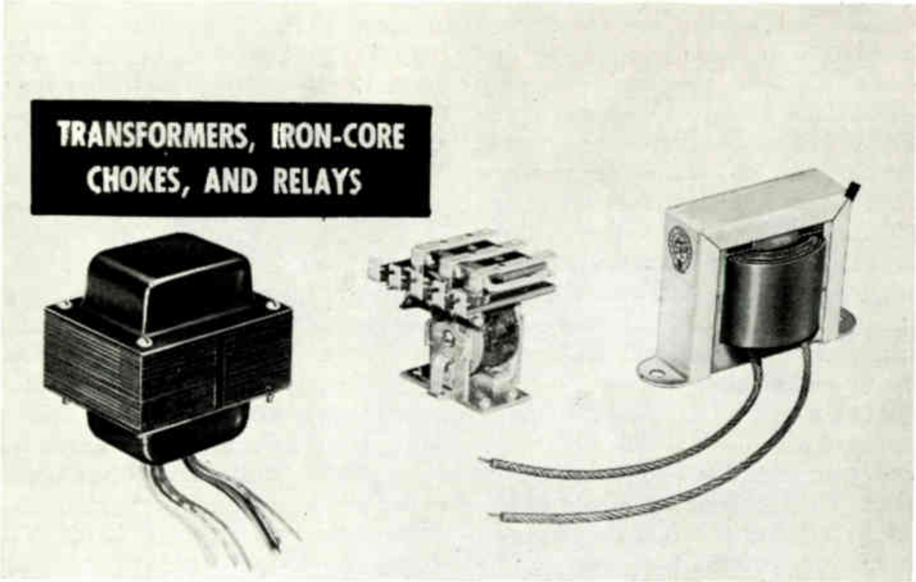
☐ 7. **Answers to Self-Test Questions** .... **Pages 36 - 40**

☐ 8. **Answer the Lesson Questions.**

☐ 9. **Start Studying the Next Lesson.**

JDL3M1174 1974 EDITION Litho in U.S.A.

TRANSFORMERS, IRON-CORE CHOKES, AND RELAYS



In this lesson we will take up three very important parts which all operate on magnetic principles; these are: transformers, iron-core chokes and relays.

Transformers.

You already have an idea of how important transformers are. Transformers are used on ac power lines either to step-up or to step-down the voltage. They are used in electronic equipment to supply the high voltage needed to operate the plates of the various tubes in the equipment and to supply the low voltage to heat the tubes. They are used in transistorized equipment to reduce the power line voltage to the voltage required by the transistors.

Transformers have uses other than supplying electric power. They are used in coupling circuits to transmit an audio signal from one stage to another. They are also used in what are called "matching" circuits to connect a device of one impedance to a device of another impedance. An example of this is the output transformer in a radio receiver, which is used to couple the low-impedance speaker to the higher impedance output tube or transistor that drives the speaker. If it were not for the transformer it would be difficult to get enough power from the tube or transistor to drive the speaker.

Transformers are also used in television receivers to transfer the power from the sweep circuits to the deflection yoke. The deflection yoke is used around the neck of the picture tube to move the electron beam over the face of the picture tube to reproduce the television picture. If it were not for transformers, it would be difficult to get the power needed into the deflection yoke to move the beam over the face of the picture tube.

Iron-Core Chokes.

Iron-core chokes are found most frequently in power-supply equipment. Chokes are used to help smooth the pulsating dc found at the output of a rectifier into pure, ripple-free dc. When chokes are used for this purpose, they are called "filter" chokes because they "filter" the ripple or hum out of the pulsating dc. You will see later that this is possible because the reactance of an iron-core choke is much higher than the dc resistance.

Relays.

There are several types of relays that you are likely to meet in your electronics career. One type of relay is nothing more than a form of automatic switch. The relay can be made either to close or to open the switch when power is applied to it.

There are also other types of relays; for example, some are used to protect circuits. This type is adjusted so that if the current flowing through it exceeds a certain value, the relay will automatically open the circuit, thus protecting the device from an overload.

Another type of relay is called a time-delay relay. This kind of relay is often found in electronic equipment where it is important for the heaters of the various tubes to have time to heat before the high plate voltage is applied to the tube. This type of relay is energized when the equipment is turned on. After a predetermined time, the relay operates, closes the circuit, and applies plate voltage to the tubes in the equipment.

Since the parts we'll study are all magnetic devices, before we look into any of them, we will review what you have already learned about magnetic circuits and learn some additional facts about these circuits.

Magnetic Circuits

As we learned previously when we studied magnetic circuits, we can compare them with electric circuits. The force that drives the flux through a magnetic circuit is the magnetomotive force. This force can be compared to the electromotive force that drives current through an electric circuit. The flux that is driven through the magnetic circuit resembles the current that is driven through an electric curcuit.

The opposition to the flux through the circuit can be compared to resistance in an electrical circuit, and is called reluctance.

MAGNETIC UNITS

There are units set up to measure many of the quantities encountered in magnetic circuits. It is not important for you to remember these units, so do not try to memorize them. We are presenting them here, however, so that you will have seen these terms and will have an idea of what they are when you run into them in the future. After you have completed your NRI course, you will have to keep abreast with new developments. In reading the literature on new developments in the electronics field, it is quite possible that you will run into many of these terms.

Units of Magnetomotive Force.

The magnetomotive force is expressed in terms of ampere-turns. If a current of 1 ampere flows through a coil having one turn, the magnetomotive force developed is 1 ampere-turn. If the coil had two turns, then the magnetomotive force would be 2 ampere-turns, and if a current of 2 amperes flows through a two-turn coil, the magnetomotive force will be 4 ampere-turns.

The ampere-turn is an entirely satisfactory term for use in expressing the magnetomotive force of an electromagnet. However, it is not suitable for use with permanent magnets, and for this reason, another unit of magnetomotive force is used. This unit is the gilbert. The gilbert is slightly smaller than the ampere-turn. To convert ampere-turns to gilberts, you multiply the number of ampere-turns by 1.25.

The magnetomotive force is the total force acting throughout the length of the entire magnetic circuit. Sometimes we want to express the magnetic force in terms of the magnetomotive force per centimeter. (The centimeter is a metric unit of measurement. There are about 2.5 centimeters in an inch.) It may be given as gilberts per centimeter. Then, if the length of the magnetic circuit is six centimeters and the magnetomotive force per centimeter is 10 gilberts, the total magnetomotive force would be 60 gilberts. The magnetomotive force per centimeter is called the magnetic force or the magnetizing force.

Units of Flux.

Previously when we were discussing magnetic flux we simply referred to the number of lines of flux. However, there is a term used for this purpose and it is the maxwell. One line of flux is equal to one maxwell. If you have a hundred flux lines, then the strength of the flux is 100 maxwells. Another unit is the kilomaxwell, which is equal to 1000 maxwells.

Another term that you will encounter is flux density. The flux density tells you how many maxwells or lines of flux pass through a given area. Flux density could be expressed in terms of maxwells-per-square-inch, or it could be expressed in terms of maxwells-per-square centimeter. A flux density of 1 maxwell or one line per square centimeter is known as a gauss. Thus if we say that the flux density is 100 gausses, we mean that there are 100 lines for each square centimeter of a cross-sectional area. If you had a magnet that was 3 × 5 centimeters, the total cross-section of the area would be 15 square centimeters. If the flux density is 100 gausses, then the total number of lines flowing would be 15 times one hundred or 1500 maxwells.

Units of Reluctance.

There is no unit of reluctance. Engineers and technicians are more concerned with the permeability of a material, which you might say is the opposite of reluctance. It is the ability of the material to conduct magnetic flux. It is similar to conductivity in an electric circuit, which is the ability of the material to conduct an electric current.

There is no unit of permeability. The permeability of magnetic materials is rated according to how much better the material conducts magnetic flux than air does. The permeability of air and all other non-magnetic materials is given the numerical value of 1. If the permeability of a magnetic material is 2, a magnetomotive force applied to it will produce twice as many flux lines as the same force applied to air. If we say the permeability of a certain magnetic material is 100, we mean that if the magnetomotive force applied to this material was applied to air, and it produced one line or one maxwell in air, then it would produce 100 flux lines or 100 maxwells in the material.

MAGNETIC SATURATION

One very important thing you should know about magnetic circuits is that they can be saturated. This means that they reach a point where all the possible lines of force exist, and increasing the magnetomotive force applied to the circuit will not produce any further increase in flux. Now let's see how this can happen.

A magnetic material such as iron is actually made up of millions of small molecules. A molecule is a tiny particle made up of a combination of two or more atoms. Each of these molecules is actually a small permanent magnet having a north pole and a south pole. When there is no magnetomotive force applied to the material, the molecules are arranged in a helter-skelter fashion as shown in A of Fig. 1. You will notice that the magnets in this material are pointing in all directions; there is no general organization so that all the north poles point in one direction and all the south poles point in another.

Let's see what happens if we apply a magnetomotive force to this material. This can be done by winding a

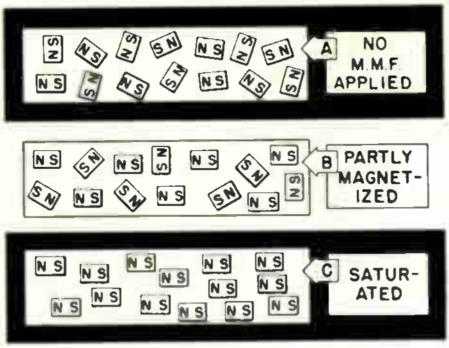


Fig. 1. How the molecules in a material line up as magnetomotive force is applied. Each molecule is like a tiny magnet.

coil around the material and passing a current through the coil. If the current is strong enough to partly magnetize the material, some of the molecules will line up as shown in Fig. 1B. Notice in this figure that there is a general tendency for the north poles to point towards the left and the south poles to point to the right. However, there are a number of molecules that do not follow this general pattern. Some of them are still not lined up.

If we increase the current flowing through the coil or if we increase the magnetomotive force by keeping the current constant and putting more turns on the coil, we will eventually reach a point where all of the molecules are aligned as in C of Fig. 1. Here all the north poles point to the left and all the south poles point to the right. When this situation exists, we say that the material is saturated. This means that any further increase in the magnetomotive force will not produce any further increase in flux. You can see why this is so--all the molecules are already aligned; therefore, it would be impossible to line any more of them up and get more flux. Thus, there would be no point in increasing the magnetomotive force. As a matter of fact, saturation is a condition to be avoided in most cases and if the current is increased beyond the amount needed to align all the molecules, some very undesirable results may occur.

Saturation is sometimes referred to simply as saturation; other times it is referred to as "core saturation" because the magnetic material is usually the core of some device. The magnet may be used as the core of a transformer or a choke. Only magnetic materials can be saturated; an air core cannot be saturated.

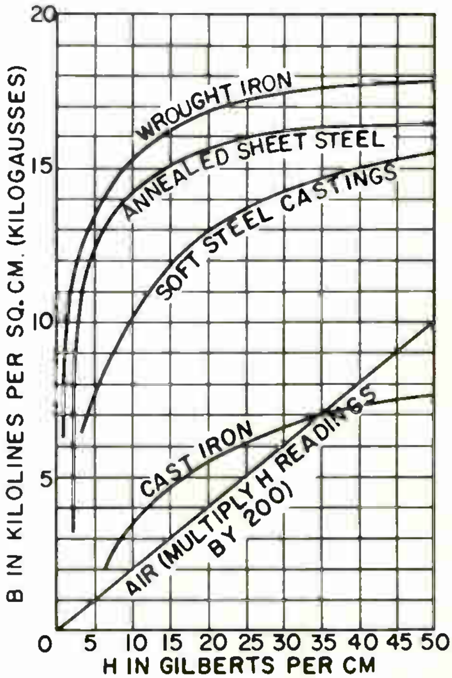

Fig. 2. B-H curves for different magnetic materials.

B-H Curves.

The characteristics of a magnetic material are often represented in the form of a curve called a B-H curve. B-H curves for several different materials are shown in Fig. 2. These curves show the flux density that can be obtained with a given magnetizing force. Notice that as the magnetizing force starts to increase from zero at the left of the graph, the flux density increases quite rapidly at first, then a point is reached where the curve starts to flatten out and it takes a substantial increase in magnetizing force to get even a small increase in flux density. Eventually a point is reached at which the flux density increases no further regardless of how much the magnetizing force is increased. This is the saturation point. However, notice on this graph that the curve for air is a straight line. This simply means that as long as we continue to increase the magnetizing force, the flux density in air will increase. In other words, an air core coil cannot be saturated.

Curves of this type are often used by manufacturers of magnetic materials to describe the characteristics of these materials.

IRON-CORE LOSSES

When we were discussing saturation, we spoke of gradually increasing the current flowing through the coil to increase the magnetomotive force applied to the material. We were discussing a dc current flowing through the coil. Even though we increased the current to show the effects of saturation, the current was still flowing in the same direction. However, we are greatly concerned with the action of coils when alternating current flows through them and the effect the ac has on the magnetic circuit. One of the important things to consider when dealing with alternating current is the losses produced in the iron-core itself.

Hysteresis.

Suppose we apply dc to a coil which in turn produces a certain magnetizing force. As the magnetizing force increases, the flux density increases, as shown by the curve A in Fig. 3, following a curve such as the B-H curves shown in Fig. 2. At zero, the material is not magnetized, and as we increase the magnetizing force, the flux density increases. Now suppose we increase the force only up to point 1 in Fig. 3, then we decide that we will not increase the current any further, but instead

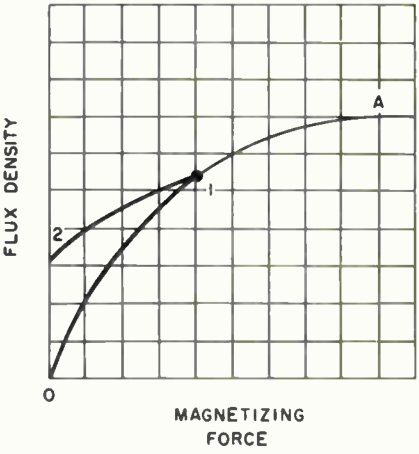

Fig. 3. Curve showing hysteresis loss in a magnetic material. If there were no loss, the curve 1-2 would coincide with the curve 0-1.

gradually decrease the current flowing through the coil, thus reducing the magnetizing force. As the magnetizing force is reduced, the flux density will decrease. However, instead of dropping back down to zero, it will follow the curve shown between points 1 and 2. At point 2, the magnetizing force has been removed entirely, but there is still a certain amount of flux. To get rid of this flux, we must actually reverse the current flowing through the coil. The power that must be applied to bring the flux density back to zero represents a loss due to the inertia of the magnetic circuit. This loss is called the hysteresis loss, pronounced hiss-ter-E-sis.

Any iron-core device operated from ac will waste part of the power applied to it in this way. There is no way that we can eliminate the hysteresis loss altogether, but the amount of power lost will depend upon the material used. By the proper choices of material, the loss can be kept to a minimum. For example, hard steel retains its magnetism and therefore the hysteresis loss in a material of this type would be quite high. On the other hand, soft iron and silicon steel retain very little of the magnetism so the hysteresis loss in the material of this type is much less than in hard steel. For this reason, the iron cores used in most transformers and chokes are made of silicon steel.

Eddy Current Losses.

Another loss that occurs in all iron-core devices is known as eddy current loss.

You will remember that when a varying current flows through a coil, a varying flux is produced in the coil. This flux will cut the turns of the coil and induce a voltage in it. The flux also cuts the turns of any nearby coil and induces a voltage in it, and if the circuit to this coil is complete, this induced voltage will cause a current to flow through it. If a transformer is made like the one shown in Fig. 4A, there are actually many paths in the core. Each path acts like a single-turn coil. We have shown two of these paths where a voltage can be induced which will result in a current flowing. These currents are called eddy currents and represent a loss.

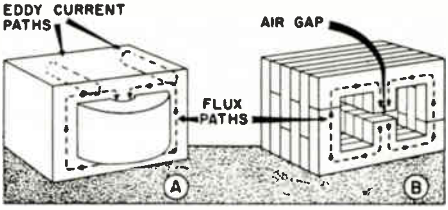

Fig. 4. If the core of a transformer is solid as at A, there are many eddy current paths in it; these can be reduced by making a laminated core as at B.

The eddy current loss in a transformer core can be kept at a minimum by making the core out of thin sheets of magnetic material called laminations. The sheets are insulated from each other by a coating of shellac or some other non-conductive material. The sheets are then stacked as shown in Fig. 4B.

Eddy current losses cannot be completely eliminated because even though the core is made of thin sheets, there are still some complete paths present that act like single shorted turns. However, making the core of thin laminations reduces the eddy current losses to a low value.

Both eddy current losses and hysteresis losses vary with the frequency. If the frequency is increased, both losses increase. Thus, although these losses do present some problem at power-line frequencies, they present an even greater problem at audio frequencies, which may extend as high as 15,000 cycles or more. These losses also explain why even laminated iron-core transformers are of no value at radio frequencies. The losses become so high that all of the energy put into the primary of the transformer would be converted into heat due to the eddy current and hysteresis losses. At radio frequencies, magnetic cores are made of finely ground powdered iron mixed with a binder to hold the particles together and insulate them from each other.

Flux Leakage Losses.

Unfortunately not all the flux produced by the magnetomotive force applied to a magnetic circuit will flow through the iron core of a device such as a transformer. Part of the flux will escape and travel through the air surrounding the core. This flux serves no useful purpose since it leaks out of the core and these flux lines do not cut the turns of the secondary winding. This loss is referred to as flux leakage loss.

In a device such as a transformer, if the magnetic material used in the core approaches the saturation point, the flux leakage losses become quite high. Therefore, to keep this type of loss as low as possible, transformers are usually designed to operate well below the saturation point. However, even then it is impossible to eliminate this loss completely, because a certain amount of the flux produced by the primary will travel in a path other than through the core.

Flux leakage is important not only because it represents a loss in the transformer, but also because the escaping flux lines may cut through some nearby part and induce a voltage in it. Thus energy in the transformer can be unintentionally fed into some other part. The amount of energy fed back may be high enough to upset the performance of the equipment.

Flux leakage can also present a problem in television receivers. Flux leaking from a transformer can deflect the electron beam in a picture tube and cause distortion in the picture. In color TV receivers flux leakage can actually cause the color picture to break up into three separate pictures of different colors or cause color fringing where objects are outlined in one or more colors.

In designing electronic equipment using transformers, engineers must consider the possibility of these undesired effects and try to keep transformer leakage fields away from the picture tube in TV receivers or other parts in the electronic equipment that could pick up interference from the field. In equipment where several transformers are used, they try to place the transformers so that there will be a minimum of interaction between them.

SUMMARY

In this section, you reviewed the facts you previously learned about magnetic circuits. You also learned some new terms. A unit of magnetomotive force that you will encounter is the gilbert and a unit of flux is the maxwell. You learned that the magnetomotive force is the force supplied throughout the entire magnetic circuit. Sometimes the force is expressed in terms of the magnetomotive force per unit length and is called the magnetizing force.

The amount of flux produced is sometimes expressed in terms of so many lines of maxwells for a given area. If the unit of cross-section area used is the centimeter, and you have 1 maxwell per square centimeter, we say the flux density is 1 gauss.

It is important for you to remember that a magnetic material can be saturated and that when the saturation point is reached, increasing the magnetomotive force will result in no further increase in flux.

The losses encountered in iron cores are important. The three most important losses are hysteresis loss, eddy current loss, and flux leakage loss. All these losses represent some energy that is being put into the primary of the transformer for which we get nothing out of the secondary. In the next section we will study transformers and you'll see the importance of these losses.

SELF-TEST QUESTIONS

(a) What is the gilbert?
(b) What is the unit of magnetic flux?
(c) What is meant by flux density?
(d) If the cross section area of a magnet is ten square centimeters and the flux density is ten gausses, what will the total number of flux lines flowing be?
(e) What is meant by magnetic saturation?
(f) Is magnetic saturation a desirable condition?
(g) How strong a magnetomotive force is required to produce saturation in air?
(h) What is a hysteresis loss?
(i) What are eddy current losses?
(j) How are hysteresis losses kept at a minimum?
(k) How are eddy current losses kept to a minimum?
(l) What are flux leakage losses?

Iron-Core Power Transformers

The ability of a varying magnetic field to induce a voltage in any conductor with which it links makes it possible to transfer power from one circuit to another without direct wiring connections. The device used for this purpose is called a transformer. In its simplest form a transformer is nothing other than two separate coils of wire wound on a common core or wound in such a way that the coils of wire are placed near each other so that the magnetic lines produced by one will cut the other.

A power transformer is wound on an iron-core. The iron-core is usually shaped like the core shown in Fig. 5A. The coils are wound on the center leg of the core as shown in Fig. 5B, one inside the other. The schematic symbol used to identify an iron-core transformer is shown in Fig. 5C.

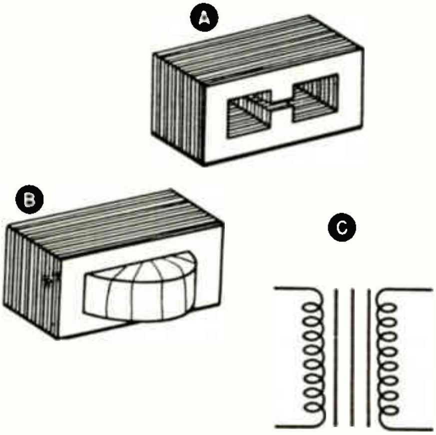

Fig. 5. The core of a power transformer is shown at A. The coils are wound on the center leg as at B. The schematic symbol for an iron-core transformer is shown at C.

Transformers are extremely important to the electronics technician, so let's learn more about them.

POWER LOSSES

In the preceding section of this lesson you learned about some of the losses that take place in magnetic cores. These losses, which are the hysteresis, eddy current, and flux leakage losses, are called "core" losses because they are characteristic of the magnetic core which is used in the transformer. However, there are also other losses in transformers.

The coils making up the transformer are wound of copper wire. Copper has a very low resistance, but nevertheless it does have some, so the current flowing through the copper wire will encounter opposition. This means power will be lost or used in forcing the current through the coil.

You know that the power is equal to voltage multiplied by the current; in other words:

$$P = E \times I$$

But from Ohm's Law we know that:

$$E = I \times R$$

Therefore, in the power formula we can substitute I × R for E, and get

$$P = I \times R \times I$$

which is usually written in the form

$$P = I^2R$$

The power lost as a result of current flowing through copper wire in a transformer will be equal to the current squared times the resistance of the wire. This loss is usually referred to as the "I squared R" loss.

Thus, in a transformer we have two groups of losses: the core losses and the copper losses. These losses appear in the form of heat. When a transformer is put into operation, it starts to heat up. The transformer will continue to get hotter and hotter until eventually a state of balance is reached where further heat generated by the transformer can be carried away by the air surrounding the transformer and by the metal chassis on which the transformer is mounted. When this balance is reached, the temperature of the transformer will stop rising, and the transformer will not get any hotter.

The amount of heat that a transformer can dissipate in this way depends upon its size. Since a large transformer will have a much greater air circulation and will be mounted on a larger area of the chassis, it can get rid of more heat than a small transformer. Therefore a large transformer is capable of handling a larger amount of power than a small transformer. As a matter of fact, the size of the transformer is usually a pretty good indication of the amount of power that it can handle safely. After you have worked on electronic equipment for a while, you'll learn to recognize from the size of a transformer approximately how much power it can handle.

Transformers can be overloaded if too much power is taken from them. When a transformer begins to overheat it is an indication that it is being overloaded. Usually when a transformer is overheated in this way you will notice a dark colored sealing compound or wax leaking out of the transformer, and often you can smell the varnish and insulation burning.

An overload of this type may be due to a defect in the transformer itself or it may be due to a defect somewhere in the equipment that is pulling excessive current from the transformer. If the transformer itself is defective, the trouble is usually that two or more turns of the transformer have touched each other so that a short circuit exists and current can simply flow around inside the transformer. When this happens there is nothing you can do except replace the transformer. However, if the defect is in the equipment rather than the transformer, and if you find it and eliminate the defect before operating the equipment any more, the chances are that the transformer will once again give satisfactory service.

If the transformer is operated with an overload, it will eventually get so hot that the insulation on the copper wire and on the terminal used to insulate one winding of the transformer from another will become overheated. Usually paper is used to insulate the various windings on a transformer. If this paper becomes too hot, it becomes charred so that it is no longer a good insulator, and the windings on the transformer will short together. When this happens, the transformer is no longer usable because it will draw more and more current and it will get hotter and hotter and eventually it will blow a fuse or the copper wire on one of the windings will melt so that the winding opens.

Transformers are designed to operate on a specific frequency. In other words, a transformer designed to operate on a 60-cycle power line will operate best only on a power line of that frequency. If you operate a 60-cycle power transformer on a 25-cycle power line or accidentally plug it into a dc power line, the transformer will burn out. A 60-cycle transformer cannot be operated on a 25-cycle power line. No transformer can be operated from dc. A 25-cycle transformer will operate on a 60-cycle power line, but 25-cycle transformers are much larger and much more costly to manufacture than 60-cycle transformers, and therefore it would be uneconomical to design a transformer for 25-cycle power and then use it on a 60-cycle power line.

In spite of the losses we have discussed, a transformer is one of the most efficient devices you will ever find. Large transformers such as those used by the power company achieve a very high efficiency, usually from 98% to 99%. Smaller transformers such as you will find in electronic equipment usually operate at an efficiency of somewhere between 95% and 98%. As far as the technician is concerned, this high efficiency means that in many cases you can ignore the transformer losses. You can consider the power output of the transformer as being equal to the power input; the difference will be only a small percent of the total power, and in evaluating the performance of the transformer, very little error will be introduced.

TURNS RATIO

The turns ratio of a transformer is the ratio of the number of turns on one winding of the transformer to the number of turns on the other winding. For convenience we usually identify the two windings on a transformer as the primary winding and the secondary winding or, more simply, as the primary and the secondary. The primary is the winding to which we apply the input power. The secondary winding is the winding from which we take power. If the primary winding of the transformer has 500 turns, and the secondary winding has 100 turns, we say that the transformer has a turns ratio of 5 to 1. This is often written 5:1. If the primary of the transformer has 100 turns, and the secondary 500 turns, then we say that the transformer has a turns ratio of 1 to 5 (1:5).

The ratio of the secondary voltage to the primary voltage will depend upon the turns ratio. If the secondary winding has five times as many turns as the primary, we can expect to get five times the voltage from the secondary that we put into the primary. Similarly, if the secondary has only half as many turns as the primary, then we can expect to get half the voltage across the secondary that we put into the primary. If we get more voltage out of the secondary than we put into the primary, the transformer is called a "step-up" transformer, and if we get a lower voltage out of the secondary than we put into the primary, then the transformer is called a "step-down" transformer.

In expressing the turns ratio of a transformer, manufacturers and technicians do not always give it as the ratio of the primary turns to the secondary turns. If a transformer has 100 turns on the primary and 200 turns on the secondary, the turns ratio is 1:2. However, sometimes this turns ratio is given as 2:1, step-up. This tells you the transformer is a step-up transformer which means there are more turns on the secondary than on the primary and the secondary has twice as many turns as the primary.

Power Consumption.

One of the things that makes a transformer so useful is that it is basically a self-regulating device. By this we mean it takes no more power from the power line to which it is connected than is needed to supply the power demanded from the secondary. In other words, if we connect a load across the transformer secondary and this load consumes 50 watts, then the power drawn from the power line by the primary will be 50 watts. Similarly, if we connect a 100-watt load across the secondary, then the power drawn from the power line by the primary will be approximately 100 watts. The primary will draw approximately the power required in order to furnish the demands of the secondary. We say approximately, because there are losses in the transformer itself, and the primary will draw the power needed to supply the secondary power plus the power needed to supply the losses within the transformer itself.

Consider what happens when the primary of the transformer is connected across the power line, but there is no load connected across the secondary. Under these circumstances, the secondary power is zero. Therefore, the primary does not have to supply any power to the secondary, and the power it will consume for this purpose will also be zero. The only power that the primary will consume from the power line will be the power to make up the core losses and a very small copper loss. Thus, when the primary of a transformer is connected across the voltage source and there is no load connected to the secondary, the transformer draws very little power from the voltage source. Under these circumstances, the transformer is very inefficient because all the power it is consuming is being wasted. However, as we load the secondary, these losses remain almost constant and as the secondary begins to use power, the primary power increases until when the transformer is being operated at its rated power, its efficiency reaches a very high value.

Because the primary power depends upon the secondary power, the actual current that will flow through the primary of a transformer will depend upon the load connected to the secondary. Ignoring the core and copper losses, if we have a 10 to 1 step-down transformer connected across a 100-volt power line, the voltage available at the secondary will be 10 volts. The turns ratio determines the ratio of the primary to secondary voltage. The ratio of the current flowing in the primary to the current flowing in the secondary also depends on the turns ratio, but it works in the opposite way. If we connect a load across the secondary that draws a current of 1 amp, then the power taken from the secondary will be 10 volts times 1 amp, which equals 10 watts. To supply 10 watts, the primary, since the voltage across it is 100 volts, needs only 1/10 of an amp and therefore this is the current that it will draw from the power line. If we increase the load across the secondary and pull 100 watts from the secondary, then the current flowing in the secondary must be 10 amps, because with a voltage of 10 volts, it will take a current of 10 amps to supply 100 watts. Under these circumstances, the primary again will pull the power needed from the power line to supply this 100 watts. This means that the primary current will be 1 amp.

Now notice what our situation is. Here we have a step-down transformer with a 10-to-1 turns ratio. This transformer steps the voltage from 100 volts down to 10 volts. However, the current acts in the opposite way. The secondary current is higher than the primary current. The secondary current will actually be 10 times the primary current if we ignore the transformer losses. Therefore in a step-down transformer, the current is stepped up and similarly in a step-up transformer where the voltage is stepped up, the current is stepped down.

Since the current drawn from the primary will vary as the loading on the secondary of the transformer varies, this means that the impedance of the primary winding must vary. If the impedance of the primary winding remained constant, then the current flowing through the transformer primary would be constant for any given primary voltage. However, since the current does vary, then the impedance must vary. This it does, in fact, and the actual impedance of the primary depends upon the impedance connected across the secondary. This is caused by the fact that when the impedance across the secondary varies, the current as well as the power demanded from the secondary will vary. The primary current and the impedance will also vary in turn.

TYPICAL POWER TRANSFORMERS

Many pieces of electronic equipment that you will service will use power transformers. Power transformers serve a number of useful purposes. First, by using a power transformer it is possible to have available a number of different operating voltages other than the single voltage available directly from the power line. Furthermore, the power transformer isolates the equipment from the power line. This is a big advantage because one side of most power lines is grounded. If you accidentally come in contact with any grounded object and some of the circuits of the electronic equipment or the metal chassis of the equipment at the same time, it is possible to get a severe shock from electronic equipment that does not use a power transformer.

The power transformer found in modern electronic equipment has a primary winding and one or more

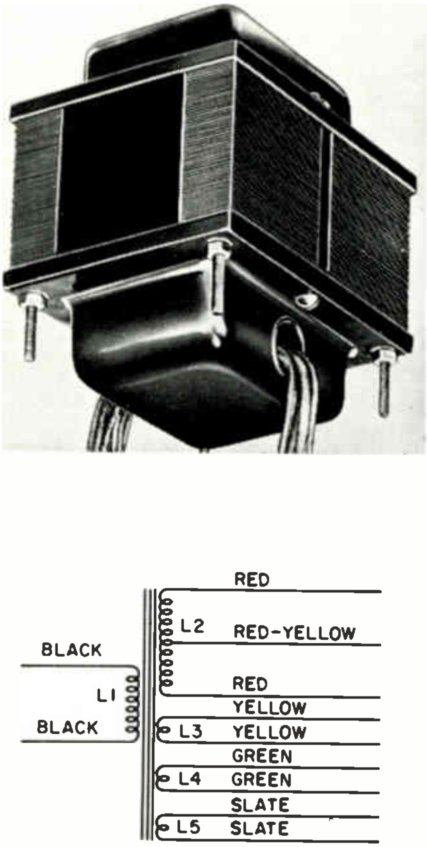

Fig. 6. A typical power transformer and its schematic symbol.

secondary windings. A photo of a typical power transformer and the schematic symbol used to represent it are shown in Fig. 6.

The winding marked L1 is the primary winding. It is usually operated from a 115-volt, ac power line.

The secondary winding marked L2 is a high-voltage secondary. Notice that this winding is center tapped. This type of winding is used with a full-wave rectifier.

A full-wave rectifier is a rectifier that rectifies both halves of each cycle. This winding is a stepup winding and is used to provide a voltage somewhat higher than that available from the power line to operate the plates of the various tubes in electronic equipment. Voltages of 250 to 350 volts are found in most circuits of modern radio and TV receivers; much higher voltages are found in transmitting equipment and in other pieces of industrial electronic equipment.

The winding marked L3 is a step-down winding. This winding is used to provide the filament voltage to operate the filament of the rectifier tube, which is used to change the ac to pulsating dc. The windings marked L4 and L5 are also low-voltage windings. These windings are used to provide the heater voltage required by the various tubes in the equipment. Some transformers have two low-voltage secondary windings like L4 and L5 on this transformer, but others have only one low-voltage secondary to heat the various tubes.

Notice that the number of turns used in the schematic symbol gives some indication of whether the windings are step-up or step-down windings. L2 has more turns than L1, and here you can expect the voltage from L2 to be higher than the primary voltage applied to L1. The windings L3, L4, and L5 have fewer turns than L1, indicating that their voltage is less than that of the primary winding. However, the schematic is not intended to show the exact number of turns or the turns ratio.

The colors have been labeled on the various leads from this transformer. This is a standard color

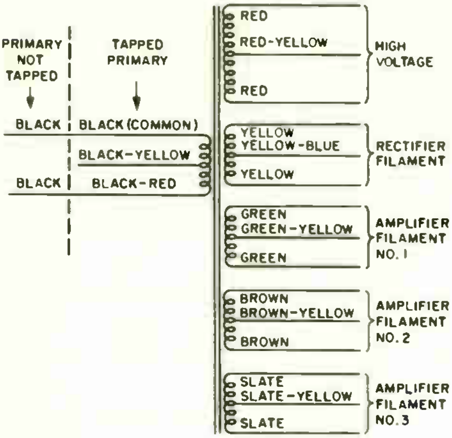

Fig. 7. The standard EIA (Electronics Industries Association) color code for power transformers.

code used to identify transformer leads. The complete color code is shown in Fig. 7. However, do not expect all transformers to follow this standard color code. Some manufacturers use a color code of their own. Therefore, even when you are using the color code to identify the leads on a transformer, you should pay some attention to how the transformer is connected into the circuit, the size of the various wires, etc., to be sure that the manufacturer has followed the standard code.

SUMMARY

We have not tried to cover all the facts about iron-core power transformers in this section of this lesson. Transformers are a subject all by themselves. Some engineers spend their whole careers designing different types of transformers. However, the information covered in this section will enable you as a technician to understand enough about transformers to know how they operate. You will learn still more about audio transformers in this lesson.

The important thing to remember from this section is that there are a number of different types of losses in transformers and that these losses cause the transformer to heat. Losses can be divided into core losses which consist of eddy current, hysteresis, and flux leakage losses, and copper losses which are called the "I squared R" losses.

Normally a transformer heats up as it is used, until it reaches a point at which it does not get any hotter. If the transformer in a piece of electronic equipment continues to get hotter and hotter and you can smell the insulation burning, it is an indication either that it is being overloaded or that there is a short either in the transformer or in the rest of the equipment.

A step-up transformer is a transformer where a higher voltage is obtained from the secondary than is put into the primary, and a step-down transformer is a transformer where a lower voltage is obtained from the secondary than is put into the primary. The power output from the secondary of a transformer is approximately equal to the power input of the primary. Thus in a step-up transformer where the secondary voltage is higher than the primary voltage, the primary current must be higher than the secondary current. Conversely, in a step-down transformer where the secondary voltage is lower than the primary voltage, the primary current will be lower than the secondary current.

Power transformers used in electronic equipment usually have several secondary windings. One secondary winding is used to provide the high voltage needed to operate the plates of the various tubes. The other secondary windings usually supply the heater voltage required by the rectifier and the other tubes in the equipment. Most transformers use a standard color code which can be used to identify the various transformer leads.

SELF-TEST QUESTIONS

(m) What is a transformer?

(n) What are the two types of losses encountered in a transformer?

(o) What happens to the power lost in a transformer?

(p) Is a transformer generally considered an efficient device?

(q) Can a power transformer designed for operation on a 60-cycle power line be used on a 25-cycle power line?

(r) What do we mean by a step-up transformer?

(s) If you have a step-down power transformer with a turns ratio of 3:1, and the current being drawn from the secondary is 3 amps, what will the primary current be?

(t) The load connected across the secondary of a power transformer consumes 230 watts. If the primary of the transformer is operated from a 115-volt power line, what will the primary current be if we consider the transformer efficiency as 100%?

(u) A power transformer has a turns ratio of 2:1. The transformer is operated from a 120-volt power line, and the device connected to the secondary winding draws a current of 4 amps. What will the primary current be?

Transformers for Specific Application

As an electronics technician, there are a number of different types of transformers that you will encounter. We are not going to try to cover all of them here, but we will discuss a few of the more common types. The material in this section of the lesson is used simply to introduce you to these special types. Later we will go into the transformers in more detail when we study the applications in which they are used.

AUDIO TRANSFORMERS

In the early days of radio, audio transformers were used as coupling devices between the various stages of the receiver. By using a step-up transformer, the strength of the audio signal could be increased in the transformer itself. This was a big help, because the tubes used in those days did not have a great deal of gain. However, modern tubes have high gain and audio transformers introduce frequency distortion, so they are no longer used with tubes for this purpose.

Impedance Matching.

You will remember that to transfer maximum power from a dc generator to a load, the load resistance must be equal to the generator resistance. In ac circuits, to transfer maximum power from a generator to a load, the load resistance must be equal to the generator impedance. To transfer maximum power from one stage in an amplifier to the following stage, the impedances must be matched. Transformers are frequently used for this purpose, particularly in transistorized equipment. For example, the output circuit of a transistor may have a much higher impedance than the input circuit of the following transistor. To transfer the power from the one transistor to the second one, an impedance-matching transformer is used.

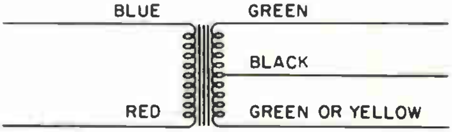

Fig. 8. An audio transformer with a tapped secondary. The colors are the standard EIA color code.

Another application in which a transformer may be used is where a single tube or transistor is used to drive two tubes or two transistors. Then an audio transformer with a tapped secondary such as shown in Fig. 8 is used. With this type of transformer, the center tap winding is either connected to ground or used to supply bias to the stage. The two tubes or transistors are driven with signals of the opposite polarity. In other words, when the signal on the top green lead in Fig. 8 is swinging positive, the signal on the lower lead that is green or yellow will be swinging negative. Thus when the current in one of the stages is increasing it will be decreasing in the other and vice versa. This type of stage is called a push-pull stage and is frequently used in the output stage of high fidelity equipment in order to obtain a high power output with low distortion. We will cover this in detail later when you study tubes and transistors.

Another place where transformers are widely used in audio circuits is in the output between the last amplifier stage and the loudspeaker. The output impedance of the power output tube or the power output transistor is generally much higher than the speaker voice coil impedance. A transformer, which is called the output transformer, is used to match the output stage to the loudspeaker in order to transfer maximum power from the output stage to the speaker. A transformer of this type will have a step-down turns ratio in order to match the higher impedance of the output stage to the lower impedance of the speaker.

You saw in an earlier lesson that to transfer maximum dc power from a generator to a load, that the generator and load resistances had to be equal. Now let's see how a transformer can be used in an ac circuit to match the load impedance to the generator impedance, so that the generator will deliver maximum power to a load that has an impedance different from the generator impedance.

In Fig. 9, we have shown how the power supplied to the load by a generator that has a no load voltage of 100 volts and an internal impedance of 50 ohms varies as different load resistors are connected across it. You will notice that when the 50-ohm load is connected across the generator, we obtain 50 watts across the load. If the load impedance is reduced below this value, then the power transferred from the generator to the load drops off.

Similarly, if the load impedance is increased above 50 ohms, the power drops off.

With a 50-ohm load connected across the generator, the total circuit resistance is 100 ohms: the 50-ohm load, plus the 50-ohm generator impedance. The 100 volts generated will be divided with 50 volts being dropped in the generator and 50 volts in the load. The current flowing in the circuit will be 1 amp.

LOAD RESISTANCE IN OHMS	POWER IN WATTS
200	32
150	37.5
100	44.4
50	50
25	44.4

Fig. 9. Power supplied by a 100-volt generator with an internal impedance of 50 ohms for various values of load resistance.

If we remove the 50-ohm load resistor, and connect some other device in its place that will draw a current of 1-amp from the generator, then there will be 50 volts across this device and the power supplied to it will be 50 watts, which we know is the maximum power that can be taken from the generator. A transformer can be used for this purpose providing it has the proper turns ratio, and providing the correct load is connected across the secondary of the transformer.

The usual problem is to have the generator and the load and then have to select the transformer. Let's assume that we have a 2-ohm load resistor we want to connect across the generator and see how a transformer can be used to get 50 watts from the generator to the load.

We know that the maximum power that can be transferred from the generator to the load is 50 watts. Now let's find out what the voltage across the resistor and the current through the resistor must be in order to get 50 watts into the resistor. Remember the formula:

$$P = I^2 \times R$$

We know that $P = 50$ watts, and $R = 2$ ohms; therefore we can find the value of I^2 in this manner:

$$I^2 = 50 + 2 = 25$$

This means that the current squared is equal to 25. We know that the square root of 25 is 5, because $5 \times 5 = 25$. Therefore the current that must flow through the resistor is 5 amps. In order to figure how much voltage we need to get a current of 5 amps to flow through a 2-ohm resistor, we use the formula: $E = I \times R$. This gives us 2×5, which equals 10 volts.

So far we have found that to get 50 watts into a 2-ohm load resistor, we must have a voltage of 10 volts across it. When we have 10 volts across the resistor, a current of 5 amperes will flow through it, and the power supplied to the resistor will be 50 watts. However, we still have the problem of getting the 10 volts across the resistor.

The transformer presents an easy method of doing this. We know that when we had maximum power transfer from the generator to the load, we had 50 volts across the load. However, in the problem we have set up, we want only 10 volts across the load. The way to satisfy both of these conditions is to connect a transformer across the generator as shown in Fig. 10. If we use a transformer with a turns ratio of 5 to 1, we will be able to satisfy these conditions.

You will remember that the transformer is a self-regulating device. The primary will take the power from the source needed to supply the power demanded by the secondary. Under these circumstances when the generator, transformer, and load are connected as shown in Fig. 10, the primary current that will flow will be 1 amp. This means that there will be 1 amp through the primary of the transformer, and therefore the power consumed by it will be 50 watts. The 50 volts applied to the primary will be stepped down by the transformer to give 10 volts across the secondary. With the 2-ohm load connected across the secondary, the secondary current will be 5 amps, and the power con-

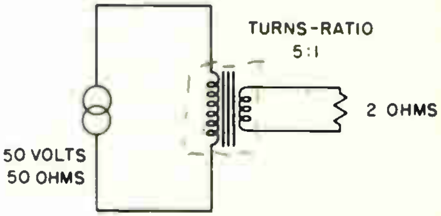

Fig. 10. A transformer used to match a 2-ohm resistor to a generator with an internal resistance of 50 ohms.

sumed by the secondary will be 50 watts. Since the transformer is a step-down transformer, the current is stepped up. The primary current of 1 amp is stepped up to a current of 5 amps in the secondary.

Under these circumstances, as far as the generator is concerned, it works exactly as it would if a 50-ohm resistor were connected across it. The transformer has matched the two-ohm resistor to the generator. Technicians say that the generator "looks into" the load and it looks like a 50-ohm load connected across it. Because the transformer matches the load impedance to the generator to provide the generator with the impedance required to transfer maximum power from the generator to the load, the transformer is called an impedance-matching transformer.

Turns Ratio.

Notice the ratio of the two impedances we matched. The generator impedance was 50 ohms, the load 2 ohms. The ratio of these two impedances is 50 to 2 or 25 to 1. The turns ratio of the transformer, however, was 5 to 1. But 5 is the square root of 25. Thus the relationship between the impedances to be matched and the turns ratio of the transformer needed to match the impedance is:

$$\frac{N1}{N2} = \sqrt{\frac{Z1}{Z2}}$$

where Z1 is the generator impedance, Z2 the load impedance, N1 the number of turns on the primary of the transformer, and N2 the number of turns on the secondary. Thus, N1/N2 is the turns ratio.

AUTOTRANSFORMERS

The schematic of another type of transformer is shown in Fig. 11. As you can see from the schematic, this transformer consists of a single winding with a tap. It is called an autotransformer because it has only one winding. (Auto is the Greek word for "self".) In the transformer shown in Fig. 11A, the secondary voltage is higher than the primary voltage because there are more turns on the secondary than there are on the primary. In the transformer shown in Fig. 11B, the secondary voltage is lower than the primary voltage because the primary has more turns than the secondary.

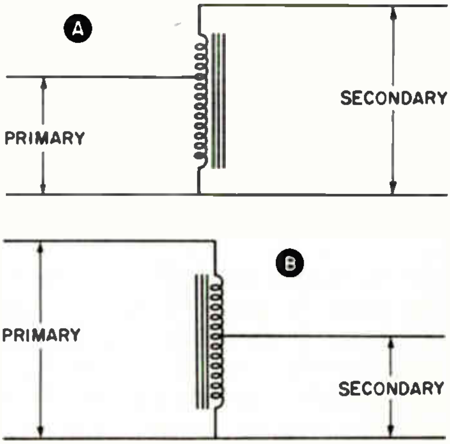

Fig. 11. Schematic of an autotransformer.

The autotransformer is different from a conventional transformer in that the primary and secondary windings are not insulated from each other. The voltage applied to the primary will set up a magnetic field, and this magnetic field will cut all the turns of the secondary, including those which may be a part of the primary, and induce a voltage in them. This voltage will appear across the secondary terminals of the transformer and if we connect a load to these terminals, current will flow through the load.

Autotransformers have the disadvantage that the primary and secondary windings are not completely isolated from each other electrically. In other words, there is an electrical connection between the primary and secondary windings. As a matter of fact, one lead connects directly to both primary and secondary windings as you can see from the diagrams in Fig. 11. However, they have the advantage over the transformer with two separate windings in that they are more economical to manufacture and therefore are frequently used in modern electronic equipment where keeping the cost as low as possible is of major importance.

RF TRANSFORMERS

Another transformer that you will encounter frequently is the rf radio frequency transformer. This type of transformer, because of the high frequencies at which it operates, is either an air-core or a powdered iron-core transformer. A typical rf transformer designed for use at standard broadcast band frequencies is shown in Fig. 12.

RF transformers are used in the stages of a radio or TV receiver that are designed to amplify the received signal frequency. In other words, in the case of a broadcast band receiver, the signal is picked up and amplified by one or more rf stages before it is processed in any way. RF transformers are used between stages of this type.

In most cases, the secondary of the transformer, at least, is used in conjunction with a variable capacitor to form a resonant circuit. The rf transformer acts very much like the step-up transformer, because if the secondary is tuned to resonance, the circuit forms a series-resonant circuit and there will be a resonant voltage step-up across the secondary of the transformer. This situation exists even though the primary of the transformer may have the same number of turns as the secondary. Here the step-up in voltage is being obtained because of the action of the resonant circuit, rather than the action of the transformer.

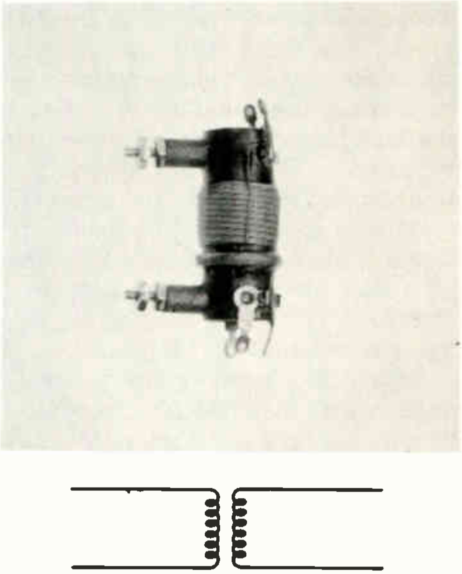

Fig. 12. A typical rf transformer and its schematic symbol.

In TV receivers where the rf stages must operate on a much higher frequency, an rf transformer may consist of only one or two turns of wire on the primary winding and the same number of turns on the secondary. If one winding of the transformer is tuned to resonance, it is usually tuned by stray circuit capacitances and capacitances in the tubes or transistors used in the stage rather than by a separate variable capacitor.

RF transformers are sometimes called rf coils, but are actually transformers. Their operation is similar to that of the iron-core transformers you studied earlier in this lesson.

I-F TRANSFORMERS

Modern radio and television receivers use what is called a superheterodyne circuit. In this type of circuit the incoming signal is fed to a stage called a mixer stage where it is mixed with a locally generated signal. The output of the mixer stage produces a new signal frequency which is called the intermediate frequency. We abbreviate this i-f and call the stages used to amplify this signal i-f stages. Between the various i-f stages we use transformers called i-f transformers.

A typical i-f transformer and its schematic diagram are illustrated in Fig. 13. The primary winding of the transformer and its capacitor form a parallel-resonant circuit, and the secondary winding and its capacitor form a series-resonant circuit. Both the primary and the secondary windings are tuned to the same frequency and usually the two windings have exactly the same number of turns on them. However, again because the secondary is a series-resonant circuit, there is a resonant voltage step-up and the voltage across the secondary winding will be higher than the voltage across the primary winding.

Even though the primary and secondary windings of an i-f transformer are tuned to resonance at a specific frequency, they are designed so that they have a certain bandwidth. By this we mean that instead of passing only one specific frequency, the transformer will pass a band of frequencies. The actual bandwidth depends upon the design of the transformer and the frequency at which it operates. The bandwidth of a transformer can be shown by means of a response curve such as shown in Fig. 14. Here you will see that the resonant frequency is 455 kc, but there is very little differ-

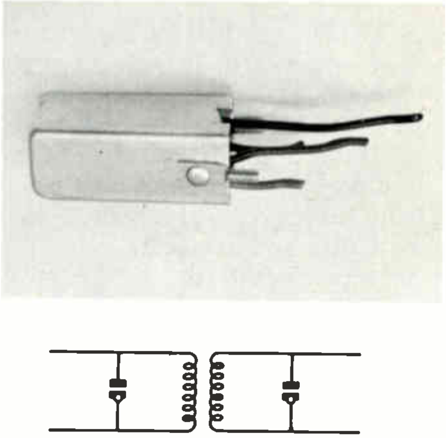

Fig. 13. A typical i-f transformer and the schematic symbol for it.

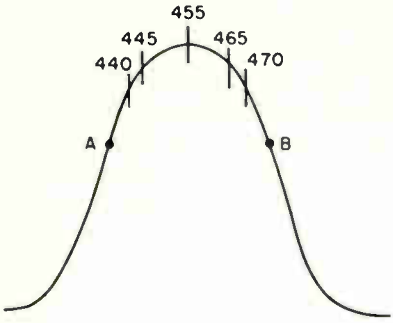

Fig. 14. An i-f transformer response curve.

ence in the response of the transformer either 10 kc below or 10 kc above this frequency. Under these circumstances, the transformer would have a bandwidth of at least 20 kc. In other words, it will pass signals having a frequency from 445 kc to 465 kc satisfactorily.

As a matter of fact, we can go a little further down the curve and see that there is not too much difference between 440 kc and 455 kc. You can see that deciding the bandwidth is a rather arbitrary thing. Engineers have set up as a standard the point where the response falls to .707 of the response at the resonant frequency. This is the half-power point you have already studied. The bandwidth of the i-f coil is the frequency between the .707 point on the low side of the curve and the .707 point on the high frequency side of the curve. These points have been marked A and B on the response curve shown in Fig. 14.

They are called the "3-db down" points. The abbreviation "db" means decibel. It is a means of expressing power ratio. The 3-db down points, A and B in Fig. 14, are within 3-db of the resonant frequency.

We do not expect you to understand the decibel at this time; we will go into it in more detail eventually. However, keep in mind the expression "3-db down", because this expression is frequently used by technicians and engineers. It is an idea that is somewhat difficult to grasp, but one of the first steps in seeing what is meant is becoming familiar with the term. Now that you have been introduced to it, the next time you will see it, it will not seem quite so strange to you.

When you look at Fig. 13 you might think that the primary and secondary windings are placed so far apart that there would be very little coupling between the two of them. However, there actually is considerable coupling between the two windings. The spacing of the transformer windings is adjusted to give exactly the desired amount of coupling. If the coils are placed too close together, then the curve shown in Fig. 14 tends to flatten out and have a dip in the center around a 455 kc point.

In TV i-f transformers, the coils are placed much closer together; in fact, often one is wound directly on top of the other. This is done in order to provide what is called very tight coupling and to spread out the response curve to pass a wide band of frequencies. You will see later that in television we must be able to pass a wide band of frequencies; otherwise, part of the picture information in black and white transmissions or part of the color information in color broadcasts will be lost.

TV i-f transformers do not have

a separate capacitor across the primary and secondary windings like the one shown in Fig. 13. There is enough capacity in the circuit and in the output and input in the various stages to provide the capacity required in order to bring the windings on the transformer to resonance.

SUMMARY

In this section of the lesson, you have been introduced to a number of new types of transformers.

You have learned that transformers are used between the audio stages in some pieces of equipment. Many of these transformers are step-up transformers so that the voltage across the secondary may be two or three times the voltage across the primary. However, in some high-power audio equipment, step-down transformers are used between audio stages. Transformers with tapped secondaries may be used when one tube must drive two tubes.

Transformers are used as impedance-matching devices. In order to get maximum power from a generator to a load, the load impedance must be equal to the generator impedance. This situation can be met by using a transformer with a suitable turns ratio to match the load impedance to the generator impedance so that the generator operates as if it were working into a load equal to its own internal impedance. Impedance-matching transformers are used between the output stage of a radio or TV receiver and the loudspeaker. Because these transformers are used at the output of the receiver they are usually called "output" transformers.

You have learned that the autotransformer is a single-winding transformer. Part of the transformer winding serves as both the primary and secondary. The autotransformer is frequently used to step up the line voltage if it is somewhat lower than normal.

We have also mentioned rf transformers. Although we did not go into a great deal of detail about them, you should recognize an rf transformer the next time you see one. An rf transformer has two windings, a primary and a secondary winding, and it operates in very much the same way as an iron-core transformer.

I-F transformers have both a tuned primary and a tuned secondary. The primary is a parallel-resonant circuit. The secondary is a series-resonant circuit. An i-f transformer has a certain bandwidth; this means that the transformer will pass frequencies above and below the frequency to which it is resonant. The bandwidth of a transformer is defined as the frequency difference between a point on the low side of the response curve and a point on the high side of the response curve at which the output from the transformer is .707 of the output at resonance. These points are called "3-db down" points.

SELF-TEST QUESTIONS

(v) Are step-up type audio transformers used in modern electronic equipment?

(w) What is the major use of audio transformers in electronic equipment?

(x) Why is it important that the

output stage in a radio receiver or a TV receiver be matched to the speaker voice coil?

(y) What type of audio transformer is used to drive a push-pull stage from a single driver stage?

(z) What must the turns ratio of an output transformer be to match a speaker with a 10-ohm voice coil to an output stage that has an output impedance of 1000 ohms?

(aa) What is an autotransformer?

(ab) Is an autotransformer a step-up transformer or is it a step-down transformer?

(ac) What is the disadvantage of an autotransformer?

(ad) What is an rf transformer?

(ae) What type of core would you expect to find in an rf transformer?

(af) In a typical i-f transformer used in a broadcast receiver, the primary and secondary windings will have the same number of turns. However, in spite of this, the voltage across the secondary winding will be higher than the voltage across the primary winding of the transformer. Why is this so?

Iron-Core Chokes

A choke is a coil used to purposely introduce a high reactance in a circuit. An iron-core choke is a coil wound on an iron core. A typical iron-core choke and the schematic symbol used to represent it are shown in Fig. 15.

Iron-core chokes are sometimes found in audio equipment, but their most important use is in power supplies. Here they are used in conjunction with capacitors to smooth the pulsating dc from the output of the rectifier. Chokes that are used for this purpose are called filter chokes or smoothing chokes.

PHYSICAL AND ELECTRICAL CHARACTERISTICS

It is sometimes difficult to distinguish an iron-core choke from a small power transformer. However, an iron-core choke usually has only two leads, whereas a power transformer has more than two leads. However, some iron-core chokes have a tapped winding. This type of choke has three leads and is very rare; most chokes have only two leads and can be distinguished easily from a transformer by this characteristic.

The core on which an iron-core choke is wound is similar to a transformer core. Thin sheets of laminated silicon steel are used in constructing the core. A frame is generally provided around the core and this frame serves the dual purpose of holding the laminations of the core together tightly and also in providing a convenient method of mounting the choke. You can see the frame in Fig. 15.

The core of an iron-core choke is made of silicon steel, which keeps the hysteresis losses in the choke as low as possible. The core is laminated to keep the eddy current losses low. The pulsating dc that is fed to a filter choke is actually a mixture of ac and dc. The ac has exactly the same effect in the choke as it has in a transformer, so both hysteresis and eddy current losses are present.

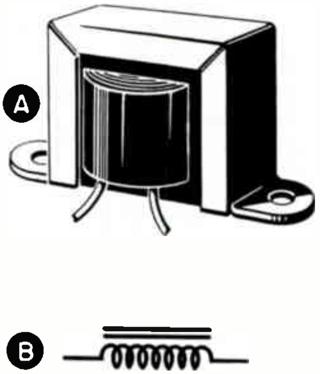

Fig. 15. A typical iron-core choke and its schematic symbol.

A choke used in a power supply usually has a fairly high inductance. Inductances from about 1 henry up to 30 or 40 henrys are quite common.

The size of wire chosen for winding a choke is determined by the current that will flow through the choke.

When an iron-core choke is used as the filter choke in the power supply, there is usually a high dc current flowing through it; superimposed on this dc is ac. The wire with which the choke coil is wound must be large enough to accommodate this current without overheating.

The current that flows through the choke coil will govern the size of core required. Saturation, which you have already studied, must be avoided in chokes. It can be avoided only by using an iron-core large enough to handle the magnetic field developed by the coil without reaching the saturation point.

If a choke becomes saturated, its inductance drops. This in turn results in a decrease in the inductive reactance and hence a decrease in its effectiveness in filtering the pulsating dc to pure dc.

In your career as an electronics technician, you will have occasion to replace defective filter chokes. When selecting a replacement, keep in mind that if you use too small a choke, it can be saturated and thus be very ineffective as a filter. Therefore, the replacement choke should be of approximately the same physical size as the original choke and the wire used to wind the choke should be at least as large as the wire used to wind the original choke. Technicians usually do not concern themselves with the wire size because manufacturers rate their chokes giving the inductance and the current that the choke is designed to handle. Thus, a choke rated at 8 henrys, 250-ma, is a choke that will have an inductance of 8 henrys when a dc current of 250 milliamperes is flowing through it. If the current flowing through the choke is higher than 250 milliamperes, the core will approach the saturation point, and the inductance will drop. If the current flowing through the choke is less than 250 milliamperes, the inductance of the choke will be somewhat higher than 8 henrys. This will not cause any trouble; the equipment will work as well as ever. If the current flowing through the choke exceeds the 250-ma current rating substantially, the chances are that the choke will overheat and may eventually get so hot that it will burn out.

HOW CHOKES ARE USED

We mentioned that chokes are used along with capacitors in power supplies to help smooth the pulsating dc at the output of the rectifier to pure dc at the output of the filter network. A typical circuit showing how a choke and a capacitor may be used is shown in Fig. 16. To see how the combination acts to filter the pulsating dc, first consider that the pulsating dc at the input actually consists of two components, ac superimposed on dc. To understand the action of the choke and capacitor, we can study their action on the two components separately.

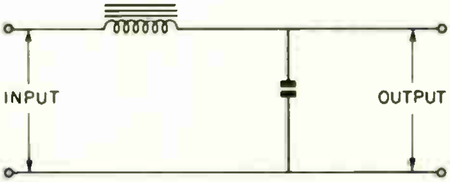

Fig. 16. A filter network made up of a choke and a capacitor.

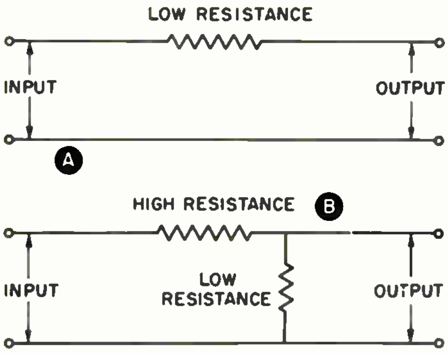

Fig. 17. The effect of the filter circuit for a dc component is shown at A, and for an ac component at B.

You know that a choke offers little or no opposition to the flow of dc through it. The only opposition the choke will offer to the flow of dc will be due to the resistance of the wire used to wind the coil. Since this is normally quite low, the dc can flow from the input through the choke coil to the output without any difficulty. The capacitor is charged by the dc, but once it is charged, it will not draw additional dc through the choke. Between the input and output circuits, we actually have a very simple circuit like the one shown in Fig. 17A insofar as the dc is concerned. Notice that we have only a low resistance in the circuit. The capacitor is not shown, and it can be completely ignored insofar as the dc flowing in the circuit is concerned.

The action of the choke and capacitor to the ac component is completely different. The choke, since it has inductance, has inductive reactance and is usually selected so that the inductive reactance will be quite high. The capacitor on the other hand is selected with a low capacitive reactance. Thus, insofar as the ac is concerned, we have a circuit like the one shown in Fig. 17B. Here we have a high resistance taking the place of the choke and a low resistance taking the place of the capacitor. Now these two "resistors" act like a voltage divider and most of the voltage will be dropped across the high resistance and very little will appear across the low resistance in the output. If the reactance of the choke is ten times the reactance of the capacitor, the ac component at the output would be approximately 1/10 the ac at the input.

If further filtering is needed to smooth the pulsating dc more than it can be smoothed by a single choke and capacitor, two chokes and two capacitors can be used as shown in Fig. 18. Here, if there is a 10-to-1 reduction of hum (which is what the ac is called since it produces hum in the output of the device) in each section, the total hum reduction in a two-stage filter network of the type shown in Fig. 18 would be 100. This means that if a 100-volt ac signal is applied to the input of the circuit, there will be a 1-volt ac signal at the output. On the other hand, dc applied to the input would flow through the filter network relatively unhampered.

In a two-stage filter network such as shown in Fig. 18, the first choke, marked L1, is called the input filter choke and the second one, marked

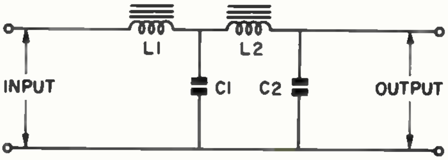

Fig. 18. A two-stage filter network.

L2, is the output filter choke. The choke, L1, is sometimes a special type of choke called a swinging choke. This type of choke is made with a rather small air gap in the core. The core is somewhat smaller than it should be for the amount of current that will flow through the choke so that it saturates rather easily and its inductance varies. The advantage of using this type of choke is that we are able to obtain better voltage regulation at the output of the power supply. By voltage regulation we mean keeping the output voltage more nearly constant as the load or current taken from the power supply vary. The second choke, marked L2, is usually called a "smoothing" choke.

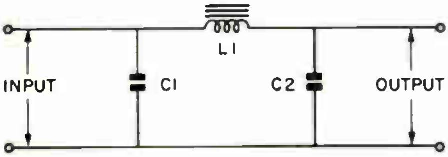

Fig. 19. A capacitor input filter.

Another type of filter network is shown in Fig. 19. This type of filter is often called a brute force filter. Notice that this network uses two capacitors and one choke. This type of network is called a capacitor input filter, whereas the one shown in Fig. 18 is called a choke input filter. In Fig. 19, C1 is called the input capacitor and C2 the output capacitor. The dc output voltage obtained from a capacitor input type of filter is somewhat higher than can be obtained from a choke input filter, but the voltage regulation is better with a choke input filter. Both types are found in modern electronic equipment.

SUMMARY

Chokes are important to the electronics technician, because he will encounter them in most pieces of electronic equipment that he is called upon to service.

Most chokes look like iron-core transformers except that they have only two leads, whereas a transformer has at least three and usually more leads. The cores of chokes are made of laminated sheets of silicon steel. This type of construction is used to keep the eddy current and hysteresis losses low.

Chokes can be saturated if the current passing through them is too high. Therefore, in replacing a defective choke in a piece of electronic equipment, the technician should use a replacement at least as large as the original. Filter chokes are used in conjunction with capacitors to smooth the pulsating dc at the output of a rectifier to pure dc at the output of the filter circuit. Chokes are used for this purpose because they offer a low-resistance path to the flow of dc through them but offer a high reactance to the flow of ac through them. The pulsating dc at the output of the rectifier actually consists of a dc component with an ac component super-imposed on it. The choke lets the dc component go through with little or no effect on it, and in conjunction with the capacitor greatly reduces the ac component.

SELF-TEST QUESTIONS

(ag) How can you tell a filter choke from a power transformer?

(ah) What is the purpose of the filter choke in a power supply?

(ai) What is the danger of passing too high a current through a filter choke?

(aj) Does a filter choke offer a high resistance or does it offer a low resistance to the flow of dc through it?

(ak) In a two-stage filter network, what are the names given to the two filter chokes?

(al) What is a swinging choke?

Relays

Another magnetic device is the relay. Although relays are used chiefly in transmitters and industrial equipment, they are found in some radio and TV receivers with automatic tuning systems. Relays are used to open and close circuits electrically. They are electric switches. In many ways a relay is similar to a mechanical switch. In order to understand relays, you should understand mechanical switches. So let's look at them first.

SWITCHES

Switches are made with several different contact arrangements. The simplest switch is one that has two positions. In one position, the circuit is open; in the other position the circuit is closed. This is called a single-pole, single-throw switch, abbreviated SPST. Fig. 20 shows an example of this kind of switch. In the position shown at A, the circuit is closed. When the blade is raised as at B, the circuit is open.

The switch illustrated in Fig. 20 is only one kind of SPST switch. They are made with different types of contact arrangements. However, although the mechanisms are different, the electrical principles are the same--in one position of the switch the circuit is open, and in the other position the circuit is closed. An ordinary light switch such as you have in your home is another example of an SPST switch.

Another type of switch, called a single-pole, double-throw switch (SPDT) is arranged so that in one

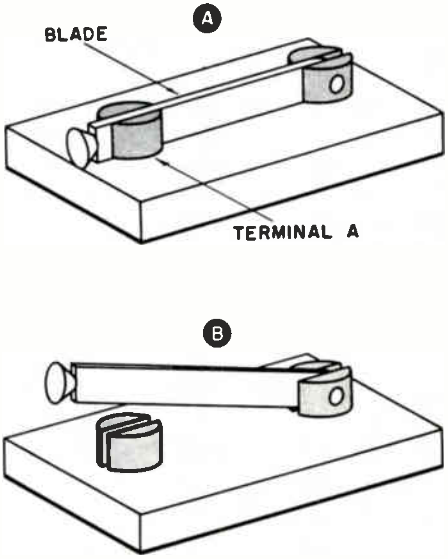

Fig. 20. A single-pole, single-throw switch is shown closed at A, and open at B.

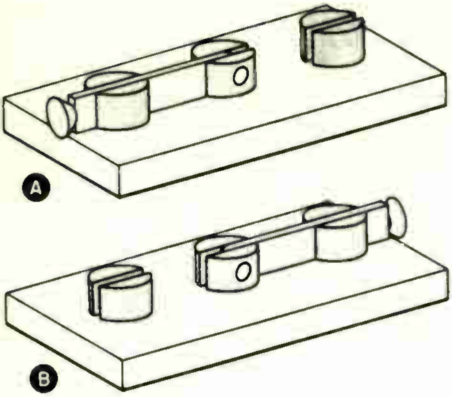

Fig. 21. A single-pole, double-throw switch makes contact in either of the two positions shown at A and B.

position it closes one circuit, and in the other position it closes another circuit. Fig. 21 shows an example of this type of switch.

A double-pole, single-throw (DPST) switch shown in Fig. 22 is really two switches in one. It has two blades, mechanically joined, so they are thrown open or closed at the same time. As in the SPST switch, when the blades are down, the circuits are closed, and when they are up, the circuits are open.

The double-pole, double-throw (DPDT) switch shown in Fig. 23 has two blades joined mechanically and two closed positions. There are also triple-pole, single-throw (TPST) switches, and triple-pole, double-throw (TPDT) switches.

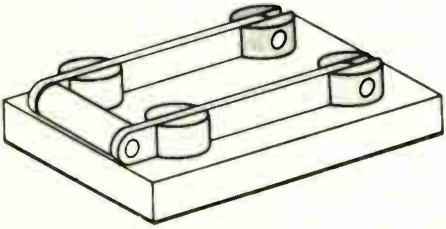

Fig. 22. A double-pole, single-throw switch.

Relays are also made with all these different types of contacts. Let's see how a relay works.

SIMPLE RELAY CONSTRUCTION

In its simplest form, a relay consists of nothing other than an iron-core coil such as shown in Fig. 24 with a bar of magnetic material placed on a pivot near one end of the core. One end of the bar is attached to a spring. The tension of the spring lifts the bar up and away from the core of the magnet. The motion of the top of the bar is usually restricted by some non-magnetic material so that when the relay is not energized, the bar will assume the position shown in Fig. 24A.

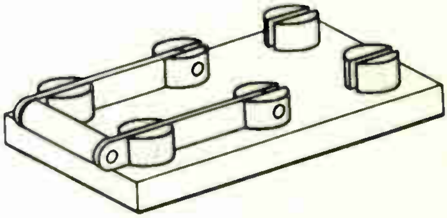

Fig. 23. A double-pole, double-throw switch.

When a voltage is applied to the relay coil, current flows through the coil and the magnetic field produced attracts the bar on top of the coil and pulls it down as shown in Fig.

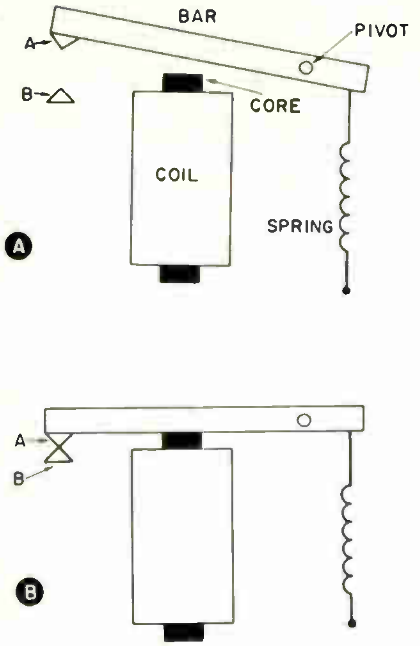

Fig. 24. Basic operation of a relay.

24B so that the contacts A and B are closed. Leads can be connected to terminals A and B so that energizing the relay closes the circuit and current will flow through the circuit.

Some relays operate from dc, but others are made that operate from ac. There is usually not too much difference between small ac and small dc relays, except that the spacing between the bar and the magnet is usually somewhat greater in an ac relay. If the bar comes too close to the magnet in an ac relay, there may be some tendency for the relay to chatter. By chatter, we mean that the bar moves up and down as the ac goes through its cycle and the strength of the magnet varies. If the bar is made of heavy enough material and kept a reasonable distance from the magnet, this problem is usually not encountered in small ac relays.

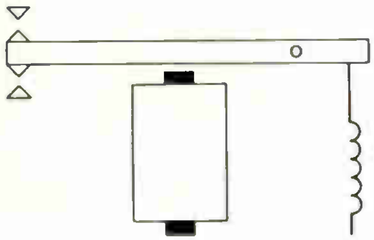

Fig. 25. A single-pole, double-throw relay.

RELAY CONTACTS

The contacts on relays are identified using the same system that is used to identify the contacts on an ordinary switch. The movable arm of a relay or switch may be made to make contact in one position and no contact in the other position, or it may be made to make contact in either of two positions.

If there is only one set of contacts on a relay, we call it a single-pole, single-throw relay. The relay shown in Fig. 24 has this type of contact.

Single-pole, double-throw relays are arranged so that when the coil is energized, it pulls the bar down and the bar makes contact with one terminal and when the coil is not energized, then the bar moves up under the tension of the spring and makes contact with another terminal, as shown in Fig. 25.

Relays are also made with all the other contact arrangements that we

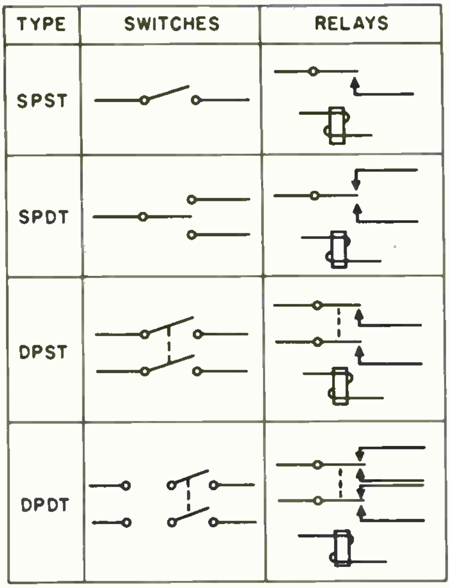

Fig. 26. Schematic symbols for different types of switches and relays.

showed for mechanical switches. Fig. 26 shows the schematic symbols for different types of switches and relays.

SPECIAL PURPOSE RELAYS

There are many special types of relays designed for specific jobs.

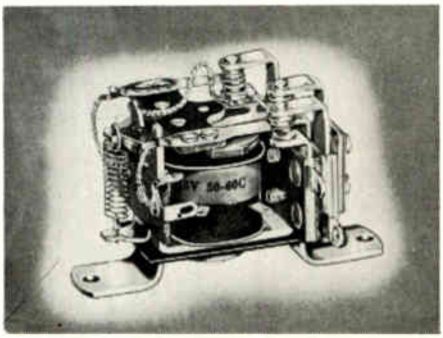
Time-Delay Relay.

One type of relay is a time-delay relay. In this type of relay, the contacts do not close until a predetermined time has elapsed after the power is applied to the relay. After this time has elapsed, the contacts are closed and the circuit is complete. Time-delay relays are usually either SPST or DPST relays. Double-throw time-delay relays are seldom used. Time-delay relays are often used in transmitting equipment where it is desirable to allow the cathode of the tubes to warm up before the other operating voltages are applied.

Overload Relay.

Another type of relay is used for protective purposes in electronic equipment. This type of relay is often called an overload relay. It is designed so that the relay is energized and the circuit opens when the current exceeds a predetermined value. Sometimes a break-down in one circuit will affect another. The current in the second circuit might rise so high that some valuable part such as a tube would be destroyed. With an overload relay in the circuit, when the current rises above a safe value, the relay automatically opens, removing the voltage from the tube, thus saving it from destruction.

As you might expect there are some circuits in which if the current drops below a predetermined value, some damage might result or the equipment might fail to operate



A relay of the type found in electronic equipment. This is a triple-pole, double-throw type.

Fig. 27. A thermal type overload device.

properly. There are relays that are set to open when the current drops below a predetermined value.

Another type of overload device that is widely used in TV receivers is shown in Fig. 27. This type of overload is not a relay, but instead is made of a metal strip which is made from two dissimilar metals. The current flowing through the strip causes the metals to heat and they expand at different rates. If the metal gets hot enough, the expansion will be great enough to distort the metal so that it springs loose from the contact holding it in place and this opens the circuit. You will run into this type of overload device frequently in TV receivers. Be sure not to confuse it with an overload relay. It serves the same basic purpose, but it is a thermal overload device rather than a magnetic relay overload device.

SUMMARY

Relays are devices used to close circuits automatically, to protect circuits either by waiting for a predetermined time before closing the circuit or by opening the circuit when an overload occurs. The relay consists of an electromagnet, a bar which can be held in one position by the magnet and returned to the other position by the spring, and one or more sets of contacts.

Relays are found in many different types of electronic equipment. About the only types of defects you are likely to encounter in relays are open coils, and burned or dirty contacts. Sometimes replacement coils are available, sometimes the contacts can be cleaned, but with some types of relays the only suitable remedy for a defect is to replace the entire relay.

SELF-TEST QUESTIONS

(am) What do we mean when we refer to a switch as an SPST switch?

(an) What is meant by SPDT?

(ao) What do the letters DPDT mean?

(ap) What causes the contacts in a relay to close?

(aq) What is a time-delay relay?

(ar) What is an overload relay?

(as) Overload protective devices are frequently found in TV receivers - are these overload devices overload relays?

LOOKING AHEAD

The iron-core devices that you studied in this lesson are all devices that will be found frequently in electronic equipment. Of the three, transformers and chokes will be found in more different types of equipment than relays, but there are many pieces of equipment that use a large number of relays. Defective transformers, chokes, and relay coils can frequently be recognized by a characteristic odor that they give off when they have been overheated. Also, you will generally notice signs of sealing wax and other compounds leaking from an overheated iron-core device. The insulation becomes brittle and can often be crumbled with your fingers. You will not go far in your electronics career before you run into one of these devices that has broken down. Usually it is a simple matter to locate and replace one of these parts that is defective.

In the lessons you have so far studied, you have covered a number of the basic components found in electronic equipment. Now, you are ready to study vacuum tubes, and then see how the components are used with vacuum tubes in amplifiers and other interesting circuits.

ANSWERS TO SELF-TEST QUESTIONS

(a) The gilbert is a unit of magnetomotive force. The gilbert is slightly smaller than the ampere-turn. The gilbert is particularly useful in expressing the magnetomotive force of a permanent magnet.

(b) The maxwell is the unit of magnetic flux. One line of flux is equal to one maxwell.

(c) The flux density is a measure of the number of flux lines passing through a given area. A flux density of one line or one maxwell per square centimeter is known as a gauss.

(d) 100 maxwells or lines. To find the total number of lines you multiply the area in centimeters by the flux density; in this case 10 × 10 = 100 lines.

(e) When magnetic saturation occurs, all of the molecules in the core material are aligned with their north poles pointing in one direction and their south poles pointing in the other so that any further increase in magnetomotive force cannot produce any further alignment of the molecules or any increase in flux.

(f) No - in fact it produces a number of undesirable effects and should be avoided.

(g) Magnetic saturation cannot be produced in air regardless of how strong the magnetomotive force is.

(h) A hysteresis loss is a loss due to the inertia of a magnetic circuit. When the core in a choke or transformer is magnetized by passing a current through the coil, the core does not return to a state of zero magnetism when the current is removed. Some magnetism will remain and power must be used to bring the flux density back to zero. This power required to bring the flux density back to zero represents the hysteresis loss.

(i) Eddy current losses are losses due to the fact that a core of the transformer choke acts like a complete turn of a coil and the flux cutting this turn induces a voltage in it which causes a current to flow. This represents a loss which is known as an eddy current loss.

(j) By selecting a material that has very little magnetic inertia. Materials such as silicon steel have much lower hysteresis loss than hard steel.

(k) Eddy current losses are kept at a minimum by making the core of a transformer or choke coil in the form of sheets of metal rather than a solid piece. The sheets are electrically insulated from each other so that the flow of eddy currents across the entire core material is prevented.

(l) Flux leakage losses are due to the fact that part of the flux escapes from the core and travels through the air surrounding the core. This flux serves no useful purpose since the flux lines in the case of a transformer would not cut the secondary winding of the transformer.

(m) In its simplest form a transformer is two separate coils of wire wound on a common core and placed near each other so that the magnetic lines produced by one coil will cut the other coil.

(n) The two types of losses encountered in a transformer are core losses and copper losses.

(o) The power lost in a transformer is turned into heat. The heat is radiated by the transformer and the chassis on which the transformer is mounted.

(p) Yes. A transformer is one of the most efficient devices you will encounter in electronics. Large power transformers may have efficiencies as high as 98% or better. This means that 98% of the power taken by the primary winding of the transformer is available for useful work at the secondary winding of the transformer.

(q) No. A transformer designed for 60-cycle operation will overheat and burn out if it is operated on a 25-cycle power line.

(r) A step-up transformer is a transformer that has more turns on the secondary winding than on the primary winding. As a result, the voltage available across the output of the secondary winding will be higher than the voltage supplied to the primary winding. The ratio by which the voltage is stepped up is determined by the ratio of the number of turns on each winding of the transformer. In other words, if the secondary winding has twice as many turns as the primary winding, the voltage available across the secondary will be twice the voltage applied to the primary.

(s) 1 amp. A step-down transformer steps the voltage down by the turns ratio; however, it steps the current up by the same turns ratio. Therefore, if the secondary current is 3 amps, the primary current will be only 1 amp.

(t) 2 amps. To find the current we divide the power by the voltage; in this case we have 230 watts divided by 115 volts equals 2 amps. The efficiency of a transformer is usually so high that we can ignore any losses and if the power consumed by the secondary is 230 watts, we can consider that the primary power will also be 230 watts.

(u) If the turns ratio of a transformer is 2:1, and the transformer is operated on a 120-volt power line, then the secondary voltage must be 60 volts. Since the current drawn by the secondary winding is 4 amps, then the power the secondary winding is supplying is 60 × 4 = 240 watts. The primary winding must take this much power from the power line and since the voltage at the power line is 120 volts then the current must be 240 watts divided by 120 volts = 2 amps.

(v) No. Step-up type audio transformers were used in the early days of radio when the gain that could be obtained with a single vacuum tube was comparatively low. By using a step-up type transformer some increase in voltage could be obtained in the transformer and this helped obtain a reasonable voltage amplification in the stage. However, with modern tubes and transistors, adequate gain can be obtained in a stage without resorting to step-up transformers.

(w) Audio transformers are most widely used in electronic equipment as impedance-matching devices. They are used to match the impedance of one stage to the impedance of the following stage, and they are also used to match the impedance of the output stage to the loudspeaker voice coil impedance.

(x) The output stage of a radio or TV receiver must be matched to the speaker voice coil in order to get maximum power transfer from the output stage to the speaker voice coil.

(y) A transformer with a tapped secondary. The center tap on the secondary is either grounded or used to feed bias to the push-pull stages and the signals supplied to the stages are 180° out of phase, so when the current is increasing in one stage of a push-pull amplifier it is decreasing in the other.

(z) The turns ratio must be 10:1. The turns ratio is equal to the square root of

$$\frac{Z1}{Z2}$$

Substituting 1000 ohms for Z1 and 10 ohms for Z2 we find that the turns ratio is

$$\frac{1000}{10} = \sqrt{100}$$

$$\sqrt{100} = 10$$

(aa) An autotransformer is a transformer that consists of a single winding with a tap.

(ab) An autotransformer can be either a step-up transformer or a step-down transformer. If the primary voltage is applied across the entire winding and the secondary voltage taken off between the tap and one of the primary connections, the transformer will be a step-down transformer. On the other hand, if the primary voltage is applied between the tap and one of the outside connections and the secondary voltage taken off across the entire winding, the output transformer will be a step-up transformer.

(ac) The disadvantage of an autotransformer is that the primary and secondary windings are not completely isolated from each other electrically.

(ad) An rf transformer is a radio frequency transformer used between radio frequency amplifier stages.

(ae) RF transformers have either an air-core or a powdered iron core.

(af) The secondary winding of an i-f transformer, along with the capacitor connected across it, form a series-resonant circuit. This results in a high circulating current and a resonant voltage step-up across the coil and across the capacitor. As a result, the voltage across the coil will be considerably higher than the source voltage. We refer to this increase in voltage as resonant voltage step-up and it explains why the voltage across the secondary winding of an i-f transformer is higher than the voltage across the primary winding.

(ag) A filter choke has only one winding and therefore it has only two leads. Transformers usually have two or three windings and therefore will have more than two leads.

(ah) The filter choke is used in conjunction with filter capacitors to help smooth the pulsating dc from the rectifier output to pure dc.

(ai) The excessive current may over-heat and burn out the wire used to wind the filter choke. In addition, the filter choke may become saturated, even if it doesn't burn out, due to the excessive current flowing through it and its effectiveness as a filter will be reduced.

(aj) A filter choke offers a low resistance to the flow of dc through it. The only opposition the choke offers to dc is the resistance of the choke which is equal to the resistance of the wire used to wind the choke. On the other hand, a filter choke offers a high opposition to the flow of ac through it.

(ak) The two filter chokes are known as the input choke and the output filter choke. The choke connected to the rectifier is the input filter choke, and the other choke is the output filter choke.

(al) A swinging choke is a choke made with a small air gap in the core. The choke is usually somewhat smaller than it would normally be for the amount of current flowing through it and as a result the choke saturates easily. Its inductance varies as the current flowing through it changes.

(am) SPST means single-pole single-throw. With this type of switch there is only one circuit and in one position the switch is closed and in the other position it is open.

(an) SPDT means single-pole double-throw. With this type of switch one circuit can be completed with the switch in one position and a second circuit can be completed with the switch in the other position.

(ao) DPDT means double-pole double- throw.

(ap) A current flowing through the relay coil produces a magnetic field which attracts a bar which is pivoted above the magnet. The magnet pulls the bar towards the magnet and the the bar closes the relay contacts.

(aq) A time-delay relay is a relay in which the contacts do not close when the relay is at first energized until after a predetermined time has elapsed. This type of relay is frequently found in transmitting equipment - its purpose is to permit the tubes to come up to operating temperature before the high voltages are applied to the tubes.

(ar) An overload relay is a relay used for protective purposes. The relay contacts are normally closed, but if the current flowing through the relay coil exceeds a certain predetermined value the relay contacts will open protecting the circuit in which the relay is used.

(as) No; overloads of this type are thermal overloads and operate when the current flowing through them causes the metal conductor to reach a certain temperature. This causes the metal to spring the contacts open. An overload device of this type is called a thermal overload and is not a relay.

Lesson Questions

Be sure to number your Answer Sheet B109.

Place your Student Number on every Answer Sheet.

Most students want to know their grade as soon as possible, so they mail their set of answers immediately. Others, knowing they will finish the next lesson within a few days, send in two sets of answers at a time. Either practice is acceptable to us. However, don't hold your answers too long; you may lose them. Don't hold answers to send in more than two sets at a time, or you may run out of lessons before new ones can reach you.

1. What do we mean when we say a magnetic circuit is saturated?

2. Name the three types of core losses encountered in iron-core transformers.

3. If the primary of a 1:3 step-up transformer is connected to a 120-volt power line, what voltage will be produced across the secondary?

4. If we connect a 200-ohm resistor across the secondary of a 1:2 step-up transformer, and then connect the primary to a 100-volt source, what will the primary current be?

5. What is the big disadvantage of interstage audio transformers?

6. What must the turns ratio be of the matching transformer used to match a tube with an output impedance of 1600 ohms to a 16-ohm speaker?

7. Why are transformers with separate primary and secondary windings more suitable than auto transformers in many applications?

8. Could a 10-henry, 250-ma choke be used as a replacement for a 10-henry, 200-ma choke?

9. Why is a swinging choke often used as the input choke in a two-stage filter network?

10. What does the abbreviation DPDT mean?

DETERMINATION

Did you ever watch a modern, diesel earthmover-- one with 10 times the horsepower of a car and rubber tires as tall as a man? Wasn't it a thrill to see that great machine level obstacles in its path, leaving a perfectly smooth roadway? The word "determination" always brings to mind that picture of an earthmover -- a machine which goes places once the throttle lever is thrown.

So, too, are you determined to go places, to achieve success and happiness. One by one you are completing your lessons, studying hard and making sure you understand everything; step by step you are approaching that greatest of all goals -- SUCCESS.

Of course, the way is long and not always easy. But whenever the going gets a little tougher than usual or you feel a bit discouraged, just bring out that old determination, and back it up with every single ounce of ambition you have.

NATIONAL RADIO INSTITUTE • WASHINGTON, D. C.

HOW VACUUM TUBES WORK

B110

STUDY SCHEDULE

By dividing your study into the steps given below, you can get the most out of this part of your NRI Course in the shortest possible time. Check off each step when you finish it.

☐ 1. **Introduction** .... **Pages 1 - 3**
Electron emission is a basic part of tube operation. Here we take a look at the different types of emission.

☐ 2. **The Diode Tube** .... **Pages 4 - 12**
You learn how a diode is made and how it works.

☐ 3. **The Triode Tube** .... **Pages 12 - 20**
You learn how adding a third element to a tube makes it possible for the tube to be used as an amplifier.

☐ 4. **Tube Characteristics** .... **Pages 20 - 29**
You study the characteristics of a tube, how they are pictured, and how they can be analyzed by using equivalent circuits.

☐ 5. **Multi-Element Tubes** .... **Pages 29 - 37**
You study screen-grid, pentode, and other tube types.

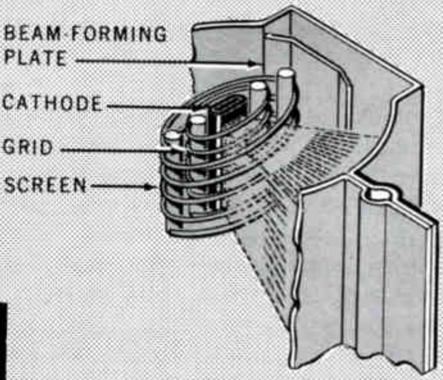
☐ 6. **Special Tube Types** .... **Pages 37 - 45**
Here we discuss gas-filled diodes, thyratrons, cathode-ray tubes, and other special types.

☐ 7. **Answers to Self-Test Questions** .... **Pages 45 - 48**

☐ 8. **Answer the Lesson Questions.**

☐ 9. **Start Studying the Next Lesson.**

JDL3M1174 1974 EDITION Litho in U.S.A.



HOW VACUUM TUBES WORK

Vacuum tubes are used not only in radio and TV entertainment broadcasting, but also in commercial radio equipment, telephone repeater systems, diathermy equipment, and in many types of industrial electronic equipment. Although transistors have taken over many of the jobs originally done by tubes, there are still many applications where the vacuum tube is superior to the transistor. Even in those applications where the transistor is superior to the vacuum tube, there are many older pieces of electronic equipment still in use using vacuum tubes which you will have to service. There are other applications where a transistor could be used in place of a vacuum tube, but vacuum tubes are used because they cost less than transistors or they can be manufactured in large quantities to closer specifications than transistors can be manufactured.

There are many different sizes and shapes of vacuum tubes. Some tubes are so small they are scarcely larger than a thumbnail; other tubes found in large radio and TV transmitters are several feet tall. Regardless of whether the tube is a miniature tube such as those found in hearing aids or a large tube such as those found in transmitters, it works on the same basic principles. In this lesson you will study tubes in detail. Later you will see how these tubes are used along with the parts you studied in previous lessons.

ELECTRON EMISSION

In the circuits you studied in previous lessons, the electrons stayed within the circuit wiring and flowed only over a solid path. For example, when you connect a resistor across a terminal of a battery, the electrons are set in motion around the circuit. Electrons flow through the resistor, the wires and the battery, but they stay within the closed circuit. Electrons do not leave the wire connecting the resistor to the battery and travel off into space around the wire, nor do they leave the resistor and move into the space around it. In a tube, however, electrons are forced to fly off into the space surrounding one of the elements in the tube. This element is called the cathode. When an electron leaves the cathode we say it is "emitted" by the cathode; the giving up of electrons by the cathode is called "emission".

You will remember that all material is made up of atoms and that one of the parts of the atom is the electron. The electrons in an atom are in a continuous state of motion. The speed and the amount of motion depend, for one thing, upon the temperature of the material. Normally the atomic force within the atom prevents electrons from escaping and flying off into space. This is true even in the case of the free electrons in a conductor that move through the conductor when current flows. However, if enough heat is supplied to a conductor, it is sometimes possible to overcome the force holding the electrons within the surface of the conductor and to drive some of the electrons off into the space surrounding it. This is what we mean by emission. This type of emission is often called "thermionic" emission; thermionic means emission by heat. Some materials give off electrons more readily and at lower temperatures than other materials. Often the cathodes of tubes are coated with these materials that will readily give off electrons at low temperatures.

Altogether there are four ways in which electrons can gain enough energy to escape from a material into the space around it. These are: (1) they can be evaporated or driven out by applying heat; (2) they can be driven off by bombardment by very small, high-speed particles such as other electrons; (3) they can be driven out of some materials by the energy in light rays; and (4) they can be jerked or pulled out by a very high positive potential placed on a nearby metallic object. All four of these methods are used in various types of electron tubes to provide the free electrons that all tubes depend upon for their operation. However, the first method, evaporation by heat, is by far the most important, and we will spend more time in this lesson on tubes using this type of emission. We will also briefly discuss the second and third types of emission.

Thermionic Emission.

As we mentioned, when electrons are driven from a metal or metallic compound by means of heat, this type of emission is called thermionic emission. Thermionic is pronounced THERM-I-ON-IK. As we mentioned, thermo means heat, ionic refers to electrons and hence the word thermionic is used to describe the type of emission where the electrons are driven from the cathode by heat.

In the operation of a vacuum tube it makes no difference where the heat comes from; if the cathode can be made hot enough it will emit electrons. However, the most convenient method of producing the heat needed is by means of a heater or filament placed inside the vacuum tube. A voltage is applied to the heater or filament and this voltage causes a current to flow through the heater or filament and causes it to heat to at least a red heat, and sometimes to a white heat. The hot filament or cathode then gives off the electrons required to operate the tube. It is important to realize the heater or filament voltage applied to the tube for the purpose of heating the tube does not actually enter into the operation of the tube in any way except to provide the energy necessary to heat the cathode. If instead of using electrical energy to heat the cathode we were able to heat the cathode with a gas flame, the heater or filament voltage could be removed entirely and the tube would perform just as well.

The terms heater, filament and cathode might be somewhat confusing at this time. A cathode is an electrode which gives off electrons. It is heated by means of an element called a heater. A filament is a combination heater and cathode. We will go into this in detail in the next section of this lesson.

Secondary Emission.

When electrons are driven off a metal by bombarding the metal with high-speed particles such as other electrons, we refer to this type of emission as secondary emission. What happens in this type of emission is that a particle travelling at a very high speed strikes the metal object with such force that it is able to dislodge a number of electrons from the material. These dislodged electrons fly off the material into the space surrounding it. You will see later that this type of emission is not always desirable; as a matter of fact, it creates a problem in some vacuum tubes.

Photoelectric Emission.

When electrons are driven out of the material by the energy in light rays, this type of emission is called photoelectric emission. Photoelectric tubes are used in the motion-picture industry in connection with the sound track. A sound track is put on the side of the film. Light passing through this sound track strikes a photoelectric tube. The density of the sound track varies as the speech or sound originally recorded on the film varies. This causes the amount of light striking the photoelectric tube to vary, which in turn varies the number of electrons emitted.

Photo-emission is not often encountered in radio and TV servicing, but it is of importance to the industrial electronics technician. Even the radio-TV serviceman should know something about it, because photoelectric tubes have been used in the past in radio-phono combinations. In addition, you may have occasion to service the sound system of a home movie projector.

Now let's see how tubes work. You already know something about how a vacuum tube operates. However, in the explanations we have given you previously, we have left out many details in order to approach the subject gradually. Now we will learn more about tubes by studying all these details. Let us start by studying the simplest tube.

The Diode Tube

The simplest tube has only two elements, one to give off the electrons and another to receive them. The element that gives off the electrons is called the cathode, and the element that receives the electrons is called the plate or anode. A simple tube having only two elements is called a diode.

Other tubes have other elements in addition to these two. Therefore as we study the diode, remember that tubes with more than two elements are really diodes with additional elements added.

TUBE CATHODES

Tube cathodes can be divided into two types, those that are directly heated and those that are indirectly heated. Directly heated cathodes are called filament-type cathodes or, more frequently, simply filaments. This type of cathode was used in early vacuum tubes and is still used in tubes designed for battery operation, and in large transmitting tubes. Indirectly heated cathodes are simply called cathodes.

Filament-Type Cathodes.

The schematic symbol used to represent a filament type of cathode is shown in Fig. 1. The voltage used to heat the filament is applied directly between the two leads from the filament.

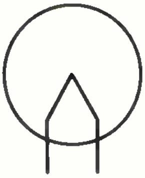


Fig. 1. Schematic symbol used to represent a filament type of cathode.

In large transmitting tubes the filament is made either of pure tungsten or of a mixture of tungsten and thorium. The very large transmitting tubes generally have a pure tungsten filament. Tungsten is a metal that can be operated at very high temperatures. Most electric light bulbs manufactured today have a large percentage of tungsten in the filament that is heated to a very high temperature to give off light.

The filaments used in many of the smaller transmitting tubes are made of a mixture of thorium and tungsten and are called thoriated filaments. The addition of thorium to the tungsten provides a material that will give off electrons at a somewhat lower temperature than pure tungsten. Thus the amount of power required to heat the filament is lower than for a pure tungsten filament. Thoriated tungsten is not as suitable as pure tungsten in large transmitting tubes. The very high voltages used on these tubes can pull the thorium right out of the filament and thus destroy the tube. In smaller transmitting tubes the voltages used are not high enough to do this.

Filament-type receiving tubes designed for operation in portable receivers were widely manufactured at one time. The filaments of these tubes were coated with oxides of certain metals. This type of filament is called an oxide-coated filament and it has the characteristics of giving off electrons at a still lower temperature than a thoriated filament. Thus the filament power required by this type of tube is even less than that required by the thoriated filament.

Even though filament-type receiving tubes operated on comparatively low voltages and required only a very small current, the fact that the heater power served no useful purpose led to the disappearance of this type of tube. Modern portable receivers all use transistors since no filament power is required. However, you may occasionally run across an older portable receiver that some set owner is particularly fond of and have to fix this receiver. Generally, filament-type tubes are available for replacement purposes.

Oxide filaments are found in some small transmitting tubes used in mobile applications. However, if the voltage applied to the tube exceeds 500 volts by very much, the oxide on the filament may be pulled off by this voltage and therefore oxide-coated filaments will be used only in small transmitting tubes.

The filaments of transmitting tubes that are made of either tungsten or thoriated tungsten can be operated on either ac or dc. However, the oxide-coated filament used in small tubes designed for use in battery-operated equipment are usually made very small and thin in order to keep the filament power required as low as possible. If these filaments are operated from ac, as the ac drops to zero and then rises to a maximum value twice during each cycle, the current flowing through the filament will vary, causing the temperature of the filament to vary. This will cause a variation in emission from the filament resulting in hum. Therefore the filament of small transmitting tubes and the older obsolete portable receiver types must be operated from dc.

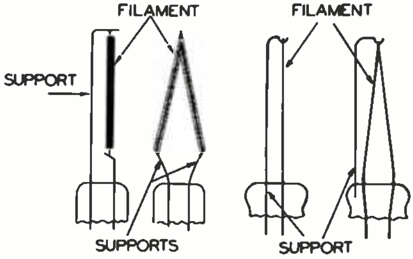

Fig. 2. Typical filaments.

The filament of a vacuum tube must be supported so it will stay in position. Typical filaments showing the type of support used are shown in Fig. 2. It is important that the filament be held tight so that it cannot sag and short to nearby elements in the tube. As a matter of fact, if the position of the filament changes, even though the filament may not touch any other elements in the tube, the characteristics of the tube will change because there are several tube characteristics that depend upon the spacing between the filament and the other elements in the tube.

Indirectly-Heated Cathodes.

The schematic symbol used to represent an indirectly heated cathode is shown in Fig. 3. The indirectly heated cathode is simply called a cathode. Notice that in addition to the cathode we have another element drawn beneath the cathode in the schematic symbol. This is the

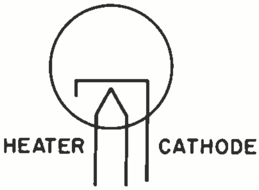

Fig. 3. Schematic symbol used for a heater and indirectly heated cathode.

heater, which is used to heat the cathode. Sometimes this is loosely called a filament because of its similarity to the filament we have just discussed and because the first tubes had directly heated cathodes. In fact the transformer winding used to supply heater voltage is still often called the filament winding.

The cathode is built in the form of a hollow cylinder like those shown in Fig. 4. The heater is placed inside of this hollow cylinder. Voltage is applied to the heater, and the heat produced by the heater is radiated and in turn heats the cathode.

The cathode is usually coated with oxide. This is done in order to provide an abundant supply of electrons at low operating temperatures. This type of cathode is used only in receiving tubes or small transmitting tubes where the applied voltage is not high enough to pull the oxide material off the cathode.

In many schematic diagrams of circuits in which an indirectly heated cathode type of tube is used, the heater is omitted. The heater actually serves no useful purpose as far as the operation of the tube is concerned, other than to heat the cathode. It does not enter into the characteristics of the tube and therefore the heater connections can be omitted to simplify the schematic diagram. The connections to the other elements in the tube are the ones that actually determine what the tube will do and how it will operate. We will follow this practice in many cases so we can emphasize the operating circuits.

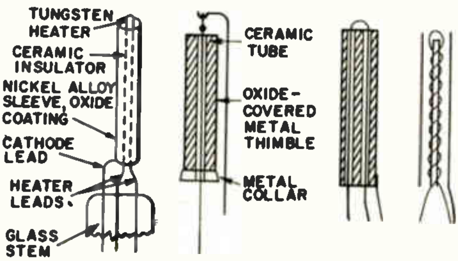

Fig. 4. Indirectly heated cathodes.

Operating Voltages.

The filament or the heater of a vacuum tube is designed to operate on a certain definite voltage. The first number used to identify receiving tubes gives an indication of the heater or filament voltage. For example, a 12L6 tube operates on a heater voltage of approximately 12 volts. The exact voltage is 12.6 volts. The number preceding the first letter indicates the heater voltage. A 35Z5 tube requires a heater voltage of 35 volts. A 6F6 tube requires a heater voltage of 6.3 volts, and a 2BN4 tube requires a heater voltage of 2.3 volts. Keep this in mind; it will be helpful to you when you start doing service work. The first number or group of numbers preceding the letters in the tube designation is an indication of the filament or heater voltage for which the tube was designed. This system is followed only for modern receiving tubes. Older receiving tubes did not use this system, and transmitting and industrial tubes do not use it.

THE PLATE

In the first vacuum tubes made, the anode that received electrons emitted by the cathode was simply a flat piece of metal, and hence was called a plate.

In modern vacuum tubes the plate completely surrounds the filament or cathode. The shape of the plate

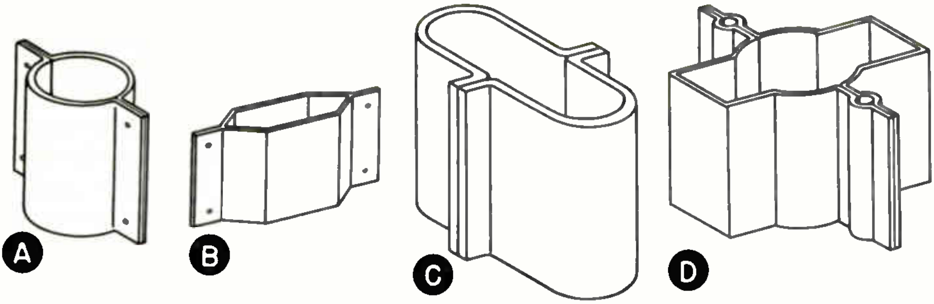

Fig. 5. Typical plate structures.

depends to some extent on the type of cathode used. If the cathode is simply a round cylinder, then the chances are that the plate will also be a round cylinder. However, if a filament type of cathode is used, such as those shown in Fig. 2, the plate will usually be rectangular in shape. Typical plate structures are shown in Fig. 5.

Vacuum tube plates may be made of any of several different materials, such as nickel, molybdenum, carbon, iron, tungsten, tantalum, and graphite. Zirconium is also sometimes applied as a coating on the plate. The plates of most receiving tubes and small transmitting tubes are made of nickel, which can easily be formed into the desired shape.

The plate of a vacuum tube is subjected to a certain amount of heating. Part of this heat comes from the filament or cathode, and part of it is produced by the electrons striking the plate. These electrons striking the plate can cause considerable heating; as a matter of fact in some transmitting tubes they produce so much heat that the plate becomes a bright red color.

The fact that the plate is heated results in a few additional problems. First, if the plate gets hot enough it will give off electrons, and if this happens the tube may not work properly because electrons may be able to travel both ways through it. The tube would simply act like a resistor. Therefore steps must be taken to keep the plate below the temperature where it will emit electrons. This is not too big a problem in small receiving tubes, but in the larger tubes it can be quite serious. The plate is often given a dull black finish because a black surface radiates heat readily and therefore will be cooler than a polished surface. The plates of many transmitting tubes are fitted with fins to provide a larger surface to dissipate or get rid of the heat produced at the plate of the tube. Large transmitting tubes are often water-cooled. As a matter of fact, in some large broadcast stations the water used to cool the tubes in the transmitter is used to heat the building in the winter.

Even if the plate is kept cool enough to prevent thermionic emission, the electrons travelling from the cathode of the tube over to the plate can pick up enough speed to strike the plate so hard that they will knock other electrons loose from the surface of the plate. Remember, this is one of the types of emission we discussed before and it is called secondary emission. The electrons that are knocked off the plate of the tube in this way leave the plate at a rather low speed. The plate normally has a positive voltage applied to it and the electron is negative, so in a diode tube, if the plate is positive, the electrons are simply attracted back to the plate. Secondary emission does not cause any difficulty in a diode. However, you will see later that in tubes having additional elements, secondary emission can be a problem.

Another problem that is created when the plate of a tube becomes very hot is that almost all metals have a certain amount of gas trapped right in the metal. When a metal plate becomes very hot, the gas trapped in it may be forced out of the metal and into the space surrounding the plate of the tube. Gas in a tube can destroy its usefulness. Now let's see why it is important that the amount of gas in a tube be kept as low as possible.

GAS EVACUATION

Tubes are called vacuum tubes because all the gases inside the tube including air are normally evacuated. There are two important reasons why these gases must be removed from inside the tube. First, if air is permitted in the tube, the filament or heater will oxidize; in other words, it will simply burn up when heated. Secondly, even if this problem could be overcome, there is another important reason why all gases must be removed from the tube. Gases are made up of molecules. Although these particles are extremely small, they are nevertheless many times the size of an electron. An electron traveling from the cathode of the tube to the plate moves at a fairly high speed. The chances are that the majority of electrons traveling from the cathode to the plate would strike one or more gas molecules if there were a large amount of gas in the tube. If a high speed electron strikes a gas molecule the electron will be deflected from its path and it will knock electrons out of the gas molecule.

Normally a gas molecule has no charge. However, if it is struck by an electron, which knocks other electrons out of the molecule, the molecule will be short of electrons, and hence will have a positive charge. We call positively charged molecules "ions". These ions are large and heavy in comparison to electrons and have a fairly high positive charge on them. Since the cathode of the tube is normally connected to a negative voltage source, it is negative, and will attract these positive ions. As a matter of fact, the positive ions will pick up a fair amount of speed traveling to the cathode and may bombard it with such force that small particles of the cathode material will be knocked loose.

Gas inside a vacuum tube is extremely undesirable. Therefore, in the manufacturing process, every effort is made to remove all the gases from inside the tube. However, some of the gas will remain in the tube and additional gas will boil out of the materials from which the tube is made the first time the tube is heated. To get rid of these gases left in the tubes a "getter" is placed inside the tube.

A getter is a small cup containing chemicals. During the manufacturing process, the tube is first evacuated by means of pumps. This will remove most of the gases from the tube. The tube is sealed and then it is heated. In the heating process gases are driven off the metals inside the tube such as the cathode and the plate. At the same time, the getter is heated and the chemicals in the getter combine with any gas molecules released, forming metal compounds, which are deposited on the glass envelope of the tube. The compounds in the getter hold onto the gas molecules and will not easily release them into the space inside the tube again. The silvery appearance that many tubes have near the base of the bulb is produced by the compounds forming on the glass envelope of the tube.

By using this procedure it is possible to obtain an excellent vacuum in tubes with a pure tungsten filament. The vacuum inside a tube with a thoriated tungsten filament is not quite as good, and the vacuum inside tubes with oxide-coated filaments is still poorer. The reason for this is that you can heat a tube with a pure tungsten filament to a higher temperature than you can the other types and hence the action of the getter is even more complete in these tubes than it is in the other types.

For this reason, tubes with thoriated tungsten filaments or oxide-coated cathodes are limited to uses where the operating voltages are somewhat lower than those that can be applied to pure tungsten filament tubes.

The leads connected to the various elements inside the tube are brought through glass seals. The glass is heated to a high temperature and it flows around the leads, providing a nearly perfect seal. Thus once the tube is evacuated, it is almost impossible for air to leak back into the tube. We say almost impossible because there is no such thing as a perfect seal and air will gradually leak back into the tube. It may take several years for enough air to get into the tube to affect its performance, but if the tube is left around unused long enough, eventually enough gas will get into the tube so that its operation will be impaired.

Tubes that have had all the gas removed from inside them are called hard tubes. Most tubes found in radio and TV receivers are hard tubes. However, there is another group of tubes into which certain types of gas have been deliberately introduced. Mercury is put inside some diode tubes. When these tubes are operated, the mercury will heat and vaporize, filling the inside of the tube with mercury vapor. This type of tube is called a soft tube or a gaseous tube. Other gases are sometimes used, but mercury vapor is the gas you will be most likely to encounter. It is easy to identify a mercury vapor tube because mercury gives off a characteristic blue glow. Therefore, if you see a tube operating with a bright blue glow, the chances are it is a mercury vapor tube.

If there is excessive gas inside a hard tube it also will have a blue glow. However, the blue glow is not as bright as it is in a mercury vapor tube. Mercury vapor tubes are almost always diode tubes, although a special type called a thyratron has three elements and hence is a triode. These tubes are usually quite easy to pick out. If you discover a blue glow between the elements of a hard tube, the tube is gassy and should be replaced.

Before leaving this subject there is one other point that should be brought out. Electrons emitted from the cathode of a hard tube frequently travel at a high speed and miss the plate of the tube and strike the glass envelope. When they do this there will often be a blue glow on the envelope of the tube. This does not indicate a defect in the tube. If a hard tube shows this blue glow on the envelope of the tube you can forget about it; it does not mean anything. However, if the blue glow appears between the elements of a hard tube, the tube is gassy.

CHARACTERISTIC CURVES

Among the information published by vacuum tube manufacturers are the characteristic curves of their tubes. These curves make it possible for the engineer or technician to predict how the tube will perform under a given set of operating conditions. The characteristic curve of a diode tube shows how much current will flow when a given voltage is applied to the plate of the tube. A typical diode characteristic curve is shown in Fig. 6.

Notice that this characteristic curve is not a straight line. It is bent on the two ends. Also notice that there is a very small current flow even when the plate voltage is zero. This is because a few of the electrons emitted by the cathode travel with sufficient velocity to reach the plate even without a positive voltage on the plate. As the plate voltage is slowly increased from zero to a high positive value the number of electrons flowing to the plate gradually increases. At first the increase is non-linear, but as the plate voltage is increased still further, eventually a point is reached where the characteristic curve becomes quite linear. By this we mean the curve is a straight line which indicates that we will get an almost constant change in plate current for a given change in plate voltage. For example, on a linear curve, if increasing the plate voltage from 25 to 50 volts causes an increase in current of 5 milliamperes, we can expect an increase in plate current of 5 more milliamperes when we increase the plate voltage from 50 volts to 75 volts. Again, if we increase the voltage from 75 volts to 100 volts and the curve is linear, we can expect another 5 milliampere plate current increase.

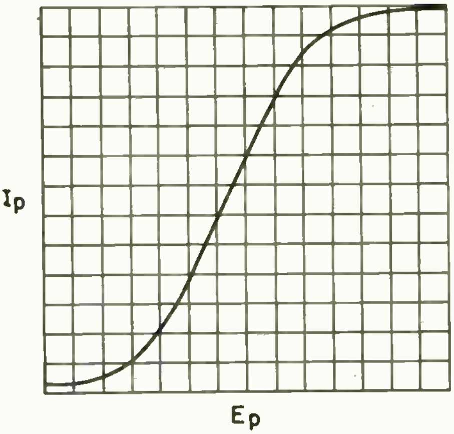

Fig. 6. Characteristic curve of a diode showing the relationship between plate current and plate voltage. Notice that there is a small plate current even when the plate voltage is zero. This is caused by a few electrons being emitted by the cathode at such a high speed that they travel over and strike the plate even when no voltage is applied to it.

Notice that the top of the curve begins to round out and become flat--this is called plate current saturation. Eventually a point is reached where all of the electrons emitted by the cathode are drawn immediately to the plate of the tube. In other words, the electrons do not form a space charge or electron cloud around the cathode, but instead travel immediately from the cathode of the tube right over to the plate. When this point is reached, increasing the plate voltage still further will result in no further increase in the plate current flowing in the tube because the plate is pulling all the free electrons over to it and is gathering them up as fast as the cathode can emit them. As a matter of fact, if the plate voltage is increased beyond this point, there is the danger that some electrons will be emitted from the cathode by the process of jerking them out of the cathode by the high plate voltage. This may cause small particles of the cathode material to jerk loose, and if this happens the cathode of the tube will soon disintegrate and the tube will no longer be usable.

SUMMARY

There are a number of important things you should remember in this section. First, the cathode found in tubes can be divided into two types-- the directly heated cathode which is called a filament, and the indirectly heated cathode, which is simply called a cathode. Remember that the heater used to heat an indirectly heated cathode performs no useful purpose other than to heat the cathode of the tube. It does not enter into the electrical circuit and operation of the tube itself.

Three types of cathode material are found in vacuum tubes: pure tungsten, thoriated tungsten, and oxide coatings.

Several different types of plates are used in vacuum tubes; the exact shape of the plate is usually determined by the shape and type of cathode used in the tube. The plate of a vacuum tube will give off electrons by thermionic emission if it becomes too hot. However, some transmitting tube plates can operate at a red temperature without giving off electrons, the materials used in the manufacture of the plates of these tubes are selected because they give off electrons only at a very high temperature. The plate may also give off electrons due to secondary emission. In some tube types this can become a problem.

The inside of a vacuum tube is normally highly evacuated. A tube with a high vacuum is called a hard tube. Gas is deliberately introduced into some tubes, and these are called soft tubes.

SELF-TEST QUESTIONS

(a) Name the two elements found in a diode tube.

(b) Into what two types can tube cathodes be divided?

(c) What is the name given to a directly heated cathode?

(d) How is the cathode of an indirectly heated tube heated?

(e) Why is the cathode of a receiving-type tube usually coated with an oxide?

(f) What useful purpose does the heater of an indirectly heated tube serve other than to heat the cathode of the tube?

(g) Approximately what would you expect the heater voltage to be of a type 8AC9 tube?

(h) What are the two names given to the element in the diode tube that receives the electrons?

(i) What two things cause the plate of a vacuum tube to be hot?

(j) What two undesirable things may happen if the plate on a vacuum tube becomes excessively hot?

(k) What is the purpose of a getter inside a vacuum tube?

(l) What is meant by a hard tube?

(m) What is a soft tube?

(n) What does a small blue glow appearing on the glass envelope of a hard-type tube indicate?

(o) What do we mean when we say that the plate current - plate voltage curve of the diode is linear over most of its range?

The Triode Tube

The development of the diode or two-element tube merely opened the door to the field of electronics. The diode tube has only limited applications. It can be used as a rectifier to change ac to dc, and in some other special circuits, but it cannot be used to amplify.

Early in the start of the twentieth century, the triode tube was developed. This tube touched off the rapid development in electronics that has occurred since then. The development of the triode tube led to the development of other multi-element tubes which have made possible circuits undreamed of not too many years ago.

You have already been introduced to the triode and know that the triode tube has three elements: a cathode, a grid, and a plate. The introduction of the grid between the cathode and the plate of the tube made it possible for a vacuum tube to amplify weak signals. You already have a general idea of how the grid works, but in this section we will review this idea, expand it, and then learn more about tube characteristics. It is extremely important for you to understand all the details of how a triode tube works, because the multi-element tubes that you will study later are simply triodes with additional elements added.

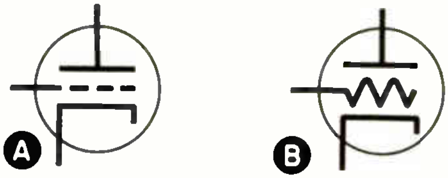

Fig. 7. Different ways of representing the grid on schematic diagrams.

HOW THE GRID WORKS

The third element inside the vacuum tube is placed between the cathode and plate and is called the grid. As the name implies, the grid is of open construction. The schematic symbol used to represent a grid is shown in Fig. 7A. On some old diagrams you might find the symbol shown in 7B used - this symbol is obsolete.

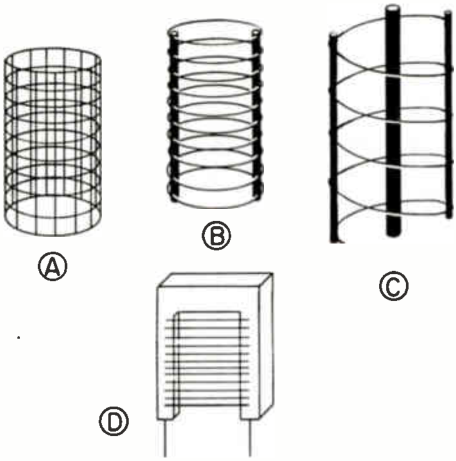

Fig. 8. Different types of grid structures.

Several different types of grid construction are shown in Fig. 8. Notice that in A the grid is made in the form of a spiral mesh, like a screen, whereas the grid shown in B is made up of a spiral-wound coil with the turns placed relatively close together. In C the same type of construction is used as in B, but the space between the turns is much greater. In D the grid is more or less rectangular in shape and is supported by the U-shaped elements at the end so that the grid is held in a very rigid position. The grid is supported by the frame and this type of construction is often referred to as a frame grid. It has this advantage over the other types: the grid wires can be placed very close together and very close to the cathode, which as you will see later makes it possible to make a tube with a much higher gain than that of the other types of grid.

Before we review how the tube amplifies, let's consider the effect of the grid on the flow of plate current when different voltages are applied to it. The first case we will take up is where the grid is connected directly to the cathode so that the voltage applied to it is zero.

Zero Grid Voltage.

When the grid is connected directly to the cathode we have the arrangement shown in Fig. 9. Here the plate is connected to the positive side of the B battery and the cathode is connected to the negative side of the battery. The grid is connected directly to the cathode, and a small battery is used to provide the heater voltage required to heat the heater, which in turn heats the cathode of the tube.

When the cathode is heated, it will emit electrons and they will fly off into the space surrounding the cathode. These electrons will form a cloud of electrons around the cathode. This cloud of electrons is called a space charge. Some of the electrons in the space charge will fall back to the cathode, others will be attracted by the positive potential applied to the plate of the tube and they will be drawn through the grid wires to the plate. A few electrons in travelling from the cathode

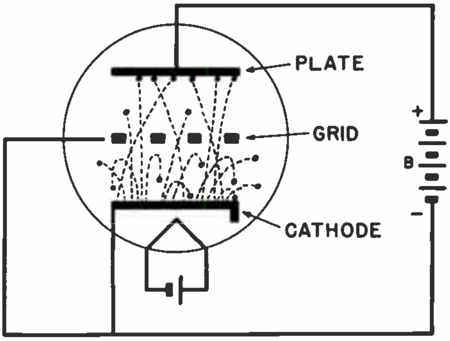

Fig. 9. When there is no grid bias, an average number of electrons flow to the plate, and the rest form a space charge between the cathode and the grid.

to the plate of the tube may accidentally strike the grid wires. These electrons will flow through the external circuit from the grid back to the cathode of the tube. As long as the grid is connected directly to the cathode, the tube acts very much like a diode and the grid has very little effect on the flow of plate current. The amount of plate current flowing will depend primarily upon the voltage applied between the plate and cathode of the tube and the spacing between the plate and cathode.

Positive Grid Voltage.

Now if we modify the circuit shown in Fig. 9, by adding a small C battery in the grid circuit as shown in Fig. 10, we will have a positive voltage on the grid of the tube. This means that the grid will be slightly positive with respect to the cathode. The B battery used between the plate and cathode has a much higher voltage than the C battery, and therefore the plate will have a much higher positive potential than the grid.

With the C battery connected in the grid circuit, the positive voltage on the grid of the tube will attract electrons from the space charge around the cathode and start these electrons speeding toward the grid. By the time the electrons travel the short distance from the space charge to the grid most of them will be travelling at such a high speed that they will pass right through the grid wires and then come under the influence of the high positive voltage on the plate of the tube. Most of the electrons will therefore continue travelling towards the plate of the tube until they eventually will reach and strike the plate.

The number of electrons reaching the plate will be much higher than it was in the preceding case where there was no voltage applied to the grid. The grid is able to increase the number of electrons flowing to the plate because the grid is placed very close to the cathode, and even though there is only a low positive voltage applied to the grid it is able to pull many electrons from the electron cloud and start them on their way to the plate.

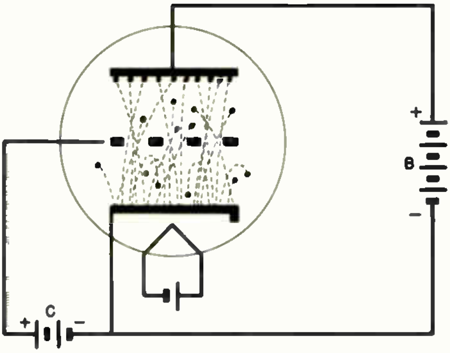

Fig. 10. Making the grid positive greatly increases the number of electrons moving to the plate.

Because the grid has a positive voltage applied to it, there will be more electrons striking the grid than there were in the preceding case when there was no voltage applied to the grid. However, even though a few electrons will be attracted to the grid, a small positive voltage applied to the grid will increase the flow of plate current. If the positive voltage is made higher, in other words if the grid is made more positive, it will start to attract more and more electrons. Eventually a point will be reached where the grid will be taking many of the electrons that would normally flow over to the plate of the tube. Then, instead of causing the plate current to increase, the large number of electrons flowing to the grid of the tube will starve the plate so that the plate current will be less than it would be if the grid were operated at zero potential.

When the number of electrons striking the grid becomes high, the energy that these electrons give to the grid upon striking it may cause the grid to become very hot. As a matter of fact, if enough electrons strike the grid, the grid will become red hot. Keep this in mind. If you see a vacuum tube where one of the grids is showing a red heat, the number of electrons reaching the grid is too high--there is something wrong in the circuit.

Negative Grid Voltage.

If instead of putting a positive voltage on the tube grid, you put a negative voltage on it, you will have the circuit shown in Fig. 11. Now the negative potential on the grid of the tube repels the electrons coming from the space charge and drives them back to the space charge so that the number of electrons getting through the grid and reaching the plate of the tube is greatly reduced. As a matter of fact, if the negative voltage applied to the grid of the tube is made high enough, all electron movement between the cathode and the plate will be stopped --there will be no flow of electrons from the cathode to the plate of the tube.

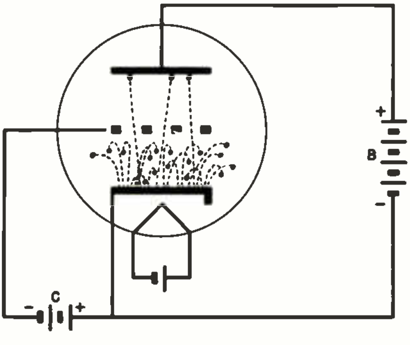

Fig. 11. Making the grid negative reduces the number of electrons moving to the plate.

Amplification Factor.

Current is actually a movement of electrons, and since the grid controls the electrons flowing from the cathode to the plate of the tube, the grid can control the current flowing from the cathode to the plate. The current flowing in the plate circuit is called the plate current. Changing the plate voltage on a triode tube will cause the plate current to change, but because the grid is closer to the cathode than the plate, it exerts a greater effect on plate current than the plate does. As a matter of fact, we may have to change the plate voltage on a tube as much as 100 volts to get the same change in plate current that can be obtained by changing the grid voltage only 1 volt. The exact ratio between the change in plate voltage and the change in grid voltage needed to get the same change in plate current is called the amplification factor. If we have to change the plate voltage 50 volts to get the same change in plate current we can get by changing the grid voltage 1 volt, the amplification factor is $\frac{50}{1} = 50$. A triode tube may have an amplification factor somewhere between 5 and about 100. The amplification factor of a tube depends primarily upon the ratio of the plate-cathode spacing to the grid-cathode spacing.

The amplification factor of a triode tube is a very important characteristic of the tube. It is a good indication of how much voltage gain you can expect to obtain from an amplifier stage using the tube. The total amplified voltage produced by the tube is equal to the amplification factor times the signal voltage applied between the grid and the cathode of the tube. It is not possible to get all of this amplified voltage out of the tube, because the tube has internal resistance, and part of the voltage will be dropped across this resistance, but in general the higher the amplification factor of a tube, the greater the gain we can expect to obtain from the tube.

To provide a short form for expressing the amplification factor of a tube, the Greek letter, mu, which is pronounced "mew", and written μ, is used as a symbol to represent the amplification factor. The amplification factor is often referred to as the mu of the tube. Thus a high-mu tube is a tube with a high amplification factor.

HOW A TRIODE AMPLIFIES

You have already had a brief explanation of how a triode amplifies a signal, so this will be primarily a review. Be sure that you completely understand how the tube amplifies because vacuum tubes are the heart of electronic equipment and if you do not know how tubes work, you will not understand the equipment in which they are used.

First, let's consider what type of signal we may want to amplify. For example, let's assume that we have a sine-wave signal that represents a certain sound. The amplitude of the signal is extremely weak. In order to use the signal to produce sound, we must increase the strength of the signal. The usual procedure is to first build up the voltage of the signal. An amplifier stage used for this purpose is called a voltage amplifier. If we apply the signal between the grid and the cathode of a vacuum tube connected as shown in Fig. 12, we know the ac signal in the grid circuit will produce variations in the plate current. We know this is true because the voltage applied to the grid has a pronounced effect on the flow of current to the plate. Thus the varying signal applied between the grid and the cathode of the tube will cause the plate current to vary.

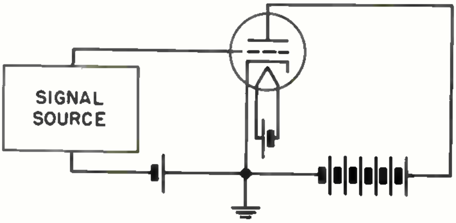

Fig. 12. The signal applied between the grid and the cathode will result in a varying plate current.

However, we are interested in a varying output voltage. If we feed a weak signal voltage into the grid of a tube to amplify it, what we want is an amplified voltage in the output. The desired result can be obtained with a circuit like the one shown in Fig. 13. Now let's stop and consider what happens in this circuit first when the signal voltage is zero.

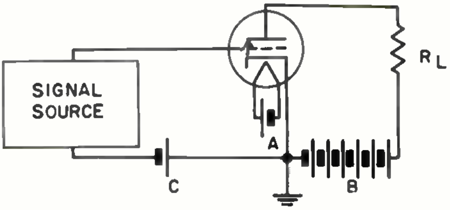

Fig. 13. The signal applied between the grid and the cathode will result in an amplified voltage in the output circuit.

When there is no ac signal applied to the input, a steady plate current will flow from the cathode of the tube to the plate of the tube. The exact amount of current is relatively unimportant, but it will depend upon the grid bias voltage supplied by the C battery, the plate voltage supplied by the B battery, the characteristics of the tube itself, and the size of the plate load resistor marked R_L.

The plate current flowing through the tube will flow from the negative side of the battery to the cathode of the tube. The heated cathode will give off electrons, which will flow through the space between the cathode and the grid of the tube over to the plate of the tube. The electrons will then flow from the plate of the tube through the plate load resistor R_L to the positive side of the battery, through the battery, back to the negative battery terminal. It sounds as though the electrons start from the negative terminal and then gradually flow around the circuit. Actually, the movement of electrons in the circuit is instantaneous. The electrons start moving in all parts of the circuit at the instant the tube is heated and power applied.

When current flows through the load resistor R_L, there will be a voltage drop produced across the resistor. The exact value will depend upon the current flow and the size of the resistor. We know this is true from Ohm's Law which states that E = IR. If there is a voltage drop across the dropping resistor, this means that the plate voltage, which is the voltage between the plate and the cathode of the tube, will be less than the B supply voltage by an amount equal to the voltage drop across the plate load resistor. Again, we know this is true because the sum of the voltage drops in a series circuit must be equal to the source voltage. In this series circuit we have the plate-cathode circuit of the tube in series with the load resistor. Therefore, the voltage across the tube equals the B supply voltage minus the voltage drop across the load resistor.

Before a signal is applied between the grid and the cathode of the tube the plate current will reach what is called a steady state. The voltage between the plate of the tube and the cathode will be some constant value.

Now let us consider what happens when a signal voltage like the sine-wave shown in Fig. 14A is applied between the grid and the cathode of the tube. Notice the first half cycle, which is numbered 1-2-3 on the input signal at A. This signal swings in a positive direction. When the ac input voltage swings positive, its polarity will be such that it will subtract from the grid bias voltage. This will make the grid voltage less negative. If we make the grid voltage less negative, we are moving it in a positive direction. When the grid becomes less negative it will allow more electrons to flow from the cathode of the tube to the plate. If the number of electrons moving in this part of the series circuit increases, then the total number of electrons in motion in all parts of

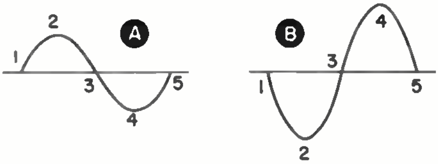

Fig. 14. A sine-wave signal voltage. The input signal is shown at A, and the output signal at B.

the series circuit must increase. The number of electrons flowing through the plate load resistor R_L increases. When this happens, the voltage drop across the plate load resistor increases, and there will be less of the B supply voltage between the plate and cathode of the tube. This means that the plate voltage will decrease.

The plate voltage will continue to decrease as the input signal moves from point 1 to point 2. The plate voltage will look like the wave shape shown in Fig. 14B and as the input moves from point 1 to point 2 on curve A, the output will move from point 1 to point 2 on curve B.

If the input signal begins to decrease from its peak point 2 back to zero voltage at point 3, the plate voltage between the plate and cathode of the tube will start to increase, because as the input signal moves from point 2 to point 3, the negative grid voltage on the tube will be increased. This means that there will be fewer electrons flowing from the cathode to the plate of the tube, and hence fewer electrons flowing through the load resistor. When the number of electrons flowing through this resistor decreases, the voltage drop across it decreases. Since the sum of the voltage drop across the load resistor and the voltage between the plate and cathode is always equal to the B supply voltage, the voltage between the plate and cathode of the tube must increase.

During the second half of the input cycle, when the input signal swings from point 3 to point 4, the signal is swinging in a negative direction, so it adds to the grid bias voltage applied to the tube by the C battery. This makes the grid even more negative, and reduces still further the number of electrons moving from the cathode to the plate of the tube. This reduction in electrons flowing in the series circuit means that there will be an even smaller voltage drop across the plate load resistor R_L and hence even more voltage between the plate and the cathode of the tube. As the input signal moves from point 3 to point 4 and then on to point 5, the output signal between the plate and cathode of the tube will follow the shape shown from point 3 to point 4 and then to point 5.

This variation in the voltage between the plate and cathode of the tube will be several times the amplitude of the input signal.

Before going ahead let's take a look at what we have in the plate circuit of the tube. Examine the waveform shown in Fig. 14B. Notice that a single ac cycle has been produced and the amplitude, frequency, and wave shape of the signal depend upon the signal applied between the grid and the cathode. This signal is an amplified version of the signal applied between the grid and the cathode of the tube.

The total signal applied between the grid and the cathode of the tube actually consists of a dc voltage applied by the C battery plus an ac voltage which is superimposed or added to it. The voltage between the cathode and grid will be the algebraic sum of the two voltages. When the signal voltage tends to swing the grid positive it will actually be subtracting from the C battery voltage so that the net negative voltage applied to the grid will be reduced. When the signal source tends to swing the grid in a negative direction, it will add to the C battery voltage so that the grid will be made more negative with respect to the cathode and will reduce the current flow through the tube.

The voltage in the plate circuit actually consists of a dc voltage applied to the tube with an ac voltage superimposed on it. Notice, however, that the ac voltage at the plate is inverted when compared to the input signal. In other words, when the input signal swings in a positive direction, the output signal swings in a negative direction, and when the input signal swings in a negative direction, the output signal swings in a positive direction. We say that the two signals are 180° out of phase.

Notice that the cathode of the tube in the circuit shown in Fig. 13 is grounded. This type of circuit is called a "grounded-cathode" amplifier. One of the characteristics of the grounded-cathode amplifier is that there is a 180° phase-shift between the input and output signals.

The signal voltage applied in series with the C bias voltage between the grid and cathode causes the plate current flowing from the cathode to the plate of the tube to vary. Actually, the current looks like a dc current with an ac current superimposed on it. Therefore, when we refer to the ac current in a tube, we mean the signal current or the variation in dc current caused by a signal applied between the grid and cathode. Remember that the current through a tube always flows from cathode to plate; it never reverses in direction. However, the variation in current through the tube due to the signal variations produces the same effect as we would have with a dc current with an ac current superimposed on it.

Remember that when you studied the amplification factor we pointed out that the amplification factor is based on a change in plate voltage and a change in grid voltage. Another way of expressing the same idea is in terms of ac voltages. We can say that it is the ratio of ac plate voltage to the amount of ac grid voltage required to produce the same ac plate current. As we mentioned previously, we are speaking of an ac current superimposed on a dc current.

SUMMARY

This section of your lesson is extremely important. Therefore we will not try to summarize it, but instead we suggest you go back and read over the entire section of the lesson again to be sure you understand it thoroughly. Read the section carefully and slowly and try to picture exactly what is going on inside the tube. Grasping clearly the idea of how a tube amplifies is extremely important. If you master this idea now, the remaining material in this book should be comparatively simple and you will also find that it will be much easier for you to understand how transistors amplify. When you are sure you understand this section of the lesson, test yourself by doing the following self-test questions.

SELF TEST QUESTIONS

(p) Why does the grid voltage have a greater effect on plate current than the plate voltage does?

(q) If the voltage applied between the grid and cathode of a triode tube places the grid positive with respect to the cathode, what effect will this have on the current flowing through the tube?

(r) If the grid is made negative

with respect to the cathode, and the voltage is slowly increased, what will happen to the plate current?

(s) What do we mean by amplification factor?

(t) Between what values would you expect the amplification factor of a triode to fall?

(u) When a signal voltage is amplified by a tube in a grounded cathode circuit, will the amplified signal be the same as the input signal?

(v) What do we mean by ac plate current?

(w) What is a grounded-cathode amplifier?

Tube Characteristics

Tube characteristics are important both to the engineer and to the technician. They are important to the engineer because he uses them in designing circuits. He must know the characteristics of the tube in order to select the correct value of parts to use along with the tube to get the best possible performance out of the circuit. They are important to the technician because often he will have to service equipment in which detailed service information is not available. By identifying the tube types used in the equipment and referring to a tube manual which describes the characteristics of the tubes used, he can obtain a great deal of useful information on how the equipment should work.

A great deal of information about tubes is given in the form of characteristic curves. The most important of these curves is the E_g–I_p (grid voltage-plate current) curve.

THE Eg-Ip CURVE

A tube is able to reproduce a signal only as long as a given change in grid voltage will produce a constant change in the plate current. Let's assume we have a tube with a voltage of 2 volts between the grid and cathode, and that the grid is 2 volts negative with respect to the cathode. If we increase this voltage from 2 volts to 2-1/2 volts, we know that the plate current will decrease. We could actually measure this change in plate current. Now, if we increase the voltage still further from 2-1/2 volts to 3 volts, we should get the same change in the plate current that we got when we changed the voltage from 2 volts to 2-1/2 volts. It is quite likely that we would get the same change, but eventually a point will be reached where changing the grid voltage 1/2 a volt will not produce this same change in plate current. When we reach this situation, we say that this tube becomes non-linear. This characteristic of a tube limits the amount of signal that can be applied between the grid and cathode of the tube.

The change in plate current that can be expected for a given change in grid voltage is shown on a curve called the E_g-I_p curve. A typical E_g-I_p curve is shown in Fig. 15. Notice how the plate current will be different for different values of grid voltage. Also notice that part of this curve is relatively straight but the two ends of the curve are quite bent. In the middle of the curve, we have a straight section that is called linear. This simply means that as long as the tube is operated within these limits a given change in grid voltage will produce the same change in plate current. As long as this change in plate current for a given change in the grid voltage remains constant, the output will be a faithful reproduction of the input signal. However, once the change becomes non-linear, the output will be distorted. This means the output signal will not be a faithful reproduction of the input signal.

Grid Bias.

The voltage applied by the C battery that is connected between the grid and cathode of a tube is called the grid bias voltage. To bias something means to fix or adjust it. The grid bias voltage fixes or adjusts the tube to operate under the most favorable conditions. The idea in back of a grid bias voltage is to apply a voltage to the grid that will place the tube operation on the desired portion of its characteristic curve. In the case of the amplifier we have been considering, we bias the tube to operate at the center of the linear or straight part of the characteristic curve. If you look at Fig. 15 you can see that the characteristic curve is comparatively straight between zero grid voltage and the grid voltage at -6 volts. Slightly to the right of zero grid voltage the curve becomes distorted, and to the left of -6 volts it also becomes distorted. Therefore, to get the tube operating on the linear part of the curve, we would apply a grid bias of -3 volts. With a grid bias of -3 volts, if the input signal drives the grid voltage 3 volts in a positive direction, we can expect the same change in plate current as we will get when the input voltage swings 3 volts in a negative direction. When the input voltage swings 3 volts in the positive direction, it will subtract from the grid bias, so the net voltage applied to the grid of the tube

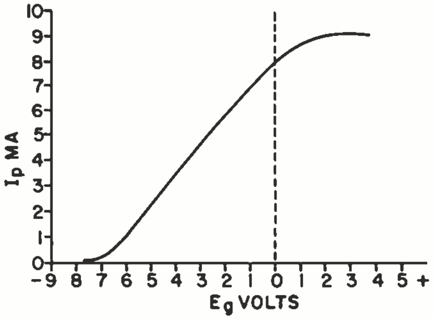

Fig. 15. A typical E_g-I_p characteristic curve.

will be zero, and when it swings 3 volts in the negative direction, it will add to the grid bias so that the net voltage applied between the grid and the cathode of the tube will be -6 volts. Changing the grid voltage between these limits produces linear or constant changes in plate current.

On the other hand, if instead of a grid bias of -3 volts we had a grid bias of -5 volts and a 3-volt input signal, when the grid swings in the positive direction we will get a total voltage of -2 volts on the grid. This will produce a change in plate current. However, when the grid swings 3 volts in the opposite direction, due to the signal, we will get a total grid voltage of -8 volts. This will produce a change in plate current, but it will not be the same as the change produced when the signal went in the opposite direction. As a matter of fact, you can see from the curve that once the signal is past -7 volts little or no change in plate current will occur.

Under these circumstances, a plate current change that is different when the signal swings in one direction is different from the plate current change when the signal swings in the opposite direction and we get distortion. This means that the signal is not reproduced faithfully. For an input signal like the one shown in Fig. 16A we would get an output signal like the one shown in Fig. 16B. Notice that in the first half cycle when the input signal swings in a positive direction the output signal swings in the opposite direction. However, the output signal is a faithful reproduction of the input signal. During the second half cycle, when the input signal swings in a negative direction, the output signal swings in a positive direction but is flattened off at the top. The amplified signal is not a faithful reproduction of the input signal. As we mentioned, this is called distortion, and this particular case of distortion is called amplitude distortion because the amplitude of one half of the cycle is compressed.

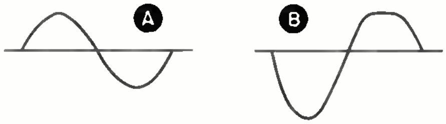

Fig. 16. The input voltage (A) and the output voltage (B) for a tube with excessive grid bias. Notice that the positive half of the cycle in the output is flattened.

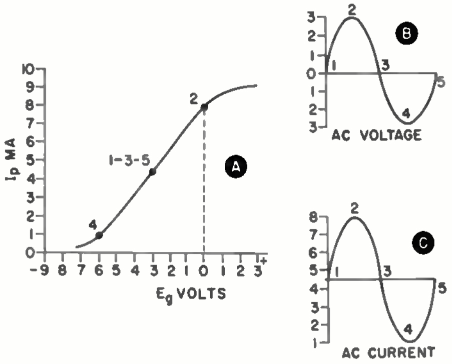

Fig. 17. A typical characteristic curve (A) showing how the grid voltage (B) and the plate current (C) vary on it.

Now let us see how different values of grid bias affect the way in which a tube amplifies a signal. As you know, the grid voltage is made up of a fixed bias voltage, and the ac signal is superimposed on it. Assume we have a tube with the E_g-I_p curve shown in Fig. 17A. The center of the linear part of the curve is at -3 volts. Now suppose we have a bias voltage of -3 volts, and the signal voltage shown in Fig. 17B, which varies from 0 to 3 volts, is superimposed on it. When the ac signal is at the start of its cycle, point 1, it will be zero, so the total grid voltage will be -3, point 1 on the curve in 17A. When it increases to point 2, the total voltage will then be zero, point 2 on the curve. At point 3 the total voltage will be -3 volts again. At point 4 the total voltage will be -6, and at point 5 the total voltage will again be -3.

Now let's draw ourselves a picture showing what is happening to the plate current at each of these points. At point 1 the current is 4.5 ma; at point 2 it is 8 ma; at point 3 it is again 4.5 ma; at point 4 it is 1 ma; and at point 5 it is 4.5 ma again. This is shown in Fig. 17C.

As you can see, this is a faithful reproduction of the applied signal.

We often show these things all on one chart as shown in Fig. 18. Notice how we have drawn the signal voltage. By drawing it in this position, we can follow up to the point it represents on the characteristic curve, and then show the curve for the corresponding plate current.

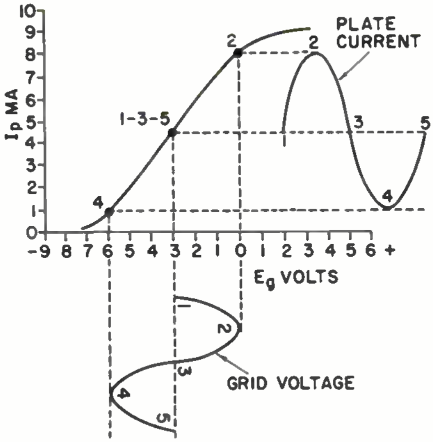

Fig. 18. We often show the information of Fig. 17. all on one diagram like this.

In Fig. 19 we have shown what happens when the operating bias is too high or too low. In Fig. 19A the operating bias is too high (too negative) and the result is that the grid is driven beyond the cut-off voltage

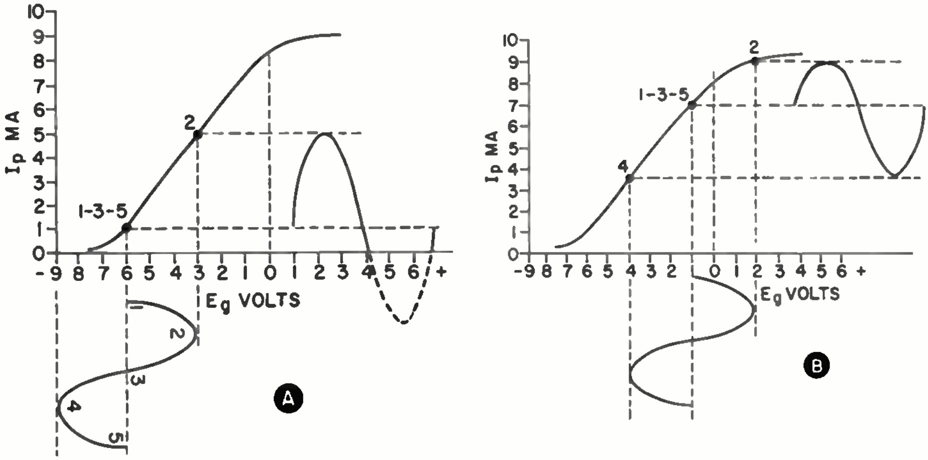

Fig. 19. The effect of too much bias is shown at A, and the effect of too little bias at B.

on the negative half of each cycle. This means that the plate current drops to zero and flattens off on the negative half of each cycle.

In Fig. 19B the operating voltage is not high enough, so during part of each cycle the grid becomes positive. When this happens the grid will start to take some of the electrons that would normally flow to the plate of the tube with the result that the top of the plate current curve is somewhat distorted. The variations in plate current for a given input signal are not linear when the bias is too low.

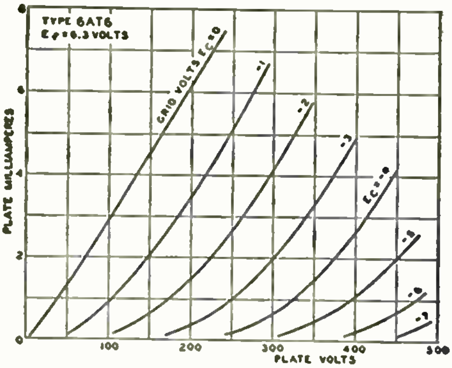

Fig. 20. E_p-I_p curves of the 6AT6 tube.

THE Ep-Ip CURVE

The characteristic curves shown in a tube manual are usually E_p-I_p (plate voltage-plate current) curves such as those shown in Fig. 20. Each curve is for a particular value of grid voltage. As you can see, when the plate voltage is higher it takes a higher grid bias voltage to cut off the flow of plate current. You can also get a good idea of how a change in grid voltage affects the plate current. Find the vertical line representing a plate voltage of 200 volts. Follow this line up until you see where it cuts the curve representing zero grid volts. It cuts this line just above the horizontal line representing a plate current of 6 ma. The -1 volt grid curve cuts the 200 volt line at about 3.5 ma. Thus, changing the grid voltage from zero to -1 volt will change the plate current from above 6 ma to 3.5 ma, or about 2.5 ma.

Notice how much more effective the grid is in controlling plate current than the plate is. We saw that a change in grid voltage of 1 volt caused a plate current change of 2.5 ma. The -1 volt grid curve cuts the 200 volt line at 3.5 ma. If we increase the plate voltage to 250 volts and keep the grid bias at -1 volt, the plate current will be 5 ma, which is a change of only 1.5 ma from the 200-volt point. Thus the change in plate voltage of 50 volts has less effect on the plate current than a change of grid voltage of only 1 volt.

PLATE RESISTANCE

As we mentioned previously, a tube has internal resistance. The tube, in amplifying a signal, acts very much like a generator with an internal resistance. This internal resistance of the tube is called the ac plate resistance. Because the tube has this internal plate resistance, the gain that can be obtained from a tube is never quite equal to the amplification factor of the tube.

The ac plate resistance is defined as the ratio of the change in plate volts to the change in plate current that it produces. The symbol r_p is usually used to represent the ac plate resistance of the tube. The symbol e_p is used to represent the change in plate voltage and the symbol i_p is used to represent the change in plate current. Thus the plate resistance of a tube in ohms is:

$$r_p = \frac{e_p}{i_p}$$

The ac plate resistance is one of the characteristics listed in manufacturers' tube manuals. When the tube manual gives a plate resistance, it is for a certain value of plate and grid voltage. The ac plate resistance of a tube is affected by the dc voltage applied to the plate and by the dc voltage applied to the grid. Therefore, if the tube is operated at voltages other than those listed, the plate resistance will not be the same as the values shown. In some engineering type tube manuals the plate resistance is given in the form of a curve so that the plate resistance can be determined with different values of plate and/or grid voltages.

So far we have been talking about the ac plate resistance of a tube. However, a tube also has a dc resistance. In a circuit such as the one shown in Fig. 13, with no input signal applied to the grid, a certain value of plate current will flow. This plate current produces a voltage drop across the tube and a voltage across the load resistor. You know from Ohm's Law that the resistance is equal to the voltage divided by the current, thus the dc resistance of the tube is equal to the dc plate voltage, which is the voltage between the plate and cathode of the tube divided by the dc plate current. Notice that both of these values are dc values and therefore we get a dc plate resistance for the tube. This particular characteristic is not usually of importance and when we refer to the plate resistance of the tube we will always mean the ac plate resistance unless we specifically say that we are referring to the dc plate resistance.

MUTUAL CONDUCTANCE

Another important tube characteristic is mutual conductance. The mutual conductance of the tube is usually represented by the symbol g_m. It is equal to the change in plate current divided by the change in grid voltage required to produce the change in plate current. The unit of mutual conductance is the mho. Notice that mho is simply ohm written backwards.

The formula for the mutual conductance of a tube is:

$$g_m = \frac{i_p}{e_g}$$

where g_m is the mutual conductance, i_p is the change in plate current and e_g is the change in grid voltage.

Since the change in plate current is usually in milliamperes, and the change in grid volts is in volts, the mutual conductance of the tube turns out to be a fraction of a mho. For example, if a change in grid voltage of 1 volt produces a change in plate current of 1 milliampere, the mutual conductance is:

$$g_m = \frac{.001}{1} = .001 \text{ mho}$$

To eliminate the fraction we usually express the mutual conductance of a tube in micromhos. A micromho is a millionth of a mho. Thus .001 mho equals 1000 micromhos.

RELATIONSHIP BETWEEN TUBE CHARACTERISTICS

So far we have discussed three important tube characteristics. They are the amplification factor, the plate resistance, and the mutual conductance. They can be represented by symbols as follows:

$$\text{Amplification factor} = \mu = \frac{e_p}{e_g}$$

$$\text{Plate resistance} = r_p = \frac{e_p}{i_p}$$

$$\text{Mutual Conductance} = g_m = \frac{i_p}{e_g}$$

Now let us look at how these characteristics are inter-related. If we multiply the plate resistance by the mutual conductance we get:

$$r_p \times g_m = \frac{e_p}{i_p} \times \frac{i_p}{e_g}$$

If you look at the second expression you will see that you have i_p both above and below the line so these two can be cancelled and we get:

$$\frac{e_p}{e_g}$$

We already know that e_p over e_g equals μ, which is the amplification factor. Thus the amplification factor is equal to the plate resistance times the mutual conductance or:

$$\mu = r_p \times g_m$$

EQUIVALENT CIRCUITS

It is sometimes difficult to visualize exactly what is happening inside a tube and in the circuit associated with the tube. However, by means of what is called an equivalent circuit we can analyze the performance of a tube more easily. A typical triode amplifier is shown in Fig. 21A and the equivalent circuit for this stage is shown in Fig. 21B. Notice that the tube is represented by a generator with a resistance connected in series with it. The voltage developed by the tube is equal to the amplification factor of the tube times the grid voltage which is written μe_g. We know, however, that the output voltage will be 180 degrees out of phase with the input, and we therefore put the minus sign in front of μe_g and indicate that the generator voltage is $-\mu e_g$. This indicates that the generator voltage, which is the amplified voltage produced by the tube, is 180 degrees out of phase with the grid voltage. In other words, at the instant the grid voltage swings positive, the generator will swing negative and then when the grid voltage swings negative, the generator voltage swings positive.

The ac plate resistance of the tube is represented by the resistor r_p. The voltage dropped across this resistance is lost as far as obtaining useful output is concerned.

Now let us see just exactly how

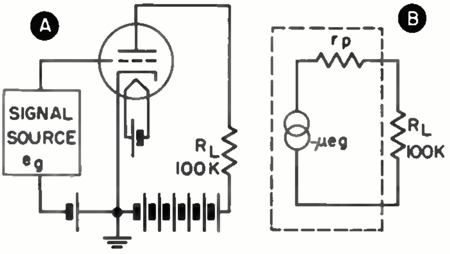

Fig. 21. A simple amplifier circuit is shown at A, and the equivalent circuit at B.

much gain we can obtain from the circuit shown in Fig. 21A. We could find the plate resistance of the tube and the amplification factor by looking them up in a tube manual. Let's assume that the amplification factor of the tube used in the circuit is 100, and the plate resistance of the tube is 50,000 ohms. The load resistance R_L is 100K ohms as shown on each diagram.

If the input signal e_g had an amplitude of 1 volt, then the generator output voltage $\mu e_g = 100 \times 1 = 100$ volts. The 100 volts produced by the generator divides between the 50,000-ohm plate resistance r_p and the 100,000 ohm load resistance, R_L. Thus, since the load resistance is twice the size of the plate resistance, the voltage across the load resistance will be twice the voltage across the plate resistance. This means that one-third of the 100 volts at the generator will appear across the plate resistance, and two-thirds, or approximately 66 volts, will appear across the load resistance. From this we can see that for an input voltage of 1 volt, the useful output voltage across the load resistor is 66 volts. The gain of the stage is equal to the output voltage divided by the input voltage, which in this case is $66 \div 1 = 66$. Therefore in this circuit using a tube with an amplification factor of 100, we obtained a gain of 66.

Consider what would happen if instead of using a 100,000-ohm plate load resistor we used a 200,000-ohm plate load resistor. Now the plate load resistor is four times the plate resistance and therefore there will be four times as much voltage across the load resistor as across the plate resistance. This means that one-fifth of the voltage, or 20 volts, will appear across the plate resistance, and four-fifths, or 80 volts, will appear across the load resistor. Therefore, the output voltage in this case would be 80 volts and the gain of the stage would be 80.

From this you might think that all we have to do is make the plate load resistor very large and we would get even more gain. This is true up to a point, but remember that the current flowing in the plate-cathode circuit of the tube must also flow through the plate load resistor. The current through the plate load resistor produces a voltage drop across the load resistor. The higher the resistance of the resistor the greater the voltage drop across it. Since the voltage available between the plate and the cathode of the tube is equal to the B supply voltage minus the voltage drop across the plate load resistor there will be very little voltage available between the plate and cathode of the tube if we make the plate load resistor too large. Eventually a point is reached where the plate-cathode voltage is so low that the amplification factor of the tube begins to fall off. When this point is reached, increasing the size of the plate load resistor results in no further increase in the gain of the stage.

A way to calculate the gain of a triode stage is by the equation:

$$\text{Stage gain} = \mu \times \frac{R_L}{R_L + r_p}$$

This equation shows that the larger the value of R_L with respect to r_p, the greater the gain of the stage. However, as we pointed out there are practical limits to this because the plate voltage does drop too low if R_L is made too large.

SUMMARY

In this section of this lesson you have greatly expanded your knowledge of tubes. There is a great deal of information in the section, and you should not expect to master and retain all the ideas presented with one reading. Be sure to go back and review this section of this lesson several times. This is particularly important because practically all of your later lessons are going to be based on the assumption that you understand how tubes work.

Characteristic curves are important because they give you an indication of how the plate current of a tube is going to change with changes in grid voltage. You can also see how large a signal a tube can handle without distortion. We do not expect you to remember what the characteristic curves we show look like, but you should remember that they are curved on both ends and this curvature in the characteristic curve limits the amount of signal that can be handled without distortion.

The three characteristics of tubes that you should remember are the plate resistance, the amplification factor, and the mutual conductance. Remember what they are:

$$\text{Plate resistance} = r_p = \frac{e_p}{i_p}$$

$$\text{Amplification factor} = \mu = \frac{e_p}{e_g}$$

$$\text{Mutual conductance} = g_m = \frac{i_p}{e_g}$$

You should also remember that the amplification factor of a tube is equal to the plate resistance times the mutual conductance.

Remember what the equivalent circuit of the simple triode amplifier looks like. We consider the tube as a generator with a resistance in series with it. The output voltage of the generator is equal to $-\mu e_g$. The resistance in series with the generator is equal to r_p, the plate resistance of the tube.

Remember that the equivalent tube circuit applies only to the ac signal-amplifying operation of the tube. We did not discuss the dc operating voltages when we discussed the equivalent circuit. Later you will see that the equivalent circuit is very valuable in analyzing and understanding the operation of amplifier stages. It will be particularly useful when we study how amplifiers amplify signals of different frequencies.

SELF-TEST QUESTIONS

(x) What is an E_g-I_p curve?
(y) What do we mean by the linear portion of the E_g-I_p characteristic curve?
(z) What is a grid bias voltage?
(aa) What will be the effect of operating the tube with too low a grid bias?
(ab) What happens when a tube is operated with too high a grid bias?
(ac) What is an E_p-I_p curve?
(ad) What is the ac plate resistance of a tube?
(ae) What is the dc plate resistance of a tube?
(af) What is the mutual conductance of a tube?
(ag) In what units is the mutual conductance of a tube measured?
(ah) What is the relationship between amplification factor, plate resistance and mutual conductance?

(ai) What do we mean by an equivalent circuit of an amplifier stage?

(aj) In an equivalent circuit used to analyze the performance of a triode amplifier, what is the generator voltage?

(ak) In the equivalent circuit of a triode amplifier, what is the resistance in series with the generator?

(al) If a triode amplifier has an amplification factor of 50 and a plate resistance of 10,000 ohms, what will the stage gain be when the amplifier is used in a circuit with a 90,000-ohm load resistor?

Multi-Element Tubes

From your study of the preceding section you can see that the triode tube is a very useful device. However, the triode has some definite limitations, and these limitations can be overcome by adding additional elements to the tubes. First, before studying the multi-element tubes, let's consider one of the big disadvantages of the triode in order to be able to understand the advantages of multi-element tubes better.

PLATE-TO-GRID CAPACITY

You will remember from your lesson on capacitors that a capacitor consists of two metal plates placed close to each other. In capacitors the metal plates are deliberately placed near each other in order to have capacity. However, when two pieces of metal that are insulated from each other are brought near each other, we will have a capacitor whether we want it or not; for example, the plate and grid of a vacuum tube. The plate, as you know, consists of a cylindrically shaped piece of metal. The grid is a spiral wire or mesh. The grid and plate, since they are placed near and are insulated from each other, actually form the two plates of a capacitor. Because the grid wire is small and there is a reasonable amount of space between the plate and grid, the capacity is small, but in some circuits, particularly where fairly high frequencies are involved, there is a high enough capacity to introduce a number of undesired effects.

As you know, at a high frequency even a small capacitor has a fairly low reactance. Therefore if a triode tube is used to amplify a high-frequency signal, the amplified signal present in the plate circuit of the tube can be fed back into the grid circuit through the plate-to-grid capacity. Under certain circumstances this signal fed from the plate back to the grid can be in phase with the signal applied to the grid of the tube so it will add to the input signal. This increase in the amplitude of the input signal in turn produces a still greater signal in the output.

The increased signal in the output in turn increases the signal fed back into the grid circuit which makes the grid signal still stronger. This increases the output signal still more. This action goes on and on until eventually a point is reached where the signal in the plate circuit takes control in the grid and the tube begins to generate its own signal voltage. This is called oscillation. The signal fed from the plate of the tube back to the grid is called a feedback signal. When the feedback signal, or more simply the feedback, is of the correct phase so that it adds to the grid signal, the tube will oscillate, which means generate its own signal, and hence will not work as an amplifier.

Not all triode amplifier stages will oscillate. It is possible to overcome this problem by means of suitable circuitry. However, in most applications it is easier and more practical to overcome the problem in the tube itself. This is accomplished by the addition of another grid inside the tube. The second grid is placed between the plate and the first grid to shield or screen the grid from the plate and is called the screen grid or simply the screen. The screen is also called the number-two grid.

THE SCREEN-GRID TUBE

The screen-grid tube is a four-element tube usually called a tetrode. The four elements are the cathode, the grid, the screen grid, and the plate. A top view of a screen-grid tube showing the four elements is shown in Fig. 22A, and the schematic symbol for the screen-grid tube is shown in Fig. 22B.

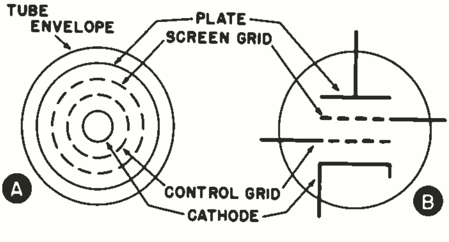

Fig. 22. A screen-grid tube: A, a cross section showing the arrangement of the elements; B, the schematic symbol.

The screen grid is usually made just like a spiral-wound coil. The screen-grid wires are placed directly behind the grid wires so they are completely hidden from the electrons by the grid wire. A cut-away view of the tube would look something like Fig. 23. Notice that the screen-grid wires are immediately behind the control-grid wires.

The effect of the screen grid is to break the capacity between the plate and the control grid into two separate capacitors. In other words, there is a small capacity between the plate of the tube and the screen, and another capacity between the screen of the tube and the grid. These two capacitors are connected in series so that the net plate-to-grid

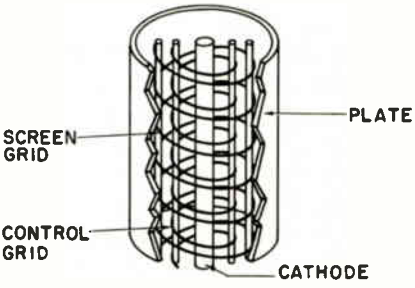

Fig. 23. A cut-away view of a screen-grid tube.

capacity is much smaller than it is in the triode. In addition, the screen grid of a tube is normally operated at signal ground potential. Therefore any energy fed from the plate of the tube back towards the grid is fed to ground at the screen. This practically eliminates the feedback from the plate to the grid of the tube.

The dc potential applied to the screen is always positive with respect to the cathode. Usually the voltage placed on the screen grid is about half the voltage applied to the plate of the tube, but in some tubes the screen-grid voltage may be as high as the plate voltage. This may appear to be a contradiction because we said that the screen grid is operated at the signal ground potential. Actually, it is possible to have a tube element at signal ground potential and still have a positive or negative dc voltage applied to it. You will remember that a capacitor offers a low reactance to the flow of ac through it. Therefore we can ground the screen of a tube so far as signal is concerned by putting a capacitor between the screen of the tube and ground. If the capacitor is large enough, its reactance to the signal is so low that the screen is practically at signal ground potential. At the same time, since a capacitor does not permit the flow of dc through it, you can connect it to a dc voltage source and apply a positive voltage to the screen.

The schematic diagram of a typical screen-grid amplifier circuit is shown in Fig. 24. Here the input signal is fed between the grid and the cathode of the tube as in the case of the triode. Electrons flow from the cathode of the tube to the plate of the tube as in the triode. However, in the tetrode tube the number of electrons flowing will depend upon the plate voltage, the grid voltage and the screen-grid voltage. In fact, the number of electrons flowing from the cathode towards the plate will depend much more on the screen and grid voltages than on the plate voltage.

As in the triode tube, small changes in grid voltage produced by the ac signal applied to the input will produce comparatively large changes in plate current. These changes in plate current will cause the voltage between the plate and cathode of the tube to vary, and this voltage will be the amplified output signal.

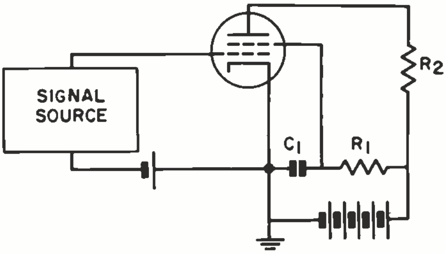

Fig. 24. Schematic of a screen-grid amplifier. R1 is used to reduce the B supply voltage for the screen, and is called the screen voltage dropping resistor, or simply the screen dropping resistor. C1 is the screen by-pass capacitor. R2 is the plate load resistor. The heater of the tube has been omitted to simplify the diagram.

A few of the electrons flowing from the cathode of the tube towards the plate of the tube will strike the screen. Thus there will be a small current flowing from the cathode of the tube, to the screen grid, through the power supply and back to the cathode.

Because the plate voltage has

much less effect on the plate current in a screen-grid tube than in a triode tube, screen-grid tubes have a much higher amplification factor than triodes. In addition they have a much higher plate resistance.

Disadvantages.

Although the tetrode is a great improvement over the triode, it does have certain disadvantages. One of these disadvantages, which led to the development of the pentode or five-element tube, occurs because of secondary emission.

As you already know, electrons travelling from the cathode of the tube to the plate reach a fairly high speed, and when they strike the plate they may knock other electrons off the plate. In a diode and a triode the plate is the only positive element in the vicinity of these loose electrons, and therefore they are attracted back to the plate. However, in a tetrode we have, in addition to the plate, the screen grid with a positive voltage applied to it. If the plate voltage is substantially higher than the screen voltage, the electrons will be attracted back to the plate, but if the screen voltage is almost equal to or even higher than the plate voltage, then the electrons knocked off the plate of the tube will be attracted to the screen instead of to the plate. Thus, for every electron reaching the plate from the cathode there may be two or three electrons emitted by the plate. This means that if the grid swings in a positive direction more electrons will strike the plate, knocking still more electrons off the plate. The net result can be that the plate current decreases when the grid swings positive. To prevent this undesirable action a third grid called a suppressor grid was added to develop the pentode tube.

PENTODE TUBES

The pentode tube is a tube with five elements. It is simply a refinement of the screen-grid tube, which is made by adding an additional grid between the screen grid and the plate of the tube. Thus, the pentode has three grids. The third grid, or suppressor grid, gets its name because it is put in the tube to suppress or eliminate the undesirable effects of secondary emission occurring at the plate of the tetrode tube. Because it is also the third grid it is sometimes called the number-three grid.

The suppressor is usually connected directly to the cathode of the tube, but sometimes it is connected directly to ground. It has very little effect upon the electrons travelling from the cathode of the tube towards the plate. These electrons are attracted from the cathode by the positive potential on the screen of the tube. They are accelerated by this voltage, but as they approach the screen, instead of stopping at the screen they pass right through the screen wires. Once they get through these wires they are attracted to the plate by its positive voltage, which is usually higher than the voltage on the screen. In the pentode tube, after the electrons have passed the screen they are moving at a fairly high velocity, and they travel right on through the suppressor grid to the plate. The suppressor does not have any appreciable effect on the progress of the electron as it moves from the cathode toward the plate.

When the electrons strike the plate they knock other electrons off the plate, as in the case of the screen-grid tube. However, these electrons are travelling at a comparatively low speed when they are knocked off the plate. The suppressor, which is connected to the cathode or to ground or may be operated with a low negative voltage applied to it, repels the electrons emitted from the plate by secondary emission, and these electrons move back to the plate of the tube. Thus, the addition of the suppressor grid eliminates the undesirable current flow from the plate of the tube to the screen grid, which we found could occur in the tetrode tube.

Because the pentode tube has a screen grid, it has the low plate-to-grid capacity that we found in the tetrode tube. In addition, the pentode has the advantage that it does not suffer from the adverse effects of secondary emission.

It might be well to point out now that the plate voltage on a tetrode or a pentode tube has very little effect on the plate current. The voltage on these tubes can be varied over wide limits without appreciably changing the plate current that will flow in the tube. For a given grid voltage, the plate current will depend primarily upon the screen voltage. The screen is the electrode that starts the electrons moving from the cathode to the plate and has more effect on the number of electrons that will flow from the cathode to the plate than the plate voltage does.

You will remember that one of the characteristics of vacuum tubes that we studied was the amplification factor. The amplification factor is the ratio of the plate voltage required to produce a given change in plate current to the grid voltage required to produce the same change in plate current. Remember that the formula is:

$$\mu = \frac{e_p}{e_g}$$

Since the plate voltage has very little effect on the plate current in a tetrode or pentode tube, it takes a very large change in plate voltage to produce the same change in plate current that can be produced by a small change in grid voltage. Thus, the amplification factor of a tetrode or a pentode tube is very high. We mentioned that the amplification factor of a triode may be somewhere between about 5 and 100. A triode with an amplification factor of 100 is called a high-mu triode because it has a high amplification factor for a triode. However, pentodes with amplification factors of over 1000 are common.

BEAM POWER TUBES

Another tube that solves the problem of secondary emission in screen-grid tubes is the beam power tube. The beam power tube, like the screen-grid tube, is a tetrode or four-element tube in which this problem has been overcome. A sketch of a beam power tube is shown in Fig. 25.

Notice the shape of the cathode of the tube. It has two flat surfaces. The construction of the cathode is such that most of the electrons will be emitted by the flat surfaces and hence there is a tendency for the electrons to form into two beams, one on each side of the cathode. Only one of these beams is shown in the drawing.

Notice the two small additional plates between the screen grid and the plate of the tube. These plates are called the beam-confining or

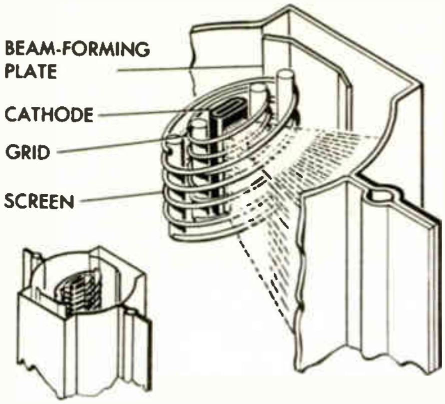

Fig. 25. A beam-power tube.

beam-forming plates. The beam-forming plates are connected internally to the cathode of the tube and repel electrons. These plates act to keep the electrons concentrated into the two beams that are formed at the cathode. The electrons flowing from the cathode of the tube towards the plate are bunched together in these beams.

You will remember that an electron has a negative charge and will repel other electrons. Therefore, if an electron travelling at a high speed from the cathode of the tube to the plate knocks additional electrons off the plate, these loose electrons, which will be travelling at a low speed, will be repelled back to the plate by the negative charge on the electron beam.

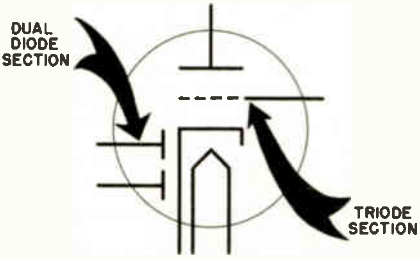

Fig. 26. A combination tube containing two diodes and a triode. This is called a duo-diode triode.

Beam power tubes are used in radio, TV, and industrial electronic equipment. Also, large beam power tubes are used in transmitters. The beam power tube has proven superior to the pentode in applications where large amounts of power must be handled.

OTHER TUBE TYPES

The diode, triode, tetrode, and pentode are the basic tube types. However, there are many special tubes that have been manufactured for special applications. In addition, there are tubes that are simply combinations of several tubes in the same envelope.

An example of a tube where several types have been combined in one envelope is the tube with a triode and two diodes in it. A schematic of this type of tube is shown in Fig. 26. This tube is called a duo-diode-triode. As this name indicates, it has two diodes and a triode in one envelope.

Other tubes consist of two triodes in one envelope such as shown in Fig. 27. In the schematic shown at A, a common cathode is used for the two triode sections; in the one shown at B, each triode section has its own separate cathode.

Another combination type is the triode-pentode shown in Fig. 28. This type of tube is used in radio, TV, and many industrial applications. In this way, one tube can be made to do the work of several.

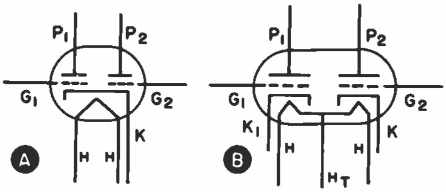

Fig. 27. Dual triode tubes. The tube at A has a common cathode. The tube at B has two separate cathodes. Notice this tube has a single heater with a center tap. Not all tubes of this type have tapped heaters.

The pentagrid tube, shown in Fig. 29, is an interesting tube. It is called a pentagrid tube because it has five grids. Tubes of this type are used as combination mixer-oscillators in radio and TV receivers. We will study this type in more detail later.

You will also run into a tube called the Compactron. The Compactron is simply a tube where several types are combined in one envelope. Compactron tubes have a base with twelve pins so it is possible to put a number of tubes in the same envelope. Some Compactrons may have three triodes in the one envelope; some may have two pentodes in the same envelope. Others are combinations of diodes, pentodes and triodes. Tubes such as Compactrons offer an advantage over tubes in separate envelopes inasmuch as they are somewhat less expensive to manufacture than separate tubes, and also it is possible to make more compact equipment because the space occupied by the multi-function tube is considerably smaller than the space that would be required for separate tubes.

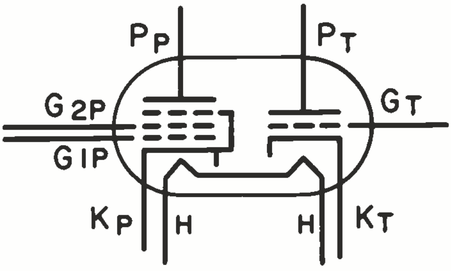

Fig. 28. A pentode-triode.

The Nuvistor tube is another important tube. Most Nuvistors are simply triode tubes but they are very small tubes. They look almost like a flat thimble. The advantage of the Nuvistor tube, in addition to its small size, is the very low capacity between the elements and the comparatively high gain that can be obtained with this type of tube. Because of the very small size of the elements used in the Nuvistor tube, this tube is quite widely used as an rf amplifier in TV receivers. Later, when we start studying specific amplifier circuits, you will see why such a tube as the Nuvistor would be advantageous as an amplifier at very high frequencies.

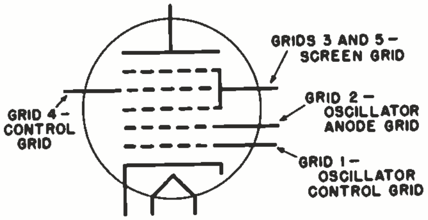

Fig. 29. A pentagrid tube.

While not all Nuvistor-type tubes are triodes, almost all the ones you are likely to encounter will be triodes. There have been a few tetrode Nuvistors manufactured, but these were primarily for industrial applications rather than entertainment-type equipment. In addition, due to manufacturing difficulties and competition from transistors, Nuvistors other than the triode types have not been too widely used.

CHARACTERISTIC CURVES

The characteristic curves for pentode tubes are quite different from those for triodes. The E_p-I_p curves for a typical pentode tube are shown in Fig. 30. Notice that the curves bend rather sharply at the left, but then are quite flat. For example, notice the curve representing the plate current with a grid bias of -2 volts. As we start at the lower left of the graph this curve rises rapidly until we reach the line representing the plate voltage of 50 volts. At this point the plate current is almost 2 milliamperes. Then, if the voltage on the plate of the tube is increased from 50 volts on up to 450 volts, there is very little change in the plate current. This simply demonstrates what we mentioned previously; in a pentode tube the plate voltage has very little effect on the current-the plate current is primarily determined by the grid voltage and the screen voltage.

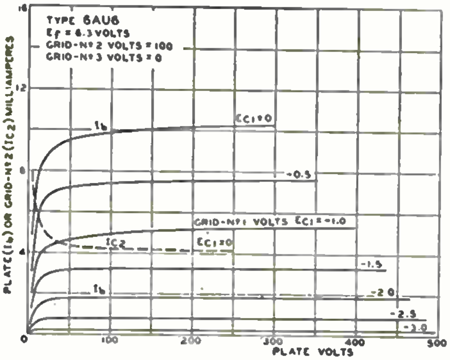

Fig. 30. E_p-I_p curves for the 6AU6 tube.

The characteristic curves for beam power tubes are quite similar to those for pentode tubes. We have not shown curves for screen-grid tubes, because the screen-grid tube has been replaced by the pentode and beam power tubes in modern design.

SUMMARY

In this section of the lesson you have studied multi-element tubes. Remember that the screen-grid tube was developed to eliminate the undesirable effects produced by the high plate-to-grid capacity found in triode tubes. A screen-grid tube is a tube with a high amplification factor and low plate-to-grid capacity. However, because the screen is operated with a positive voltage, the electrons emitted from the plate by secondary emission were attracted both to the plate and to the screen of the tube. Some of the electrons would flow to the screen and introduce a number of undesirable effects.

To overcome the problem created by secondary emission in the screen grid tube, the pentode or five-element tube was developed. The pentode contains three grids: a control grid, a screen grid, and a suppressor grid. These grids are often referred to as grids 1, 2, and 3.

The undesirable effects of secondary emission can also be overcome by constructing a flat type of cathode and using beam-forming plates. This led to the development of the beam power tube. The beam power tube is a tetrode tube, but it differs substantially in performance and construction from the old screen-grid tube.

In addition to the screen grid, pentode, and beam power tubes, there are a number of special tubes. These tubes may actually be tubes designed for one specific application such as the pentagrid converter type tube, or may simply be two or three different tubes combined in the one envelope. Tubes of this type consist of twin triodes, triode-pentode combinations, and duo-diode-triodes.

SELF-TEST QUESTIONS

(am) What is the purpose of the screen grid in a tetrode tube?

(an) What dc operating potential is applied to the screen of a tube?

(ao) How is the screen of a tetrode tube operated in order to provide maximum shielding between plate and grid?

(ap) Name the five elements in a pentode tube.

(aq) What elements control the flow of plate current in the pentode tube?

(ar) How are the undesirable effects of secondary emission overcome in the beam power tube?

(as) What is a Compactron?

(at) What is a Nuvistor?

Special Tube Types

There are a number of special-purpose tubes that have been designed for particular applications. Many of these tubes were designed for use in transmitting and industrial electronic equipment, but some of these tubes will also be found in equipment that the radio-TV serviceman may be called on to service. In most cases it is not particularly difficult to understand how these tubes operate.

GAS-FILLED DIODES

We mentioned earlier that gas is sometimes deliberately introduced into a tube. A common application of this principle is found in some diodes where mercury is placed inside the tube. The mercury vaporizes, filling the inside of the tube with mercury vapor. This particular type of tube makes an excellent rectifier. One of its characteristics is that the voltage drop across the tube is almost constant regardless of the current flowing through the tube. Let us look into the mercury-vapor diode tube and see how it differs from a high-vacuum diode.

The circuit shown in Fig. 31 can be used to compare the characteristics of the vacuum diode and the mercury-vapor diode. If we use a vacuum diode in this circuit, we will find that when the voltage applied to the circuit is zero, the voltage between the plate and the filament of the tube is zero, and the current flowing in the circuit is zero. If we increase the voltage to 5 volts, we

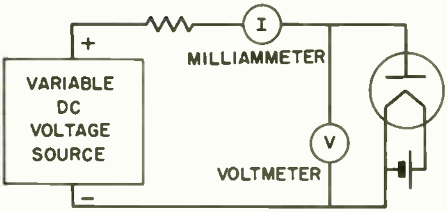

Fig. 31. A circuit for comparing vacuum and gas-filled diodes.

will notice a reading on the voltmeter indicating that there is voltage between the plate and the filament of the tube and that current is starting to flow in the circuit. If we then increase the variable voltage source to 10 volts, we will find that the voltage between the plate and the filament of the tube has increased and that the current flowing in the circuit has increased. If we keep increasing the voltage in 5-volt steps, we will find that the reading on the voltmeter will gradually increase, and at the same time the current flowing in the circuit will increase. This will continue in this way until a plate voltage is reached where all the electrons being emitted by the tube are being attracted to the plate. Then, increasing the voltage would result in little or no increase in current flowing through the tube. If we plotted the curve to show the relationship between the voltage across the tube and the current flowing through the tube, we would get a curve like the one shown in Fig. 32A.

If we perform the same experiment with a mercury vapor diode, we would obtain somewhat different results. If we started with the voltage from the variable voltage source at zero, we would find the reading on the voltmeter connected between the plate and filament of the tube was zero and again that the current flowing in the circuit was zero. When we increase the source voltage until we get a reading on the voltmeter of about 5 volts, there will be a current flowing in the circuit. A further increase to 10 volts would result in a further increase in the current flowing in the circuit. If we increase the voltage to 15 volts, we would get another increase in the current flowing in the circuit. However, when we increase the voltage above 15 volts something unusual will happen. At some voltage above 15 volts, the tube will fire; this means that it will suddenly start to glow with a blue glow. When this happens, the reading on the voltmeter connected between the plate and the filament of the tube will drop back to 15 volts. We would find that increasing the voltage from the variable voltage source further would not result in any increase in the voltage between the plate and the filament of the tube. However, the current flowing in the circuit would continue to increase as long as we increased the voltage of the source. If we plotted a curve to show the relationship between the voltmeter reading and the milliammeter readings for this tube, we

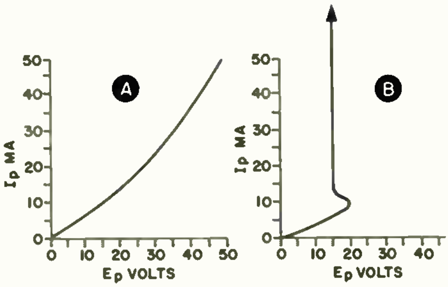

Fig. 32. The E_p-I_p curve for a vacuum diode is shown at A, and the curve for a mercury-vapor diode is shown at B.

would get a curve similar to Fig. 32B. Notice that up to some voltage slightly over 15 volts this curve is very similar to the curve obtained for the vacuum diode, but when the firing point is reached, the voltage between the plate and the filament of the tube drops down to 15 volts and then remains constant at this value, while at the same time the current through the tube can increase almost indefinitely.

Now let us see what is happening inside the mercury vapor tube. When the low positive voltage is applied to the plate of the tube, electrons emitted by the filament are attracted to the plate. These electrons do not reach any great velocity, so they simply travel over to the plate of the tube. Some of them will strike the gas molecules inside the tube, but they are not traveling at a high enough speed to knock any electrons off the molecules. As the plate voltage is increased, eventually a voltage is reached where the electrons travelling from the filament to the plate of the tube reach a high enough speed to knock electrons off the gas molecules that they strike. When this happens, the electrons knocked off the gas molecules travel over to the plate of the tube, thus increasing the number of electrons reaching the plate. At the same time, the molecules that have had some electrons removed will have a positive charge on them, and they will travel over towards the filament of the tube. As these molecules enter into the area of the space charge around the tube filament, they will pick up electrons from the space charge, lose their positive charge, and then begin to drift away from the tube cathode. They, in turn, will be hit by other electrons travelling from the filament of the tube to the plate, which will knock electrons off the gas molecule again, give it a positive charge, and once more it will start back to the space charge to pick up additional electrons in order to get rid of the positive charge.

If the right amount of mercury vapor is present in the tube, the gas molecules will neutralize or eliminate the effects of the space charge around the filament of the tube. Thus, the electrons will be able to leave the filament and travel directly to the plate of the tube with little or no opposition. This results in a tube with a very low internal resistance. The voltage drop across a tube of this type is almost constant and is about 15 volts regardless of the current flowing through the tube.

When the gas inside the tube ionizes, it gives off a bright blue glow. When this happens we say that the tube fires. The firing point for a mercury vapor tube is slightly above 15 volts, but once the tube has fired the voltage drop across the tube will drop back to approximately 15 volts and remain essentially constant at this value.

Mercury vapor diodes are used as rectifiers. It is a great advantage to have rectifier tubes that have a constant voltage drop, particularly in equipment where the current drawn from the power supply varies appreciably. If the current varies and a vacuum type rectifier is used, there will be considerable variation in the voltage drop across the tube, and as a result a variation in the output voltage from the power supply. However, in a mercury vapor tube, since the voltage drop across the tube is practically constant regardless of the current flowing through it, the output voltage from

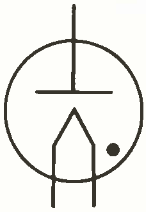

Fig. 33. Dot inside the envelope is used to indicate a gas-filled tube. This is the schematic symbol for a gas-filled diode.

the power supply will be almost constant even though the current drawn from the supply and through the tube may vary appreciably.

To distinguish tubes containing gas from vacuum tubes in a schematic diagram, a dot is usually placed inside the tube envelope on the schematic symbol. The schematic symbol for a gas-filled diode rectifier is shown in Fig. 33.

Mercury is not the only gas used in gas-filled tubes, but it is the most commonly used in rectifier tubes. Mercury-vapor tubes are not found in modern radio and TV receivers but are used in many other applications.

An example of another gas-filled diode is the Tungar tube. This tube is somewhat similar to and operates on the same principle as the mercury-vapor diode, but instead of mercury, argon gas is introduced into the tube. This tube has many of the characteristics of the mercury-vapor diode; it has an almost constant voltage drop of about 10 volts across it. It is particularly suitable for applications requiring a low voltage and a high current.

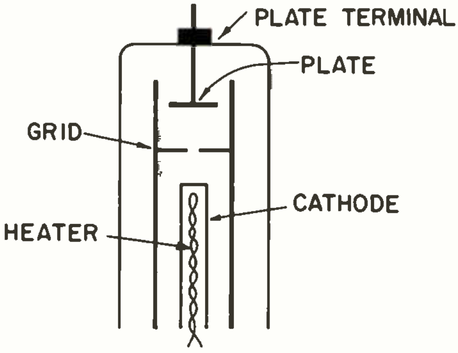

Fig. 34. Construction of a thyratron.

THE THYRATRON

In addition to mercury-vapor diodes, mercury-vapor triodes are also used. A mercury-vapor tube with a grid is called a thyratron. The construction of a thyratron is somewhat different from the construction of a vacuum-type triode tube. A sketch of a thyratron is shown in Fig. 34.

The control that the grid has over the flow of plate current in the thyratron is quite different from the control the grid has in the high-vacuum rectifier. In a thyratron, as long as the grid is maintained sufficiently negative to cut off the flow of plate current, there will be no electron flow from the cathode of the tube to the plate. Even with a high positive voltage on the plate of the tube, the grid, if it is negative enough, can block the flow of electrons to the plate. Electrons emitted by the cathode are simply driven back into the space charge and to the cathode.

Up to this point the action of the grid in a thyratron is similar to the action of the grid in a vacuum triode. However, if the grid voltage on the thyratron is reduced below the value required for cut-off, something entirely different happens.

A circuit using a thyratron is shown in Fig. 35A. If the grid is made negative and a positive voltage

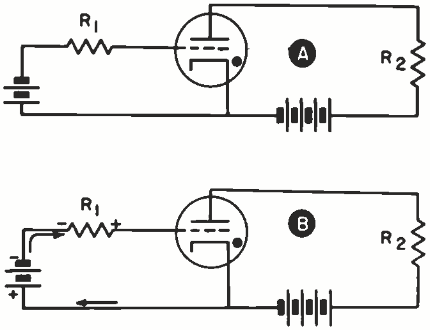

Fig. 35. Circuit using a thyratron.

is applied to the plate, the grid is able to cut off the flow of plate current. Once the grid voltage is reduced below cut-off, electrons begin flowing from the cathode of the tube to the plate. These electrons flowing through the tube will strike the gas molecules and knock electrons off them. These electrons will flow over to the plate of the tube. Meanwhile, the gas molecules that now have a positive charge on them will drift to the space charge to pick up electrons to neutralize the positive charge. In doing this, they remove the electrons in the space charge which in effect reduces the internal resistance of the tube, and permits a high current to flow.

If we try to cut off the flow of plate current by increasing the negative grid voltage to the cut off value again, the negative grid will attract positive ions which are gas molecules that have had electrons knocked off them. These positive ions will, in turn, attract electrons from the grid. These electrons are coming to the grid through R1, and as a result there will be a voltage drop across this resistor as shown in Fig. 35B. This voltage drop has a polarity opposite to that of the grid battery and will tend to neutralize the negative voltage applied in the grid circuit so the grid itself does not become very negative. Therefore, the grid is unable to gain control of the plate current, so the plate current continues to flow from the cathode to the plate of the tube even though the negative voltage applied to the grid circuit may be considerably greater than the applied voltage that would originally cut off the flow of plate current. If we increase the negative grid voltage to a very high value to try to cut off the flow of plate current, we simply attract more ions to the grid. These positive ions will attract more electrons from the grid, with the result that the number of electrons flowing from the grid to the ions may become quite high. This current could become so high the tube would be destroyed if it were not for the resistor R1 placed in the grid circuit which helps to keep the grid current down to a safe value.

In a thyratron, if the plate current is to be cut off by the grid voltage, the negative voltage needed to cut off the flow of plate current must be applied to the grid of the tube before the plate voltage is applied. Then the positive voltage can be applied to the plate of the tube, and the grid will prevent the electrons from reaching the plate of the tube. But once the grid voltage is reduced to a point called the "starting" point, where electrons can begin flowing from the cathode to the plate, the tube will fire, just as the mercury-vapor diode does, and the positively charged molecules will neutralize the space charge. This will permit a high current to flow through the tube and at the same time be attracted to the grid and neutralize any negative voltage placed on it to try to cut off the flow of plate current.

In a circuit using a thyratron, once the grid has lost control of the flow of plate current, the only way it can regain control is by removing the plate voltage from the tube. Once the plate voltage is removed, the grid can regain control; plate voltage can then be reapplied to the tube and no current will flow through it as long as the grid voltage is kept sufficiently negative to prevent any electrons from flowing from the cathode to the plate of the tube.

Thyratrons are extremely useful in industrial electronic applications. In some circuits, ac is applied to the plate of the tube instead of dc.

THE CATHODE-RAY TUBE

Another important tube found in many pieces of test equipment and also in TV receivers is the cathode ray tube. A photo of a cathode ray tube is shown in Fig. 36.

In the neck of a cathode ray tube is a device known as an electron gun. A typical electron gun is also shown in Fig. 36. The electron gun contains a heater, which heats a cathode; the cathode emits electrons; and these electrons are attracted by the high positive voltage on the anodes in the tube. Between the first anode and the cathode is the grid, as shown in the figure. The grid is used to control the number of electrons passing from the cathode towards the anodes.

The anodes in a cathode ray tube are arranged with a hole in the center of them so that instead of attracting electrons to themselves, they accelerate the electrons down the neck of the tube. The electrons pass right through the holes in the anodes and travel at a very high speed towards the face of the cathode ray tube. The face of the cathode ray tube is covered with a phosphorescent type of material. When this surface is struck by electrons, it glows and gives off light.

If the electrons accelerated down the electron gun were permitted to travel directly towards the face of the tube, they would all strike the face at approximately the same spot--somewhere near the center of the tube. However, the electron beam

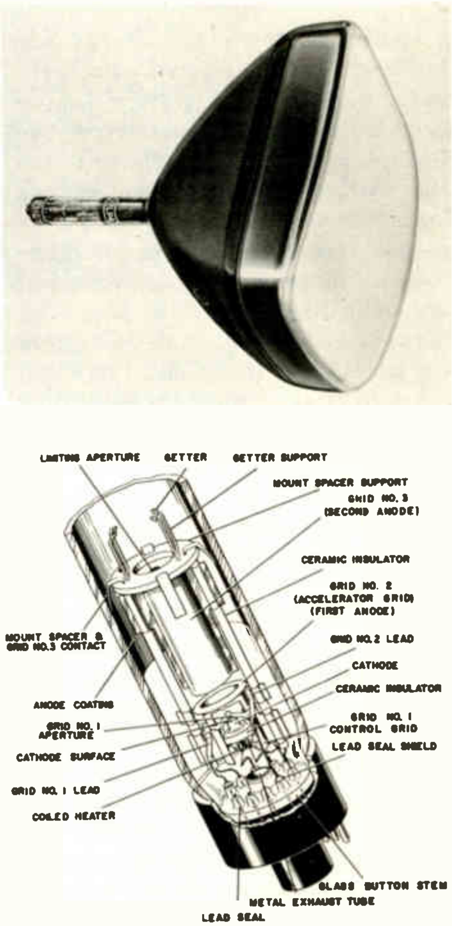

Fig. 36. A cathode ray tube is shown above; an electron gun of a crt below.

can be deflected so that it can be made to strike any point on the face of the tube.

The electron beam can be deflected by means of plates inside the neck of the cathode ray tube. If a positive voltage is put on one plate and a negative voltage on another, the positive plate will attract and bend the electron beam towards it and at the same time the negative plate will push the beam away from it. If two sets of parallel plates are installed in a tube, one in the horizontal plane and the other in the vertical plane, the horizontal plates can be used to move the electron beam up and down, and the plates installed in the vertical direction can be used to move the electron beam from side to side. Such a tube is called an electrostatic cathode ray tube.

The electron beam may also be deflected by magnetic fields produced by two pairs of coils. This is called electromagnetic deflection. The picture tubes used in TV receivers use this type of deflection.

Color picture tubes are similar to the tubes shown in Fig. 36 except that three electron guns are used inside of the tube. One gun is used for each of the three primary colors, red, blue and green. These guns are arranged to produce three electron beams that travel to the face of the picture tube and strike phosphors that will give off colored light. In other words, the blue gun strikes a phosphor dot that produces blue; the red gun strikes a phosphor dot that produces red, and the green gun strikes a phosphor dot that produces green. Hundreds of thousands of dots are placed on the face of the tube, and by sweeping the electron beams over the face of the tube it is possible to produce color pictures. Of course, the color tube is more complex than this, and there are other parts that we have omitted. We will study them later, but this will give you a general idea of what a color tube is like.

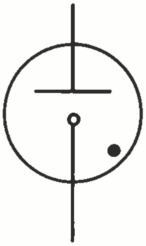

Fig. 37. Schematic symbol of a VR tube.

OTHER SPECIAL TUBE TYPES

There are many other special tube types found in electronic equipment.

Voltage Regulator Tubes.

One type that is quite common is the voltage regulator tube, often abbreviated the VR tube. The schematic symbol used to represent a VR tube is shown in Fig. 37.

Notice that the VR tube is a gas-filled tube. It is often used in a circuit like the one shown in Fig. 38. An important characteristic of this type of tube is that it maintains an almost constant voltage drop across it. If the voltage tends to increase, the tube will draw current, which will result in a greater voltage drop across the resistor so that the volt-

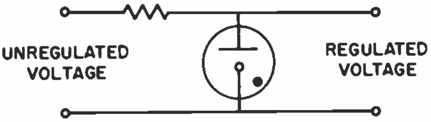

Fig. 38. A circuit using a VR tube.

age across the tube will remain constant. This type of tube is used to regulate the voltage in circuits where it is important for the voltage to be held as constant as possible.

Photo Tubes.

Another type of tube found in electronic equipment is the photo tube. This tube has a cathode and an anode, or plate. Instead of emitting electrons by thermionic emission, this tube is designed to emit electrons when light strikes its cathode. Electrons travel over to the plate of the tube and thus current flows through the tube. In Fig. 39 we have shown a picture of a photoelectric tube and the schematic symbol for it.

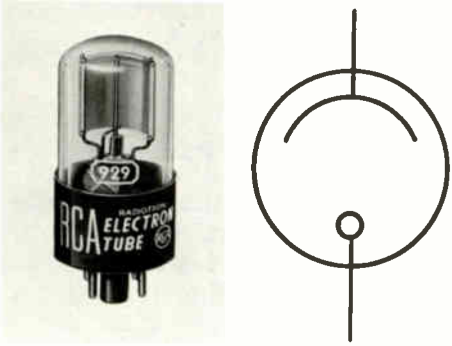

Fig. 39. A photoelectric tube and its schematic symbol.

SUMMARY

There are many special tube types in electronic equipment. Among these are the gas-filled tubes. Gas-filled diodes are frequently used in power supplies, particularly where the current drawn from the power supply goes through wide variations. Mercury-vapor rectifier tubes are found in many pieces of industrial electronic equipment and in the power supplies of most radio and TV transmitters.

A three-element mercury-vapor tube is called a thyratron tube. The most important characteristic of a thyratron is that the grid can prevent the flow of current from the cathode to the plate if it is made negative enough before the plate voltage is applied to the tube. However, once the current begins to flow from the cathode to the plate of the tube, putting a negative voltage on the grid of the tube will not cut off the flow of plate current because the negative voltage attracts the positive gas ions in the tube and these ions draw electrons from the grid. If the grid voltage is high enough, this will cause such a high grid current that the tube may be destroyed.

The cathode ray tube is found in TV and in many pieces of test equipment. It contains an electron gun which is used to shape the electrons into a beam and to accelerate them down the gun towards the face of the tube. Electrons striking the face of the tube cause the tube to glow and give off light. Cathode ray tubes are made in two types, those using electrostatic deflection and those using electromagnetic deflection.

Other special tubes are the photo tubes and the voltage regulator tubes. You will see more of these tube types later.

SELF-TEST QUESTIONS

(au) What do we mean when we say a mercury-vapor fires?

(av) What is the advantage of a mercury-vapor diode over a vacuum-tube diode as a rectifier?

(aw) What is a thyratron?

(ax) What is the main difference between a thyratron and a conventional triode tube?

(ay) What is the purpose of the anodes in the electron gun of a cathode-ray tube?

(az) What two types of deflection may be used with a cathode-ray tube?

LOOKING AHEAD

Now that you have studied the various tube types and have learned how they operate, the next thing is to see them actually used in typical circuits. In your next lesson you will study the most common circuits found in electronic equipment. These circuits are the basic circuits from which more complex circuits have been developed.

ANSWERS TO SELF-TEST QUESTIONS

(a) A cathode and a plate.

(b) Tube cathodes can be divided into directly heated and indirectly heated types.

(c) A filament.

(d) By means of a heater which is a coil of wire placed inside the cathode. The cathode is usually made in the form of a hollow tube.

(e) To provide an abundant supply of electrons at low operating temperatures.

(f) None. Other than to heat the cathode the heater serves no useful purpose and therefore it is often left off the schematic diagram in order to simplify the diagram.

(g) Approximately 8 volts. The first number or numbers preceding the first letter in a tube type indicates the approximate heater voltage required by the tube.

(h) The plate or anode.

(i) The plate receives a certain amount of heating from the cathode of the tube and the remainder is produced by electrons striking it.

(j) The plate may begin to emit electrons and the excessive heat may force gases out of the plate material into the space surrounding the plate of the tube.

(k) The getter is used to eliminate gases that are released inside the tube the first time it is heated after it has been sealed.

(l) A tube from which all of the gases have been removed.

(m) A tube into which a certain amount of gas has been deliberately introduced. An example of the type of gas frequently introduced into diode tubes is mercury vapor.

(n) It simply indicates that a few electrons are missing the plate and striking the glass. This often happens and does not mean that there is anything wrong with the tube.

(o) When we say the plate current-plate voltage is linear we mean that a given change in plate voltage will produce a constant change in plate current. In other words, if we increase the plate voltage from 70 volts to 80 volts it will cause a certain increase in plate current. If we increase the plate voltage another 10 volts it will cause a similar increase in plate current.

(p) The grid is much closer to the cathode than the plate and therefore the voltage applied to the grid of the tube has a greater effect on plate current than the same voltage applied to the plate will have.

(q) The positive voltage applied to the grid of the tube will cause the number of electrons flowing from the cathode to increase. Most of these electrons will flow through the grid structure to the plate because the plate will normally have a much higher positive voltage than the grid. By the time the electrons have reached the grid they will be travelling at such a high speed that they will pass right through the grid and flow over to the plate. However, some of the electrons will be attracted by the grid and will cause some current to flow in the grid circuit.

(r) As the negative grid voltage is increased, the plate current will decrease until eventually the grid voltage will become negative enough to prevent any electrons from reaching the plate. When this happens we say that the plate current is cut off.

(s) The amplification factor of a tube is the ratio of the change in plate voltage to the change in grid voltage required to produce the same change in plate current.

(t) Between 5 and about 100.

(u) The amplified signal will normally be the same as the input signal except it will be 180° out of phase. In other words, when the input signal reaches its maximum positive value, the amplified signal will reach its maximum negative value and when the input signal reaches its maximum negative value, the amplified signal will reach its maximum positive value. We say that the output signal is inverted or 180° out of phase with the input signal.

(v) The ac plate current is the changing plate current produced by the input signal voltage. It acts like an ac current superimposed on the dc plate current that flows through the tube when the input signal is zero.

(w) A grounded-cathode amplifier is an amplifier using a tube in which the cathode is at signal ground potential.

(x) An E_g-I_p curve is a grid voltage-plate current curve. It shows how the plate current varies with different values of grid voltage.

(y) The linear portion of the E_g-I_p characteristic curve is the straight portion of the characteristic curve. In Fig. 15, the linear portion is between approximately -6 volts and 0 volts.

(z) A grid-bias voltage is a voltage applied between the grid and the cathode of the tube to fix the operating grid voltage so that the tube will operate over the linear portion of the E_g-I_p characteristic curve.

(aa) When a tube is operated with too low a grid bias, the signal may drive the grid in a positive direction. When this happens, the grid will draw current with the result that the increase in plate current will not be linear. This results in a flattening of one half of the amplified output signal.

(ab) When the operating grid bias on a tube is too high, the input signal may drive the grid so far in a negative direction that the flow of plate current may be completely cut off. This will result in a flattening of the negative half of the plate current cycle which will produce amplitude distortion.

(ac) An Ep-Ip curve is a characteristic curve which shows the plate current for different values of plate voltage. A series of these curves are usually given, one curve for each value of grid voltage.

(ad) The ac plate resistance of a tube is the ratio of a change in plate voltage to a change in plate current that it produces. It is represented by the formula:

$$r_p = \frac{e_p}{i_p}$$

(ae) The dc plate resistance of a tube is the dc plate voltage measured between the plate and cathode of the tube divided by the dc plate current flowing through the circuit.

(af) The mutual conductance of a tube is equal to a change in plate current divided by the change in grid voltage required to produce the change in plate current. Mutual conductance is usually represented by g_m and the formula for mutual conductance is

$$g_m = \frac{i_p}{e_g}$$

(ag) The mutual conductance is measured in mhos. However, the mho is a rather large unit and thus we usually convert this to micro-mhos by multiplying it by 1,000,000.

(ah) $\mu = r_p \times g_m$.

(ai) An equivalent circuit is a circuit used to analyze the performance of an amplifier stage.

(aj) The generator voltage is $-\mu e_g$. The voltage is negative to indicate the fact that it is inverted by the stage. In other words, the output voltage is 180° out of phase with the input voltage.

(ak) The generator internal resistance is the plate resistance of the tube.

(al) The stage gain will be 45. To find the gain of the stage we use the formula

$$\text{stage gain} = \mu \times \frac{R_L}{R_L + r_p}$$

and substituting 50 for the amplification factor, 90,000 for the load resistance and 10,000 for the plate resistance we get

$$\text{stage gain} = 50 \times \frac{90{,}000}{90{,}000 + 10{,}000}$$

$$= 50 \times \frac{90{,}000}{100{,}000}$$

$$= 50 \times \frac{9}{10}$$

$$= 45$$

(am) The screen grid reduces the plate-to-grid capacitance and prevents oscillation due to feedback from the plate to the grid of the tube.

(an) The screen of a tetrode tube is operated with a positive potential applied to it. Usually the positive potential is about half the plate potential.

(ao) The screen is operated at signal ground potential. We accomplish this by connecting a suitable capacitor between the screen of the tube and ground. The capacitor offers a low reactance to ac signals on the screen so, insofar as the signals are concerned, the screen is essentially at ground potential.

(ap) The five elements in the pentode tube are the cathode, the grid, the screen grid, the suppressor grid and the plate.

(aq) The grid and the screen grid. The voltage applied to the grid and the voltage applied to the screen grid will control the flow of plate current in a pentode tube. The plate voltage on a pentode tube has very little effect on the plate current flowing in the tube.

(ar) In a beam-power tube the electrons are focused in two beams. Electrons knocked off the plate are moving at a slow speed and they are repelled by the high-speed electrons in the beam back to the plate of the tube.

(as) A Compactron is simply a tube where several types have been combined in just one envelope. The base of the Compactron tube has twelve pins so that it is possible to combine a number of complete tubes in the same envelope.

(at) A Nuvistor is a miniature tube shaped something like a thimble with a flat top. The tube is extremely small and therefore the capacity between the plate and grid is quite low, making the tube suitable for use in rf amplifiers.

(au) When we say a mercury vapor tube fires we mean that the gas inside the tube ionizes.

(av) The mercury vapor tube has a constant voltage drop regardless of the current flowing through the tube. The vacuum type rectifier does not have this desirable characteristic; the voltage drop across the tube will depend upon the current flowing through the tube.

(aw) A thyratron is essentially a triode tube that has been filled with a gas such as mercury vapor.

(ax) In a thyratron, the grid can keep the plate current cut off if a high negative voltage is applied to the grid before voltage is applied to the plate of the tube. Once the plate current begins to flow, the grid loses all control of the flow of plate current and normally cannot be used to reduce or cut off the plate current. In a vacuum-type triode tube, however, the grid always maintains control over the flow of plate current.

(ay) The anodes are used to accelerate and focus the electron beam. They are not designed primarily to attract electrons as is the plate in the conventional tube, but rather they are used to accelerate electrons in the form of a beam down the electron gun towards the phosphor on the face of the cathode-ray tube.

(az) Electrostatic deflection and electro-magnetic deflection.

Lesson Questions

Be sure to number your answer sheet B110.

Place your Student Number on every Answer Sheet.

Most students want to know their grade as soon as possible so they mail their set of answers immediately. Others, knowing they will finish the next lesson within a few days, send in two sets of answers at a time. Either practice is acceptable to us. However, don't hold your answers too long; you may lose them. Don't hold answers to send in more than two sets at a time or you may run out of lessons before the new ones can reach you.

1. What type of emission is used in a vacuum tube with either a directly or an indirectly heated cathode?

2. Approximately what heater voltage would you expect a 12BE6 tube to require?

3. Why does secondary emission occur at the plates of most tubes?

4. If we find that in a certain triode tube a change in grid voltage of 2 volts produces the same change in plate current as a change in plate voltage of 100 volts, what is the amplification factor of the tube?

5. When the signal voltage swings the grid of the amplifier shown in Fig. 13 in a positive direction, in what direction does the plate voltage swing? Why?

6. Why do we apply grid bias to a tube?

7. Name the three important tube characteristics and give the formula for each.

8. Why can the stage gain of a triode amplifier never quite equal the amplification factor of the tube?

9. How does the suppressor in a pentode tube prevent the undesirable effects of secondary emission that occur in a tetrode?

10. How can you stop the flow of plate current in a thyratron once the tube has fired?

ENTHUSIASM

Starting work in a new field of endeavor just naturally arouses an intense and eager interest in what you are doing -- an enthusiasm which not only makes study and work a pleasure, but also betters your chances for success.

My students have enthusiasm for their Course of training because it is preparing them for a definite goal -- an independent business or a good job. They are continually finding, in the lessons studied, explanations for mysteries which they have encountered. Discovering immediate uses for fundamental facts keeps their enthusiasm high.

When enthusiasm is aroused in an ambitious man, he reacts like a thoroughbred race horse, giving all the speed and effort in him. If you try to arouse enthusiasm in a mule, however, all he will do is kick!

A real and lasting enthusiasm for electronics will make your study and work as pleasant as play, and will make your life much happier.

HOW TUBES ARE USED

B111

STUDY SCHEDULE

By dividing your study into the steps given below, you can get the most out of this part of your NRI Course in the shortest possible time. Check off each step when you finish it.

☐ 1. Introduction . . . . Pages 1 - 2

☐ 2. Types of Amplifiers . . . . Pages 2 - 8

You learn that amplifiers can be divided into classes according to operation, and into voltage amplifiers and power amplifiers according to the applications for which they are used.

☐ 3. Typical Amplifiers . . . . Pages 9 - 18

In this section you study examples of both audio and rf amplifiers.

☐ 4. Detectors and Rectifiers . . . . Pages 19 - 23

We study detectors and rectifiers together in this section, because they both work on the principle of allowing current to flow in only one direction.

☐ 5. Oscillators . . . . Pages 24 - 28

You study the Hartley oscillator, the Colpitts oscillator, and the multivibrator.

☐ 6. A Complete Superheterodyne Receiver . . . . Pages 29 - 37

We take the various circuits you have studied and put them together to form a complete receiver.

☐ 7. Amplifier Variations . . . . Pages 38 - 43

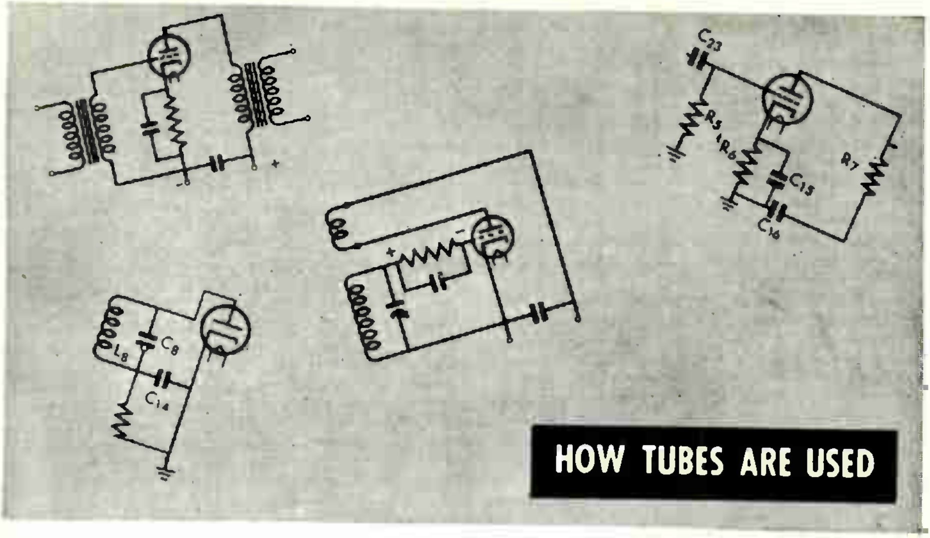
We take up grounded-cathode, grounded-grid, and grounded-plate (cathode-follower) amplifiers.

☐ 8. Answers to Self-Test Questions . . . . Pages 44 - 48

☐ 9. Answer the Lesson Questions.

☐ 10. Start Studying the Next Lesson.

JDL3M1174 1974 EDITION Litho in U.S.A.



HOW TUBES ARE USED

In the preceding lesson you studied tube fundamentals and learned how a vacuum tube works. You learned that a tube is a unilateral device. By this we mean that it works in only one direction. Current will flow from the cathode to the plate of the tube, but it will not normally flow from the plate to the cathode.

You learned that in a three-element tube, a grid placed near the cathode can control the flow of electrons from the cathode to the plate. Because the grid is closer to the cathode than the plate is, it has a greater effect on the flow of plate current than the plate. Hence, a small signal voltage applied to the grid of a vacuum tube will cause the plate current to vary. This varying plate current can develop a voltage several times the original grid voltage across the plate load. This ability of the grid to control the flow of current from the cathode to the plate of the tube is what makes it possible for the tube to amplify a signal.

The purpose of this lesson is to increase your understanding of how tubes operate and to study a number of important basic tube circuits. You will study amplifiers similar to those used to amplify an audio or a video signal. You will study rf amplifiers, detectors and oscillators. All of these circuits will be found in modern electronic equipment. You will also study rectifiers. Although tube-type rectifiers are no longer used in new receiving-type equipment, they are still used in transmitters, in industrial applications and in many older radio and TV receivers.

These are the basic circuits that you are most likely to encounter. Later on, you will study many other circuits.

After we have looked at the basic circuits separately, we will see how these different circuits are used together to form a complete radio receiver. The basic principles used in radio receivers are similar to those used in both black and white and color television reception.

In the last section of the lesson we will take up some variations in amplifier circuits. In the simple amplifier you studied in the preceding lesson, the load was placed in the plate circuit of the tube and the cathode was operated at signal-ground potential. This type of amplifier is called a grounded-cathode amplifier. However, there are different circuits in which one of the other elements is operated at ground potential. In one type of amplifier the plate is grounded, and the load is placed in the cathode circuit. This type of amplifier is called a grounded-plate amplifier or more frequently a cathode-follower. In still another type of amplifier the grid is operated at ground potential, and the input signal is applied between the cathode and ground. The load is placed in the plate circuit. This type of amplifier is called a grounded-grid amplifier. In this lesson you will study all three types. While most of the amplifiers you will find are grounded-cathode amplifiers, grounded-grid amplifiers are used both in transmitting and receiving equipment. Also, cathode-followers are quite widely used in industrial applications, and they have been quite widely used in color TV receivers. The material you will study in this lesson is primarily an introduction to the different types of amplifiers. You will study them all in greater detail later.

Types of Amplifiers

Amplifiers can be divided into classes according to the amount of bias applied to the tube. You will remember that the bias is a negative voltage applied between the grid and cathode of a tube. If the bias applied to a tube is midway between zero bias and cut-off bias, the amplifier is called a Class A amplifier. A Class A amplifier operates on the linear or straight portion of the characteristic curve. Most of the amplifier stages found in radio and TV receivers are Class A amplifiers.

In some, the dc operating bias applied to a tube is equal to cut-off bias. This simply means that the negative voltage applied to the grid of the tube reduces the plate current to zero or almost to zero. This type of amplifier is called a Class B amplifier. It is found in medium and high power audio and video amplifiers and in radio and TV transmitters.

In still another type of amplifier the grid voltage applied to the tube is several times the negative voltage required to cut off the flow of plate current. This type of amplifier is called a Class C amplifier. Class C amplifiers are used as radio-frequency power amplifiers and as oscillators. You will see examples of all three classes of amplifiers in this lesson.

Amplifiers can also be divided into two general types, voltage amplifiers and power amplifiers. In a voltage amplifier we are interested in amplifying the signal voltage. A weak signal voltage is applied to the input circuit of the stage, and we are interested in getting as much amplification as possible. In other words we want as high an amplified voltage in the output as possible.

Usually, in order to get a high output voltage, the load used is a fairly high impedance or resistance.

In a power amplifier we are not particularly concerned about the amplitude of the voltage in the output. Instead, we are interested in getting as large a current variation from the tube as possible. Usually the load impedance is much lower in a power amplifier than it is in a voltage amplifier. However, in many cases it is difficult to tell a voltage amplifier from a power amplifier simply by looking at the circuit unless you know something about the value of the components used in the circuit and the conditions under which the tube is operated.

Voltage amplifiers are Class A amplifiers; power amplifiers may be Class A, B, or C.

VOLTAGE AMPLIFIERS

A simplified schematic of a typical voltage amplifier is shown in Fig. 1. Here the signal source is applied in the grid circuit between the grid and the cathode of the tube in series with the bias voltage. In the plate circuit of the tube we have the load connected in series with a B supply battery. The load and battery are connected between the plate and cathode of the tube. With a high-impedance load, small current variations flowing between the cathode and plate of the tube and through the load will result in comparatively large voltage variations across the load.

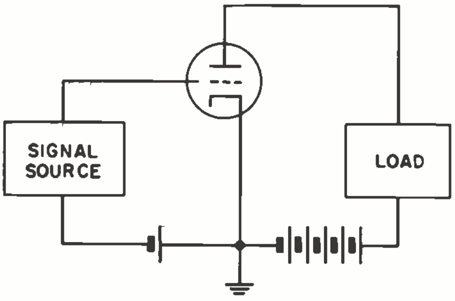


Fig. 1. A grounded-cathode amplifier.

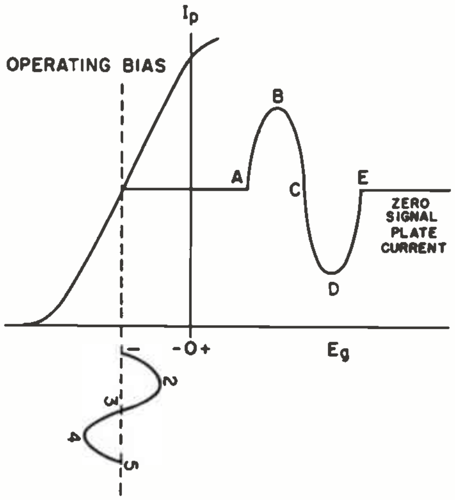

Fig. 2. Operating conditions of a typical voltage amplifier.

The graph in Fig. 2 shows how a voltage amplifier operates. Sufficient bias is applied to the tube to place the operating bias on the grid approximately midway between 0 and cut-off voltage. The idea is to bias the tube so that the tube will be operating on the linear portion of its characteristic curve. If we have too little bias on the tube, the grid may be driven positive, which will cause the grid to draw current; also the variations in plate current will not be linear. Similarly if too much bias is put on the tube, the grid will be driven beyond the cut-off point and there will be no plate current flow at all during part of the cycle of the input signal.

With the tube operated as shown in Fig. 2, the plate current variations follow the grid voltage. If the input signal swings in a positive direction it subtracts from the grid bias, making the bias less negative. This is what happens as the input moves from point 1 to point 2. As the input signal swings between these two points, the plate current moves from point A to point B.

During the next quarter of the input cycle, the grid voltage is swinging in a negative direction because the input signal is decreasing and dropping to zero as it moves from point 2 to point 3. At this point the signal has dropped to 0, and the voltage applied to the grid at this instant is the operating bias. During this quarter of the cycle the plate current moves from point B to point C.

During the next quarter cycle the input signal is swinging negative as it moves from point 3 to point 4. The signal now adds to the grid bias, making the voltage more negative. This results in the plate current dropping still further from point C to point D. When the input signal voltage reaches point 4 and starts to swing back to 0 again towards point 5, the grid becomes less negative, with the result that the plate current begins to increase and move from point D to point E.

There are several important things to be noted from the curve shown in Fig. 2. First, notice that the operating bias is approximately midway between 0 grid voltage and the grid voltage required for plate current cut-off. This places the operation of the tube on the linear or straight portion of the characteristic curve. As we have mentioned, an amplifier operated in this way, that is biased midway between zero voltage and cut-off voltage, is called a Class A amplifier.

Also notice that the input signal is small enough so that it neither drives the grid into the positive region nor does it drive it beyond cut-off. If the grid is driven positive or beyond cut-off, distortion will result, and the output signal will not be a faithful reproduction of the input signal.

Let us consider what happens to the plate current flowing in the tube. The line marked plate current represents the plate current that will flow when there is no input signal. Notice what happens when an input signal is applied. During one half cycle the plate current flow increases; during the other half cycle it decreases. The increase during one half cycle is equal and opposite to the decrease during the next half cycle. Therefore, if we consider the average plate current, it does not change. In other words, although the plate current does increase during one half cycle, it decreases by an equal amount during the next half cycle; the average plate current flowing remains the same as it was when no signal was applied to the input. Thus, if a dc milliammeter is placed in the plate circuit of a Class A amplifier, there will be no change in the reading when a signal is applied to the input because the meter will indicate the average dc flowing, and this does not change. If there is a change in the plate current, either the bias on the tube is incorrect or else the signal applied to the input is too strong and is driving the tube onto the non-linear portion of the characteristic curve.

The voltage amplifiers found in modern electronic equipment are Class A amplifiers. Thus, in a voltage amplifier you can expect to find that the output signal is a faithful reproduction of the input signal.

Furthermore you can expect to find the bias midway between zero bias and cut-off bias and also you can expect the average plate current flowing in the stage not to change when a signal voltage is applied to the input.

POWER AMPLIFIERS

Class A Amplifiers.

Class A amplifiers are used as power amplifiers but usually only when the amount of power required is comparatively low. The reason for this is that the Class A amplifier has relatively poor efficiency. The efficiency is the ratio of the power output to the power input.

It is easy to see why the efficiency of a Class A amplifier is poor. First, let's consider the operating curves shown in Fig. 3. Let's assume the tube is operating with a voltage of 200 volts applied to it and a plate current of 100 milliamperes. Thus the power input to the tube is 200 × .1 = 20 watts. This is the dc power input; it represents the power being taken from the power supply and fed to the tube.

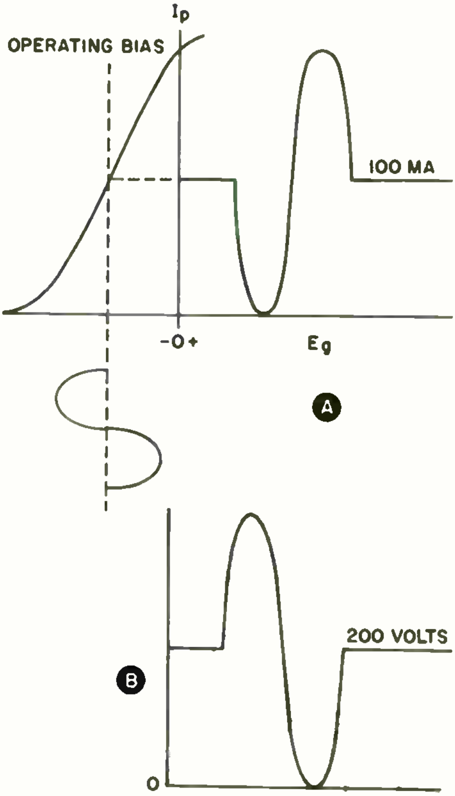

Fig. 3. Operating conditions for Class A operation.

Now let us consider how much signal power we can get out of this tube. If the current flowing in the tube is 100 milliamperes as shown in Fig. 3A, the maximum current change we can get in a half cycle is 100 milliamperes. In other words, if the grid voltage is swung all the way to the cut-off point by the input signal, then the plate current would drop to zero. This means that the peak current change is 100 mils, or .1 amp. The rms or effective current change, in amperes, will be only .707 of this value, or .1 × .707.

Similarly, the plate voltage applied to the tube is 200 volts as shown in Fig. 3B. The maximum change that could be made in plate voltage is 200 volts. To do this, the plate voltage would have to drop all the way to zero as the current through the load changed. Again this is the peak change, and the rms or effective change, in volts, is 200 × .707.

The maximum ac power output is equal to the effective ac voltage times the effective ac current. Therefore, the power output is equal to:

$$200 \times .707 \times .1 \times .707$$

If we multiply .707 × .707 we have .5, so we can express the formula as: 200 × .1 × .5. Now you will recognize the 200 × .1 as the input power, and we know that .5 is equal to 50%. Thus, the maximum power output that can be obtained from a Class A power amplifier is equal to 50% of the input power. Therefore, the best efficiency that can be obtained from a Class A amplifier is 50%. In fact, it is usually impossible to obtain this high an efficiency under actual operating conditions, because the grid would have to be driven all the way to cut-off on one half cycle, and all the way to zero on the other half cycle. Under these conditions, considerable distortion would result. Actually, the plate current would not be a sine wave as shown in Fig. 3, but would be flattened somewhat on both top and bottom. Efficiency of somewhere around 30% to 35% is usually about all that can be obtained from a Class A amplifier if reasonable linearity is to be maintained.

Class B Amplifiers.

Better efficiency can be obtained from a power amplifier if the bias on the tube is increased to approximately cut-off bias and a signal large enough to drive the grid positive is used. Under these conditions the operating curves for the tube will look like those shown in Fig. 4. When there is no signal applied to the input of the stage, the plate current flowing through the tube will be low. When the input signal swings in a positive direction, plate current flows in the form of a large pulse. When the signal swings in a negative direction, it soon drives the grid beyond the cut-off point and there will be no plate current flow in the tube. Thus you can see that the only time the tube is called on to furnish a large amount of power is when the grid is driven in a positive direction. For approximately half of each cycle there is no current flow through the tube at all.

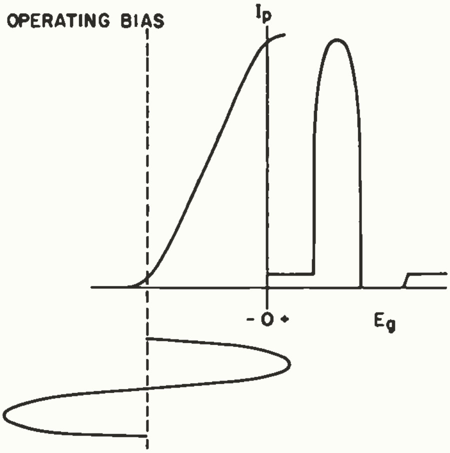

Fig. 4. Operating conditions for Class B operation.

It is immediately apparent that with this type of operation only one-half of the input signal is being reproduced. In an audio amplifier this would result in a great deal of distortion. However, this problem can be overcome by the use of two tubes, one to reproduce each half of the audio signal. By recombining the output from these two tubes, both halves of the audio signal can be reproduced. We will see examples of these circuits later in this lesson.

It is easy to see that this type of amplifier is more efficient than a Class A amplifier, because the current flowing through the tube when there is no signal present is comparatively small. Almost all of the current capabilities of the tube are reserved for the reproduction of the output signal. This type of operation, with the tube biased to cut-off, is called Class B operation. It is used quite extensively where large amounts of audio or video power must be developed, and it is also used to develop rf power in certain types of rf equipment.

Class C Amplifiers.

A still more efficient power amplifier than a Class B amplifier is the Class C amplifier. The curve shown in Fig. 5 shows how a tube is operated as a Class C amplifier. Notice that the operating bias is greater than the bias required to cut-off the flow of current through the tube. The Class C amplifier tube is generally operated with a bias somewhere between 2 and 4 times cut-off bias.

The input signal required for a Class C amplifier is considerably higher than that required for a Class A or Class B amplifier. The input signal drives the grid well into the positive region so that the grid draws substantial current. Plate current flows only in a series of pulses and these pulses actually flow for considerably less than half a cycle.

Class C amplifiers are not used for audio work, but they can be used as radio-frequency power amplifiers. They are used in conjunction with resonant circuits. If a parallel resonant circuit is placed in the output of a Class C amplifier, the pulse from the Class C amplifier will shock-excite the parallel resonant tank circuit into oscillation. If the tank circuit receives a pulse once each cycle, this pulse fed into the tank circuit is able to make up any losses in the tank circuit. Meanwhile, the current flows back and forth in the tank circuit so that the voltage appearing across it is actually a sine wave, even though it is being supplied energy only in the form of pulses. The tank circuit in a Class C amplifier has sort of a flywheel effect, and once oscillations are set up in it they can be maintained by pulsing it once each cycle.

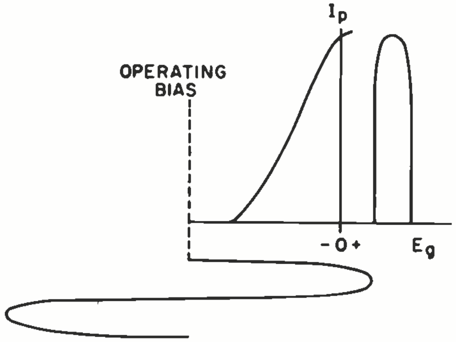

Fig. 5. Operating conditions for Class C operation.

As a matter of fact, the tank circuit can often be designed so that it does not need a pulse once each cycle but can maintain oscillations by receiving a pulse every other, or perhaps every third cycle. By designing the tank circuit in this way, it is possible to double or triple the frequency of the signal.

In addition to Class A, Class B, and Class C amplifiers there are also amplifiers known as Class AB amplifiers. As the name suggests, these are simply amplifiers operated midway between Class A conditions and Class B conditions. The operating bias applied to the tube is a little higher than that needed for Class A operation, but not as high as that needed for Class B operation. Beam power tubes are often operated under Class AB conditions.

SUMMARY

The important points to remember from this section are that there are three classes of operation for vacuum tubes. A tube that is operated with a bias midway between zero bias and cut-off bias is a Class

A amplifier. The output of this type of amplifier should be an exact duplicate of the input.

The Class B amplifier is operated at approximately cut-off bias. The zero-signal plate current flowing in this type of stage is low, and only the positive half of each cycle is reproduced. A Class C amplifier is an amplifier operated with bias several times cut-off bias. Plate current flows in this type of stage for less than half of each cycle.

Voltage amplifiers are Class A amplifiers. Power amplifiers may be Class A, Class B, or Class C. A Class A power amplifier has relatively poor efficiency. The efficiency of a Class B amplifier is better than that of a Class A amplifier, and the efficiency of a Class C amplifier is still better than the efficiency of a Class B amplifier. Class AB amplifiers are amplifiers operated under conditions between Class A and Class B.

SELF-TEST QUESTIONS

(a) What is a Class A amplifier?

(h) What is the maximum possible efficiency that can be obtained from a Class A power amplifier? What is the practical efficiency of a Class A amplifier?
(i) Can a Class B power amplifier be used in audio power amplification?
(j) What type of signal is the Class C power amplifier used to amplify?
(k) What is a Class AB amplifier?

Typical Amplifiers

Look at Fig. 1 again, where we have shown a simplified diagram of an amplifier. As you can see from this diagram, the basic parts of an amplifier are the tube, the load, and batteries or some other power source to supply the power needed to operate the tube. Now, let us study some practical amplifiers to see how the various electronic components you have already studied are used in conjunction with tubes in order to amplify signals.

AUDIO AMPLIFIERS

An audio amplifier is an amplifier designed to amplify signal frequencies within the range normally heard by our ears. Some amplifiers are capable of doing this job better than others. The audio amplifier found in the average radio or TV receiver is not capable of reproducing all of the frequencies that our ears can hear. However, an amplifier designed for use in a piece of high-fidelity equipment has a much better frequency response and can amplify a wider range of frequencies. Amplifiers found in most radio and TV receivers can amplify frequencies from about 50 or 60 cycles per second up to 8000 or 9000 cycles per second. Amplifiers designed for use in high-fidelity equipment can amplify frequencies from about 10 cycles per second up to at least 15,000 cycles per second and sometimes as high as 100,000 cycles per second.

Audio amplifiers may be either voltage amplifiers or power amplifiers. Voltage amplifiers are used to build up the strength of the weak audio signal until it is strong enough to drive a power amplifier. A power amplifier is then used to supply the power to drive the speaker.

Voltage Amplifiers.

A typical voltage amplifier is shown in Fig. 6. This amplifier is called a resistance-capacitance coupled amplifier because resistors and capacitors are used to couple the signal to the amplifier and to the output or to the following stage.

In the circuit shown in Fig. 6, capacitor C1 is used to couple the signal source to the grid of the tube. C1 will block any dc in the input circuit and keep it away from the grid of the tube. At the same time, if C1 is large enough, it will offer a low reactance to the flow of an ac signal through it and act, as far as the ac signal is concerned, as though it were not there at all. The input signal is therefore applied between the grid of the tube and ground.

Resistor R1 is called a grid leak. Some of the electrons travelling from the cathode to the plate of the

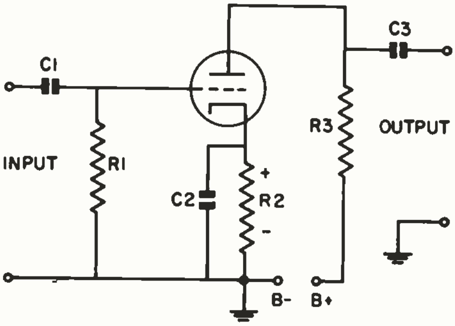

Fig.6. A typical resistance-capacitance coupled amplifier.

tube will accidentally strike the grid. If there is no way for these electrons to get off the grid of the tube, they will be trapped on the grid and eventually build up a high negative charge on the grid. This negative charge will reduce the flow of current from the cathode to the plate of the tube. As a matter of fact, in some tubes this charge may become so high it can actually cut off the flow of electrons from the cathode to the plate of the tube.

As long as R1 is in the circuit, electrons striking the grid can flow through R1 back to ground and then through R2 back to the cathode of the tube. Of course, when electrons flow through a resistor they build up a voltage across the resistor. Electrons flowing from the grid of the tube back to ground will develop a dc voltage across R1 having a polarity such that the grid end of the resistor is negative. Normally in an amplifier of this type, however, the number of electrons flowing through the grid resistor is not large enough to develop any appreciable voltage across the grid resistor, R1, even though the value of the resistor may be quite large. Resistors of 100,000 ohms to 500,000 ohms are frequently used as grid resistors. Usually it will be impossible to detect any voltage across these resistors, even with quite sensitive measuring equipment.

Capacitor C1 and resistor R1 actually form a voltage-divider network that divides the ac signal voltage. If R1 is made large in comparison to the reactance of C1, most of the signal voltage will appear across R1. This means that most of the signal voltage will be applied between the grid of the tube and ground, which is essentially where we want it. On the other hand, if R1 is small compared to the reactance of C1, then C1 and R1 will divide the signal voltage so that only a small part of it will appear across R1; the remainder will be lost across C1. This situation is to be avoided if maximum output is to be obtained from the amplifier. For this reason, designers make R1 as large as practical.

While we are discussing the combination of C1 and R1, remember that the reactance of a capacitor depends upon the frequency of the signal voltage. As the frequency decreases, the reactance increases. Therefore, at low frequencies the reactance of C1 may become large enough to appreciably reduce the voltage across R1. When this happens, the signal amplification will fall off; the amplifier will not amplify low-frequency signals as well as it does higher-frequency signals. Making R1 large tends to extend the low-frequency gain of an amplifier.

On the other hand if R1 is made too large, then the electrons accidentally striking the grid of the tube will develop an appreciable dc voltage across R1 when they flow through it. In an amplifier like the one shown in Fig. 6, this voltage is undesirable. Therefore the value of R1 must be a compromise. It is made as high as possible, so that the signal voltage will be high, without making it so high that a troublesome dc voltage will be developed across it.

The dc voltage supply used to supply the plate voltage to the tube is represented by the terminals B- and B+. This could be a B battery or it could be the terminals of a power supply. A power supply is a unit that converts ac from the power line to dc for use in applications such as this. You will study power supplies shortly.

Resistor R2 is put in the cathode circuit of the tube to eliminate the need for a C battery to supply a grid bias voltage. Let's consider what happens with this resistor in the circuit. Electrons flowing through the tube are emitted by the cathode, attracted by the plate, then flow through R3, then through the B supply to ground, and finally through R2 back to the cathode. The minute power is applied, this action is instantaneous, and electrons start flowing in all parts of the circuit. The electrons flowing through R2 will develop a voltage across this resistor with the polarity indicated on the diagram. This makes the cathode slightly positive with respect to ground. If the tube is designed to operate with a grid voltage of -3 volts, R2 is selected so that the electrons flowing through it will develop a voltage of 3 volts across the resistor. This will make the cathode 3 volts positive with respect to ground.

To see how this voltage biases the tube and eliminates the need for a C battery, let us consider the potential of the grid with respect to ground. The number of electrons flowing through R1 is so small that little or no voltage is developed across it. Therefore, the grid is normally at ground potential. This means that the cathode is positive with respect to the grid. If the cathode is positive with respect to the grid, then the grid is negative with respect to the cathode.

R2 is often called a cathode bias resistor. By using this resistor in the cathode circuit, we can eliminate the need for a C battery. Batteries deteriorate and have to be replaced periodically, whereas the resistor will last almost indefinitely providing it is not overloaded.

Capacitor C2 is connected across R2 in order to stabilize the voltage across R2. Without C2, as the input signal caused the tube current to vary, the current through R2 would vary. This would result in varying voltage or varying bias across the resistor. To eliminate this effect, we connect capacitor C2 across the resistor. C2 must be large enough to maintain the voltage across R2 constant. It does this by charging when the current through R2 increases and the voltage tends to rise, and discharging through R2 when the voltage tends to fall. The capacitor actually acts as a low reactance path for the ac signal through it. The grid of the tube, in causing the plate current to vary, is actually producing an ac signal superimposed on the dc in the plate-cathode circuit. This ac signal component flows through C2; the dc component flows through R2.

Resistor R3 is the plate load resistor. The value of this resistor is usually quite large. The larger the resistor, the closer the gain of the stage will approach the amplification factor of the tube. You will remember that the tube acts like a generator, and this generator has an internal resistance, the ac plate resistance of the tube. Resistance R3 is, in effect, connected in series with the plate resistance of the tube, and the voltage developed by the tube is divided between the plate resistance and the plate load. By making the plate load resistor as large as possible, we will get as much of the amplified signal voltage across this resistor as possible.

However, there is a limit to how large we can make this resistor.

Since the plate current flows through the resistor, there will be a voltage drop across the resistor. This voltage drop subtracts from the supply voltage so that the net voltage available to operate the tube is equal to the supply voltage minus the voltage drop across the plate load resistor. If we make the plate load resistor too large, there will be a very high voltage drop across it with the result that there is very little voltage left to operate the tube. Again, the selection of the size of resistor to be used is a compromise. A value is chosen that will give a reasonably high gain without an excessive voltage drop. If the voltage drop across R3 is excessive, then the power supply voltage must be very high in order to get the voltage we need on the plate of the tube. This could require a costly power supply, so it is often more economical to use two stages to get the gain we need than to try to get it from one stage by using an excessively large plate-load resistor.

A schematic diagram of another voltage amplifier is shown in Fig. 7. This amplifier is called a transformer-coupled amplifier. Notice that in some respects the circuit is similar to the circuit shown in Fig. 6. In the transformer-coupled amplifier, transformer T1 is taking the place of C1 and R1 in the resistance-coupled stage. Similarly, transformer T2 is taking the place of load resistor R3 and blocking capacitor C3 in the output. Both transformers can be step-up transformers, so that there will be voltage amplification in the transformers themselves as well as in the tube. Bias for the stage is still obtained by placing a resistor in the cathode circuit of the tube. R1 in Fig. 7 is the cathode-bias resistor, and it is bypassed by the capacitor C1.

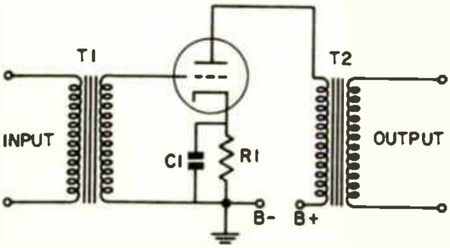

Fig. 7. A transformer-coupled amplifier.

Transformer-coupled amplifiers of this type are not used in modern electronic equipment. The transformers are more expensive than the resistor-capacitor combination, and modern tubes have such high gain that it is not necessary to rely on the step-up transformer to get a reasonable gain in the stage. However, you may be called on to service an older piece of equipment that might employ a transformer-coupled stage, so you should be aware that this type of coupling exists.

Power Amplifiers.

Fig. 8A shows a power amplifier using resistance-capacitance coupling in the input circuit. The input circuit is essentially the same as the circuit used in Fig. 6.

The output transformer is a step-down transformer. This transformer is primarily an impedance-matching device. It is used to match the low-impedance speaker, which would be connected across the output terminals, to the plate circuit of the tube. Remember that the tube works like a generator, and maximum power transfer will be obtained when the load matches the generator. The transformer matches the load impedance to the generator or tube impedance.

Fig. 8B shows a transformer-

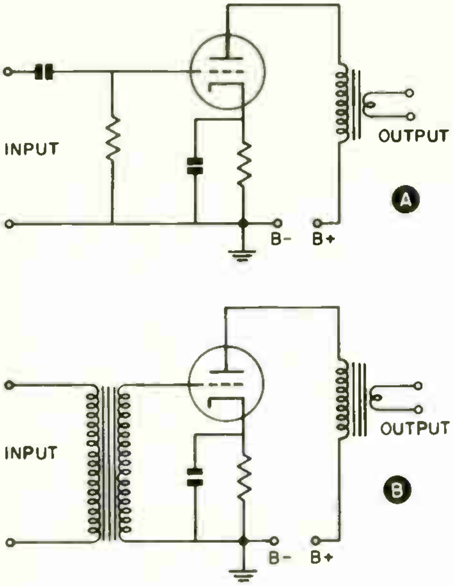

Fig. 8. Two single-ended power amplifier stages.

coupled power amplifier. The input transformer is a step-up transformer, and the output transformer will be a step-down transformer to serve as an impedance-matching device. The circuit shown in Fig. 8B is obsolete; you will not run into a circuit of this type except in old equipment.

Both of the amplifiers shown in Fig. 8 are Class A power amplifiers. They are also called single-ended stages because each circuit uses a single tube. In some audio amplifiers, in large radio receivers, and in some TV sets you will run into a double-ended power output stage such as the one shown in Fig. 9. This circuit is called a push-pull amplifier. It can be operated as either a Class A, Class AB, or a Class B power amplifier. If the stage is operated as a Class A power amplifier, the stage preceding it can be a voltage amplifier and T1 may be a step-up transformer. On the other hand, if the stage is operated as a Class B amplifier the stage preceding it must be a power amplifier because power must be supplied to the grid circuit, and T1 must be a step-down transformer.

If the stage is a Class AB$_1$ power amplifier, the preceding stage can be a voltage amplifier since the grid does not draw current and no power is consumed in the grid circuit. On the other hand, if the stage is a Class AB$_2$ power amplifier, the grid does draw grid current and power must be supplied to the grid circuit. The preceding stage, therefore, must be a power amplifier.

This stage is called a push-pull amplifier because it acts as though one tube is pushing electrons through the primary of T2 while the other is pulling electrons in the opposite direction. Briefly, the operation of

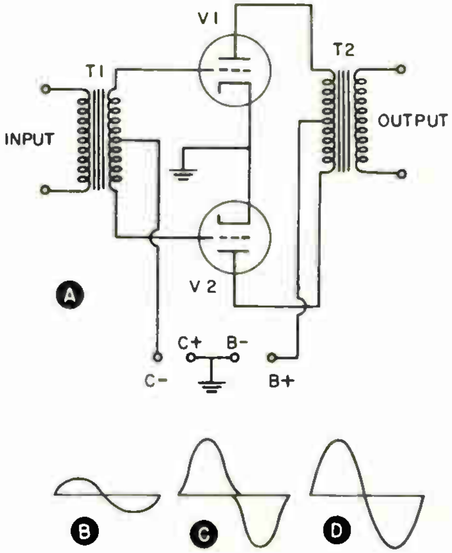

Fig. 9. A push-pull amplifier stage is shown at A, the input signal is shown at B, the output pulses from the two tubes at C, and the combined output at D.

the stage is as follows: the secondary of transformer T1 is tapped, and the center tap is at signal ground potential. When the end of the secondary of T1 that is connected to V1 is swinging positive with respect to ground, the other end will be swinging negative with respect to ground. The positive voltage applied to tube V1 will cause its plate current to increase, while the negative voltage applied to the grid of V2 will cause its plate current to decrease. Thus the current in one half of T2 increases while the current in the other half of T2 decreases. During the next half cycle, when the end of the secondary of T1 that is connected to V2 is positive with respect to ground, the other end will be negative. At this time the plate current of V2 will increase while the plate current of V1 decreases.

When this type of stage is used as a Class B amplifier, the tube that is driven positive conducts current heavily while the other tube does not conduct current at all. During the next half cycle the second tube carries the whole load while the other tube rests. If the input signal is a sine wave like that shown in Fig. 9B, the plate currents for the two tubes look like Fig. 9C and combine to produce a signal like Fig. 9D in the secondary of transformer T2. This explains how two tubes can be used in a Class B amplifier to amplify an audio signal when each tube conducts during only half of each cycle. One tube reproduces one half of the cycle; the other tube reproduces the other half of the cycle. The two signals are combined in transformer T2 to give an output signal that is an amplified reproduction of the input signal.

Push-pull amplifiers are used in some radio and TV receivers. They are found in high-fidelity equipment and in many radio and television transmitters. Push-pull amplifiers are used wherever it is necessary to develop a large amount of audio or video power. Operating these tubes as Class B amplifiers gives much better efficiency than operating them as Class A amplifiers. As a matter of fact, the same amount of audio power can usually be developed more economically by using two small tubes operated as Class B amplifiers than by using one large tube operated as a Class A amplifier.

RADIO-FREQUENCY AMPLIFIERS

Radio-frequency amplifiers like audio amplifiers can be divided into two types, voltage amplifiers and power amplifiers. The radio-frequency amplifiers found in receiving equipment are voltage amplifiers, whereas those found in transmitting equipment are power amplifiers. In receiving equipment, we are interested in taking the weak radio-frequency signal picked up by the antenna and amplifying it in order to extract whatever intelligence it may carry. In transmitting equipment, we are interested in developing power to feed to the antenna in order to radiate a strong signal.

Voltage Amplifiers.

A radio-frequency voltage amplifier is shown in Fig. 10. Notice that in many respects it is similar to the single-ended transformer-coupled audio amplifier. In the rf amplifier, we have used a pentode. Triodes are not as suitable as pentodes in rf amplifiers in most cases. Notice that both the input and output circuits are tuned. These circuits are

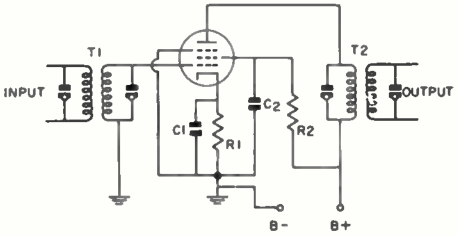

Fig. 10. A radio-frequency voltage amplifier.

adjusted to resonance at the frequency of the rf signal.

As in the audio amplifiers we studied, operating bias for the stage is obtained by inserting a resistor in the cathode circuit. This is the resistor marked R1 on the diagram; it is bypassed by capacitor C1. The purpose of capacitor C2 is to ground the screen of the tube insofar as signal voltages are concerned. Capacitor C2 is selected so that its reactance is low at the operating frequency. Thus, insofar as the signal is concerned, the screen is in effect operating at ground potential. This isolates the plate from the grid of the tube so that there is not enough energy fed from the plate of the tube back to the grid to cause the tube to go into oscillation. Resistor R2 is called the screen dropping resistor. Its purpose is to drop the B supply voltage to a suitable value for the screen. In many voltage amplifiers of this type, the screen voltage is somewhat less than the plate voltage. Plate voltage is applied to the tube through the parallel resonant circuit installed in the plate circuit.

With modern pentode tubes, a comparatively high voltage gain can be obtained in a stage of this type. It is easy to get a gain on the order of 100.

Power Amplifiers.

Radio-frequency voltage amplifiers are biased to operate at the mid-point of the characteristic curve. In other words, they are Class A amplifiers. However, rf power amplifiers are usually operated either in Class B or in Class C, although some rf power amplifiers operate in Class AB. A schematic diagram of a Class C rf power amplifier is shown in Fig. 11. Notice that this circuit differs somewhat from the voltage amplifier.

In this circuit, bias is obtained by means of a resistor in the grid instead of the cathode circuit. In a Class C amplifier a high value of bias is used. The signal applied to a Class C stage must be sufficient to drive the grid positive. When the grid is driven positive, electrons will leave the cathode and strike the grid to charge C2 with the polarity shown. During the time when the input signal is not positive, C2 will discharge through RFC and R1, making the grid negative with respect to ground. By selecting the proper value of R1, the correct bias can be developed across this resistor.

Since the tube in a Class C amplifier is normally operated at bias voltages several times cut-off, plate current does not flow through the tube except when the input signal

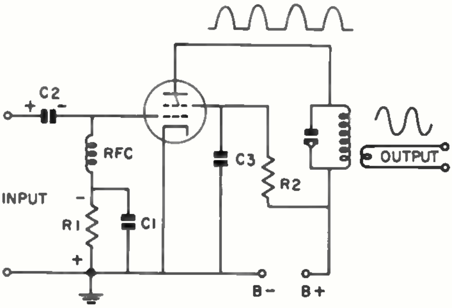

Fig. 11. Schematic of a Class C rf power amplifier.

swings positive and drives the grid into the region where plate current can flow. Current then flows from the cathode to the plate of the tube in the form of a series of pulses as indicated. These pulses shock-excite the parallel resonant tank circuit, consisting of the primary of the output transformer and the capacitor across it, so that current flows back and forth between the coil and capacitor, producing the sine wave output shown.

Class C rf power amplifiers have very high efficiency--in the range of 75%. This means that for each watt that is fed into the amplifier plate circuit, about 3/4-watt of rf power can be developed. The efficiency of this type of amplifier is somewhat better than that of a Class B amplifier and is much better than that of a Class A amplifier.

The stage shown in Fig. 11 is a single-ended stage. Push-pull Class C rf amplifiers can also be used. The power output of this type of stage is approximately double what could be obtained from a single-ended stage using the same tube type.

EFFICIENCY OF AMPLIFIERS

The amount of power you can get from a tube depends on which class of amplifier stage it is used in. As you have learned, a Class A stage has a practical efficiency of about 30 per cent. This means that 70 per cent of the power fed to the stage is lost. Most of this power is wasted at the plate of the tube. We say it is "dissipated" by the tube.

All power tubes have a rating known as the plate dissipation. This rating tells how much power can be dissipated at the plate of the tube without overheating the tube. Consider a power tube with a plate dissipation rating of 10 watts. If we use this tube in a power amplifier, we cannot let the plate dissipate more than 10 watts. This means that if the amplifier is a Class A amplifier with an efficiency of 30 per cent, 70 per cent of the input must not exceed 10 watts. The total power input to the stage must not exceed:

$$10 \times \frac{100}{70} = 14.28 \text{ watts}$$

This means the total power input to the stage should be about 14 watts, and the power output will be about 4 watts. The remaining 10 watts will be dissipated by the tube.

In a Class B amplifier we will get much better efficiency than in a Class A amplifier. The efficiency will be between 50 and 60 per cent. Let's see what power we can get out of the same tube as in the preceding example in a Class B stage with 50 per cent efficiency.

In the Class B stage, the total power input to the stage must not exceed:

$$10 \times \frac{100}{50} = 20 \text{ watts}$$

This means that with an efficiency of 50 per cent, the power input will be 20 watts and the useful power output 10 watts. The remaining 10 watts will be dissipated by the tube. Notice that we have over twice the power output that we got from a Class A amplifier, and that the plate dissipation rating of 10 watts has not been exceeded.

Let's go one step farther and see what would happen if we used the same tube in a Class C amplifier with an efficiency of 75 per cent. Here the maximum power input to the stage can be:

$$10 \times \frac{100}{25} = 40 \text{ watts}$$

This means that with an efficiency of 75 percent, the power input to the stage can be 40 watts and the useful power output 30 watts. The remaining 10 watts will be dissipated by the tube.

Notice how the efficiency of the amplifier improved as we went from a Class A amplifier to a Class B amplifier. We got a higher per cent of the input power out as useful output power. You can see a still further improvement in going to a Class C stage. Another point that you should notice is the increase in total power that can be handled by a tube in going from a Class A stage to a Class C stage. In a Class A stage, the power input could be a maximum of about 14 watts, but in a Class C stage we can feed 40 watts to the stage. Thus, the efficiency of the stage and the plate dissipation rating of the tube determine the permissible power input to the stage. The input must be limited so that the power wasted in the stage does not exceed the plate dissipation rating of the tube. The power wasted will be determined by the input power and the efficiency of the stage.

SUMMARY

In this section of this lesson we have covered a number of different types of circuits. We do not expect you to remember all the details of each type of circuit at this time. The important thing for you to remember is that there are two types of amplifiers, voltage amplifiers and power amplifiers. Remember also the general appearance of the different circuits. The best way to remember these circuits is by actually drawing them. Notice the similarity between the different types of circuits. In the input of each stage, there is a means of applying the signal between the control grid and cathode of the tube. In each stage, there is some method of developing the required bias. In addition, in each stage you will find some type of load in the plate circuit. By carefully studying these different circuits you will see that there is a great deal of similarity between them and that each circuit is in fact like the basic circuit shown in Fig. 1, but modified for the particular application for which it is designed.

You will study all these circuits in more detail later on, but if you can learn what the circuit looks like now and in general how the amplifier works, you will find it much easier to pick up the various circuit details later.

SELF-TEST QUESTIONS

(l) Into what two types of amplifiers can we divide audio amplifiers?

(m) Try to draw from memory a schematic diagram of a resistance-coupled voltage amplifier.

(n) How is the grid-bias battery eliminated in a typical voltage amplifier?

(o) What limits the size of the resistor that can be used as the grid leak in a voltage-coupled amplifier?

(p) What is the purpose of the bypass capacitor connected across the cathode-bias resistor?

(q) In the power amplifier circuit shown in Fig. 8A, is the output transformer a step-up transformer or a step-down transformer?

(r) Fill in the missing words: a power amplifier using one tube such as shown in Fig. 8 is called a ____________ ended stage whereas one using two tubes such as shown in Fig. 9 is called a __________ ended stage.

(s) What type of amplifier, a voltage amplifier or a power amplifier, is used as the rf amplifier in a radio or TV receiver?

(t) What is the purpose of the capacitor C3 in the rf power amplifier shown in Fig. 11?

(u) Which class of power amplifier has the best efficiency? Which class has the poorest efficiency?

Detectors and Rectifiers

Tubes were used for many years as detectors and rectifiers. However, they are not used for this purpose in modern equipment nearly as often as solid-state devices are. You will study solid-state detectors and rectifiers shortly, but now you will study tube detectors and rectifiers. You will find some tubes used as rectifiers even in modern equipment and, of course, you will probably service many pieces of equipment where tubes have been used as both detectors and rectifiers.

We will study detectors and rectifiers together, because the detector is basically a rectifier. They both work on the principle of allowing current to flow in only one direction. There are, however, some differences in their application. A rectifier is used to change alternating current to direct current. A detector is used to extract information from a radio-frequency carrier.

RECTIFIERS

There are a number of different types of rectifier circuits found in electronic equipment. We will look into two of these circuits in some detail and see in general how these circuits work. There are many details that you will study later.

Half-Wave Rectifiers.

A half-wave rectifier is one that rectifies only half of the ac power-line cycle. During one half cycle, one terminal of a generator is positive and the other terminal is negative. During the next half cycle the terminal that was originally positive becomes negative, and the terminal that was originally negative becomes positive. In a half-wave rectifier circuit the rectifier is arranged so that it conducts when one of these generator terminals is positive but does not conduct when this terminal becomes negative.

A schematic diagram of a half-wave rectifier along with a filter network is shown in Fig. 12. This type of rectifier and power supply is called a universal ac-dc power supply. It is the type of power supply that was used for many years in almost all of the table-model radio receivers manufactured. Even though it is seldom used in modern receivers, the chances are that receivers using this type of supply will be around for many years, and you'll be called on to service a set using this type of power supply. It's called an ac-dc power supply because when it is used in a receiver the receiver can be used on either ac or dc power.

During ac operation, when terminal 1 is positive with respect to terminal 2, the plate of the tube is positive. Thus electrons will be at-

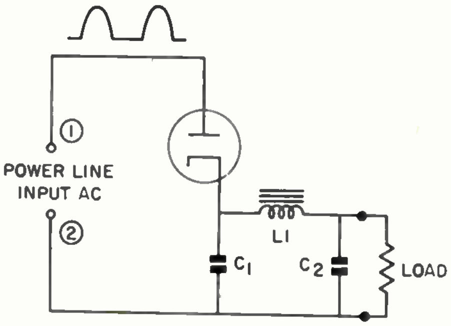

Fig. 12. A half-wave rectifier circuit and a filter network.

tracted from the cathode of the tube to the plate. The complete path for electrons is from terminal 2 through the load, through the filter choke L1, to the cathode of the tube and then through the tube to the plate and back to the other side of the power line. When the polarity of the power line reverses, the plate of the tube becomes negative, and there will be no current flow through the tube and hence no current drawn from the power line.

In a half-wave rectifier, current flows from the power line in a series of pulses as shown in the figure. When the power-line voltage becomes greater than the voltage stored in capacitor C1, there is a large pulse of current that flows through the rectifier tube. This charges capacitor C1. During the remainder of the cycle no current flows through the rectifier tube, and capacitor C1 can be considered as supplying power to the circuit during this part of the cycle. The action of filter choke L1 and filter capacitor C2 is to help smooth the pulsating current to pure dc. The action of these components will be treated in a later text.

Although tube type half-wave rectifiers of the tube just studied are not used in modern receivers, very similar types of rectifier circuits using tubes are still widely used as high-voltage rectifiers in both black and white and color TV receivers and in a circuit called the damper stage in TV. When you study these circuits later in your course, you will see that they are both forms of the half-wave rectifier circuit.

Full-Wave Rectifiers.

The schematic diagram of a full-wave rectifier is shown in Fig. 13. This type of circuit was widely used in both radio and television receivers for many years. Therefore, even though it has been replaced by power supplies using solid-state rectifiers, you should know how it works because you can be sure you will run into power supplies of this type.

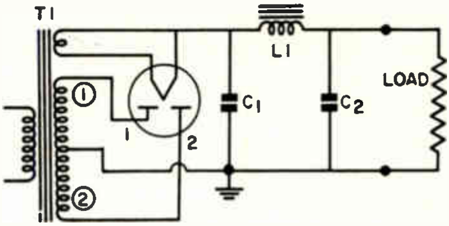

Fig. 13. A full-wave rectifier circuit and a filter network.

In this type of circuit, the high-voltage winding on the power transformer is center tapped, and the center tap is connected to ground. One end of the high-voltage winding is connected to one plate of the rectifier tube, and the other end is connected to the other plate of the rectifier tube. Insofar as the tube operation is concerned, it acts like two separate diodes. When the terminal marked 1 on the high-voltage secondary is positive with respect to the center tap, terminal 2 will be negative with respect to the center tap. Thus the rectifier plate that is connected to terminal 1 will be positive and the rectifier plate connected to terminal 2 will be negative. During this half cycle, current flows from the center tap of the high-voltage winding on the transformer, through the load, through the filter choke to the filament of the rectifier tube. Current then flows from the filament to plate 1 to terminal 1 of the power transformer.

During the next half cycle, terminal 1 of the transformer will be negative with respect to the center tap, and terminal 2 will be positive. During this half cycle, current flows from the center tap through the load, through the filter choke, to the filament of the rectifier tube, to plate 2 of the rectifier tube and then to terminal 2 of the transformer.

As you can see, in the full-wave rectifier circuit of this type current flows first through one half of the high-voltage secondary winding and one half of the tube and then through the other half of the high-voltage secondary winding and the other half of the tube. Thus, if the power supply is operated from a 60-cycle power line there will be two current pulses each cycle. This means that there will be 120 pulses available to charge the filter capacitor marked C1. This is twice as many pulses as can be obtained from the half-wave rectifier. The greater the number of pulses, the easier it is to obtain pure dc. Therefore, it is much easier to filter the pulsating dc at the output of a full-wave rectifier than at the output of a half-wave rectifier.

Pulsating dc at the output of the rectifier is often referred to as dc with a ripple voltage or hum voltage superimposed on it. You will see later that there will always be some ripple present at the output of the power supply regardless of how effective a filter network is. The filter network is designed to cut the ripple to such a low value that it does not appreciably affect the performance of the equipment. The filter systems in most power supplies reduce the ripple voltage so that it is 1% or less of the dc output voltage.

DETECTORS

There have been a number of different kinds of detectors used in electronic equipment, but most pieces of modern electronic equipment use a diode detector. A schematic diagram of a diode detector using a vacuum tube is shown in Fig. 14.

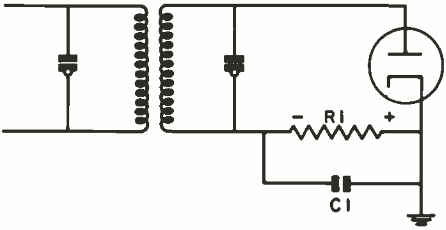

Fig. 14. A diode detector circuit.

The diode detector shown in Fig. 14 works in much the same way as the half-wave rectifier. When the plate of the tube is positive, current flows through the tube; when it is negative, current cannot flow.

To see how the diode detector can extract intelligence from a radio-frequency signal, let's look at the modulated rf carrier shown in Fig. 15A. We see here an example of amplitude-modulated radio frequency signals. The amplitude or strength of the radio-frequency signal is varying at an audio rate. The audio signal is the intelligence being transmitted.

In the diode detector circuit the current that flows will depend upon the strength of the rf signal applied to it. Thus, as the strength of the rf signal varies, the strength of the pulses of current flowing through the tube will vary. The current flowing through the tube will flow from the cathode to the plate of the tube, through the secondary of the i-f transformer and then through the load resistor R1, setting up a voltage drop across this resistor having the polarity shown on the diagram. The voltage across this resistor will charge capacitor C1. As the strength of the signal varies, causing the current to vary, the voltage across R1 and hence the charge across C1 will vary. Since the strength of the rf signal is varying at an audio rate, the voltage across R1 will vary at an audio rate. This will cause a voltage to appear across R1 and C1 like the voltage shown in Fig. 15B. Notice that this is the audio signal that was actually being carried by the rf signal.

It might be well to point out at this time that the current flows through the diode in a series of pulses like those shown in Fig. 15C. Notice that these pulses are somewhat similar to the pulses obtained from a half-wave rectifier with the exception that the amplitude of these pulses is varying. These pulses tend to charge capacitor C1. The charge across the capacitor will be determined by the amplitude of the pulses, which in turn is determined by the strength of the signal being received and the amplitude modulation on the signal.

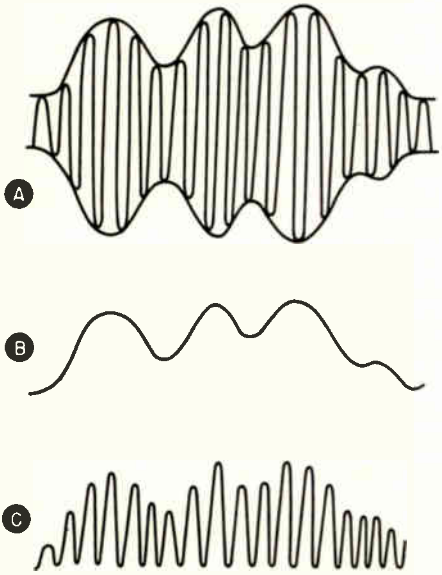

Fig. 15. A modulated rf carrier is shown at A, the extracted audio signal is shown at B, and the series of current pulses flowing through the diode are shown at C.

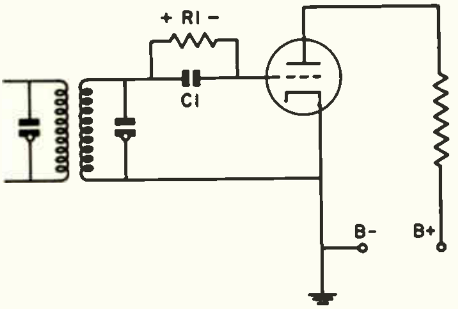

Fig. 16. A grid-leak detector.

In the interval between each cycle there is some tendency for the capacitor to discharge through the resistor, but if the values of the capacitor and the resistor are selected correctly, the discharging is so small that it does not cause any appreciable difficulty. On the other hand, C1 and R1 must be selected so that they are not too large, because C1 must be able to discharge rapidly enough to follow the audio signal variations.

Triode Detectors.

A diode is not the only tube that can be used as a detector. One of the earliest forms of detector was the triode grid-leak detector. The schematic of a grid-leak detector is shown in Fig. 16. The operation of this type of detector is not a great deal different from the operation of a diode detector followed by a triode audio amplifier. If for the present we ignore the plate of the tube and consider only the grid and the cathode, you will see that the circuit is very similar to that of a diode detector. All we would need to do is move the resistor and capacitor to the other side of the transformer to give us the identical circuit.

In a grid-leak detector the rectification actually occurs in the grid circuit with the grid acting like a diode plate. When the rf signal drives the grid positive, electrons are attracted to the grid and current flows to charge the grid capacitor C1. When the rf signal swings negative and there is no grid current flow, capacitor C1 discharges through grid resistor R1, setting up a voltage drop across this resistor as shown. The net result is that we have an audio signal voltage appearing across the grid capacitor and grid resistor. This will cause the grid potential to vary at an audio rate so the tube now acts like a triode audio amplifier and amplifies this audio signal.

The grid-leak detector was quite widely used in the early days of radio, but it has disappeared almost entirely in favor of the diode detector. However, as you can see, the operation is similar to that of a diode detector followed by a triode audio amplifier.

SUMMARY

In this section of the lesson you have seen examples of both detectors and rectifiers. You have learned that a detector is a rectifier inasmuch as it operates on the principle of allowing current to flow through it in only one direction. There is a great deal of similarity between the operation of a detector and that of a rectifier. However, a rectifier is used to convert ac power to dc power where a detector is designed primarily to extract information from an rf carrier signal.

The half-wave rectifier operates on only one half cycle, whereas the full-wave rectifier operates on both half cycles, producing two pulses for each ac power-line cycle.

The diode detector is the most widely used detector in modern electronic equipment. As the amplitude of the signal applied to the diode detector varies, the current flowing through it varies. This causes the voltage across the diode load resistor and capacitor to vary at a rate that follows the intelligence superimposed on the rf signal.

The grid-leak detector is an example of a triode type detector. Its operation is similar to that of a diode detector followed by a triode audio amplifier.

SELF-TEST QUESTIONS

(v) On what principle do detectors and rectifiers operate?

(w) If a half-wave rectifier circuit is operated from a 60-cycle power line, how many current pulses per second will be fed to the filter network?

(x) How many pulses per second will the filter network receive from a full-wave rectifier circuit operating on a 60-cycle power line?

(y) What is the advantage of a full-wave rectifier over a half-wave rectifier?

(z) Draw a schematic diagram of a diode detector circuit.

(aa) What causes the amplitude of the pulses flowing through a diode detector to vary?

(ab) In the grid-leak detector, where does rectification occur?

(ac) To what type of circuit can we compare the grid-leak detector?

Oscillators

One of the most important uses of vacuum tubes is in oscillator circuits. An oscillator is a stage that generates its own signal. Without oscillators, the entire field of electronics would be extremely limited.

In communications, vacuum tubes are used in oscillator circuits to generate radio-frequency signals. Although it is possible to generate ac by mechanical means, there is a limit to how high a frequency can be generated. To generate signals of a very high frequency, electronic means rather than mechanical means must be used.

Practically all oscillators work on the same basic principle: part of the signal from the output of the stage is fed back to the input. The signal fed back to the input is called a feedback signal, or simply feedback. The feedback must be in phase with the signal in the input in order to reinforce it, so the stage can generate an ac signal. Actually, this stage simply converts the dc supplied by the power supply to ac. The exact frequency of the ac signal depends upon the circuit and the value of the components used in the circuit.

HARTLEY OSCILLATORS

Fig. 17 shows an oscillator circuit called a Hartley oscillator. In this circuit, energy is fed from the plate of the tube through C2 to coil L1. This energy is fed through the lower half of the coil to ground. The energy, in flowing through the lower half of L1, sets up a magnetic field which cuts the turns of the upper half of L1 and induces a voltage in it. This voltage is applied between the grid of the tube and ground and produces additional current flow in the plate circuit which will set up a field that will reinforce the signal in the grid circuit still further.

The coil that is marked RFC and is located in the plate circuit of the tube is a radio-frequency choke. It is put in the plate circuit to act as a high impedance to the flow of signal current and thus keep signal currents out of the power supply and force them through capacitor C2 to coil L1.

One of the interesting characteristics of an oscillator circuit is that it develops its own bias. The energy fed from the plate into L1 is of sufficient magnitude to produce a strong enough field to induce a high enough voltage in the upper half of the coil to drive the grid of the tube positive. When this happens, the grid will attract electrons; these electrons will charge the grid capacitor C1 with the polarity shown on the diagram. During the rest of the cycle, when the grid is negative, capacitor C1 discharges through grid resistor R1 and sets up a voltage drop across this resistor, as shown in Fig. 17.

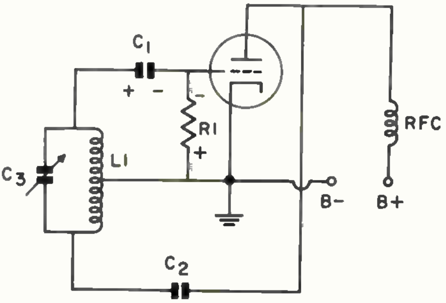

Fig. 17. A Hartley oscillator circuit.

Thus, the grid of the tube is maintained at a negative potential with respect to the cathode. If the amount of feedback from the plate circuit to the grid circuit is increased, the grid will be driven even more positive, charging capacitor C1 still higher, which will increase the bias on the grid of the tube. This in turn will automatically tend to reduce the plate current flowing through the tube. This automatic action tends to adjust the plate current of the tube and maintain it at a nearly constant value.

The frequency at which the circuit will oscillate will be determined primarily by the inductance of L1 and the capacity of C3. This coil and capacitor form a parallel resonant circuit. Changing the value of these components will change the frequency of oscillation.

COLPITTS OSCILLATORS

Another type of oscillator, the Colpitts oscillator, is shown in Fig. 18. Here the feedback is controlled by a capacitive voltage-divider network consisting of C3 and C4. Bias for this stage is produced by grid capacitor C1 and grid resistor R1 as in the Hartley oscillator.

The frequency at which this circuit will oscillate depends primarily on the inductance of coil L1 and the capacity of capacitors C3, C4, and C5. Capacitor C5 is variable; the frequency of the oscillator can be adjusted by changing the capacity of C5. Increasing the capacity will cause the oscillator to operate at a lower frequency; decreasing the capacity will cause the oscillator to operate at a higher frequency.

The output of the Colpitts oscillator as well as that of the Hartley oscillator is a sine wave. However, not all oscillators have sine-wave outputs. In some cases an output signal other than a sine wave is desired. An example of an oscillator that produces a signal other than a sine wave is the multivibrator.

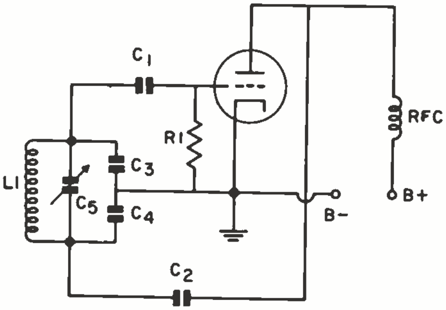

Fig. 18. A Colpitts oscillator circuit.

MULTIVIBRATORS

The multivibrator is widely used in television and in many industrial applications. The output from this type of oscillator is not a sine wave, in fact it is almost a square wave.

The schematic diagram of a typical multivibrator is shown in Fig. 19. This type of multivibrator is called a plate-coupled multivibrator

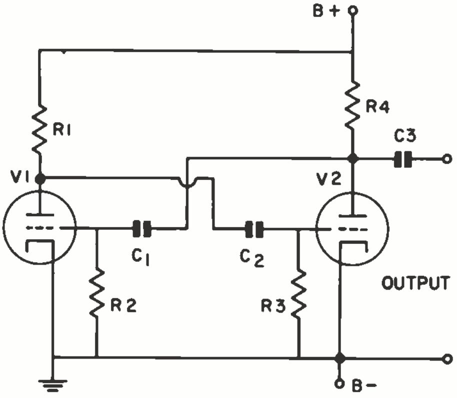

Fig. 19. A plate-coupled multivibrator.

because the energy necessary for oscillation is fed between the tubes from the plate of each tube to the grid of the other tube.

The multivibrator is a rather interesting circuit. Let us see how it works. When the multivibrator shown in Fig. 19 is first turned on, the cathodes of the tubes will not immediately be hot enough to emit electrons, so no current will flow through either tube. Meanwhile the power supply will heat and begin to operate so there will be B+ voltage available. Since there is no current flow through the tubes, there will be no voltage drop across R1 or R4 due to plate current flowing through them. Therefore C1 and C2 will start to charge to a voltage equal to the full power-supply voltage.

To understand this action better, look at Fig. 20. We have shown just the parts involved. The parts shown at A could be drawn as in B; and those shown at C could be drawn as at D. As you can see, when the B supply is operating, C1 will charge through R2 and R4; and C2 will charge through R3 and R1. As these capacitors are charging, the tubes V1 and V2 will be heating and will start passing current.

When V1 and V2 start to pass current, there will be plate current flow through R1 and R4 that will result in voltage drops across these resistors. If C1 and C2 have charged to a voltage higher than the voltage between the plates of the tubes and ground, they must now discharge through R2 and R3 respectively. This will result in a voltage across these resistors that will make the grid end of the resistors negative. The exact voltage will depend on how big a charge the capacitors must get rid of. This in turn will depend on how much current flows through the tubes. It is very unlikely that the two tubes will pass exactly the same current, so one of the capacitors will be discharging at a faster rate than the other, and this will result in a higher negative voltage appearing across one grid resistor than the other.

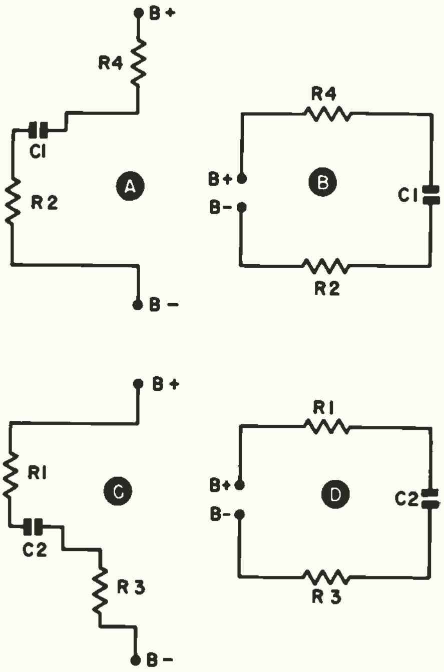

Fig. 20. When the multivibrator shown in Fig. 19 is first turned on, C1 and C2 will charge. This part of the circuit is shown here.

Let's assume that the current through V1 is higher than the current through V2. This will mean that there will be a higher voltage drop across R1 than across R4. C2 will be discharging at a fairly high rate through R3, which will produce a high negative voltage on the grid of V2. This negative voltage on the grid of V2 will reduce the plate current through this tube still further, so the voltage drop across R4 will decrease. C1 will now start to charge to the higher voltage between the plate of V2 and ground. To charge, the capacitor will draw electrons through R2. These electrons will flow through R2 in a direction that will make the grid end of this resistor positive. This positive voltage on the grid of V1 will cause V1 to draw still more current. The higher current through V1 will result in more current flowing through R1, which will cause a greater voltage drop across the resistor. The voltage between the plate of V1 and ground will therefore drop, and capacitor C2 will have to discharge still further. In discharging it will make the grid of V2 even more negative, so the flow of plate current through this tube will be completely cut off.

With plate current through V2 cut off, C1 will eventually charge up to a voltage equal to the B supply voltage. When the capacitor is charged to this voltage, the charging current through R2 will stop flowing, and the positive voltage on the grid of V1 will disappear. When this happens, the current flowing through V1 will drop, causing the voltage drop across R1 to decrease. This will mean that the voltage between the plate of V1 and ground will increase. As soon as this happens, C2 will begin to charge through R3, putting a positive voltage on the grid of V2. Almost instantly V2 will start conducting heavily; the plate voltage on V2 will drop, and capacitor C1 will start to discharge through R2, placing a high negative voltage on the grid of V1 and cutting off the flow of plate current through this tube. When this happens, current will stop flowing through R1, so there will be no voltage drop across this resistor and the voltage between the plate of V1 and ground will jump up to a value equal to the supply voltage. C2 will now have to charge to an even higher voltage, so the grid of V2 will be driven highly positive by the current flowing through R3 to charge this capacitor.

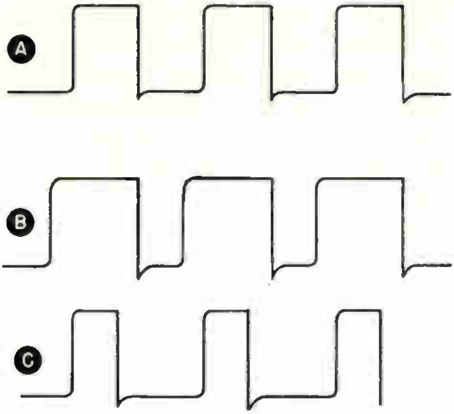

Fig. 21. Output of symmetrical and non-symmetrical multivibrators.

This action of first one tube conducting and cutting off the flow of plate current through the other, and then reversing so that the other tube conducts and cuts off the first tube, will continue as long as power is applied to the oscillator.

Notice that in the multivibrator two tubes are used, whereas in the oscillators we studied before only one tube was needed. In actual practice a dual triode tube that has two separate triodes in the one glass envelope is often used in a multivibrator circuit. Even though this may look like only one tube, we have two-tube action.

The frequency of oscillation will depend primarily on the values of C1-R2 and C2-R3.

If the combination of R2 and C1 has a time constant equal to that of

R3 and C2, the multivibrator is called a symmetrical multivibrator. Each tube will conduct and be cut off for the same length of time, and the output will look like Fig. 21A. However, if the time constant of C2 and R3 is longer than that of C1 and R2, V2 will be cut off for a longer time than V1, and the output will be like Fig. 21B. On the other hand, if the time constant of C1 and R2 is longer than that of C2 and R3, V1 will be cut off longer than V2, and the output will be like Fig. 21C.

The plate-coupled multivibrator is only one type of multivibrator; there are several other types that you will study later.

SUMMARY

Oscillators are important to the electronics technician. You will find them in radio and TV receivers. Every superheterodyne has a local oscillator. Television receivers have oscillators similar to the multivibrator to generate the signals that move the electron beam over the face of the picture tube.

The Hartley oscillator and the Colpitts oscillator both generate a sine-wave output. In the Hartley oscillator, feedback is obtained by inductive means, whereas in a Colpitts oscillator feedback is obtained by means of a capacitive voltage divider. The two oscillators are otherwise basically similar.

The multivibrator is an RC coupled oscillator. Its output is not a sine wave. It is useful in TV receivers and in many industrial applications. Two tubes are needed in a multivibrator circuit. The two conduct alternately; when the first tube is conducting, the second is cut off, and when the second tube is conducting, the first is cut off.

SELF-TEST QUESTIONS

(ad) On what principle do oscillators operate?

(ae) Draw a schematic diagram of a Hartley oscillator.

(af) Across what part is grid bias for the Hartley oscillator developed?

(ag) In the Hartley oscillator circuit shown in Fig. 17, which two parts primarily control the oscillator frequency?

(ah) What controls the feedback in the Colpitts oscillator circuit shown in Fig. 18?

(ai) What parts primarily determine the oscillator frequency in the Colpitts oscillator shown in Fig. 18?

(aj) What type of output signal is obtained from the Hartley and Colpitts oscillators?

(ak) What type of output signal is obtained from a multivibrator?

(al) What parts primarily control the frequency of the multivibrator shown in Fig. 19?

(am) What is the name given to the particular multivibrator shown in Fig. 19?

A Complete Superheterodyne Receiver

Now let us see how the different circuits are put together in a radio receiver. We have already mentioned that modern radio receivers use what is called the superheterodyne circuit. A block diagram of a typical superheterodyne receiver is shown in Fig. 22. In Fig. 22A we have shown the various functions performed in the receiver. The block diagram is often drawn like the diagram in B because the mixer and oscillator are usually combined in one tube and the second detector and first audio stage are also combined in the tube. Therefore the diagram, shown in Fig. 22B, shows in block diagram form the functions performed by the various tubes.

In the superheterodyne receiver, the signal is picked up by the antenna and is fed to the first stage which is the mixer stage as shown in Fig. 22A. At the same time, a signal from a local oscillator is also fed to the mixer stage. The local oscillator always operates at a fixed frequency above the frequency to which the mixer is tuned. In modern radio receivers the oscillator is usually operated 455 kHz above the incoming signal. In the mixer circuit the in-

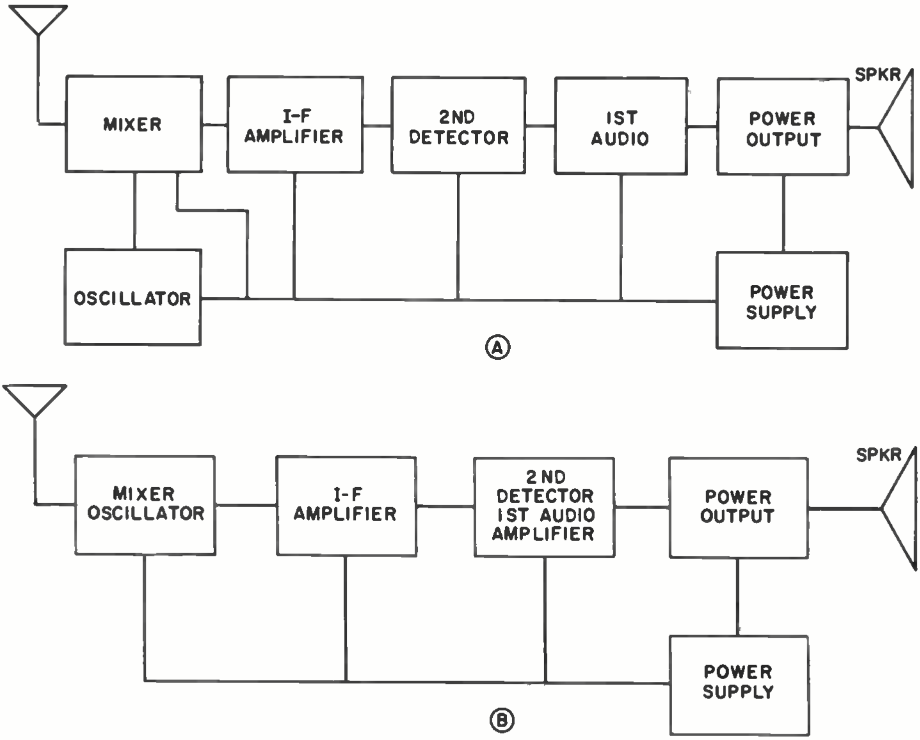

Fig. 22. A block diagram of a 5-tube superheterodyne receiver.

coming signal is mixed with the signal produced by the local oscillator. This mixing of the two signals results in two new signal frequencies appearing in the output of the mixer, one equal to the sum of the local oscillator and the incoming signal frequency, and the other equal to the difference between the two frequencies.

We mentioned that the oscillator is operated 455 kHz above the incoming signal frequency. Therefore the difference between the incoming signal frequency and the oscillator signal frequency will be 455 kHz.

The second stage in the superheterodyne is a radio-frequency amplifier stage called the i-f amplifier. It is tuned to the i-f frequency. which is equal to the difference between the frequency of the incoming signal and the frequency of the local oscillator in the receiver.

The i-f amplifier is what is called a fixed-frequency amplifier. In other words, it is always tuned to the same frequency, which in most cases is 455 kHz. Because the amplifier is tuned to a fixed frequency, it is possible to design a stage with a very high gain without running into any problems such as instability or oscillation. Therefore the i-f amplifier amplifies the i-f signal substantially.

The i-f signal is then fed to the stage called the second detector, which is usually a diode detector. Here the intelligence is separated from the radio-frequency carrier. The intelligence signal is the audio signal used to modulate the carrier signal at the transmitter. The audio signal produced by the second detector is fed to the first audio stage where it is amplified and finally fed to the output stage, which is a power amplifier that produces the power necessary to drive the loudspeaker.

A schematic diagram of a superheterodyne receiver is shown in Fig. 23. We will not go through this receiver stage by stage to see how each stage works. We have already studied most of these stages in this lesson, so we will now concentrate on taking up a few additional details and also seeing how the stages are used together.

THE MIXER-OSCILLATOR

The tube used in the mixer-oscillator stage is a 12BE6 tube marked V1. This tube is a pentagrid converter. Pentagrid means five grids; the tube is called a converter because it is designed for service as a frequency converter, which is what the mixer-oscillator stage is often called.

In this tube the first and second grids in conjunction with the cathode act like a triode tube. The first grid is the control grid and the second grid acts as the plate of the triode section of the tube. Thus the cathode, the first grid, and the second grid are used as an oscillator. This oscillator modulates the stream of electrons flowing from the cathode to the plate of the tube. The incoming signal picked up by the loop antenna is fed into the No. 3 grid. This signal also modulates the electrons flowing from the cathode to the plate of the tube so that the resultant flow of electrons from the cathode to the plate of the tube will be modulated both by the signal produced by the local oscillator and by the incoming signal. This modulation will produce a signal with a frequency equal to the difference in the frequency of the

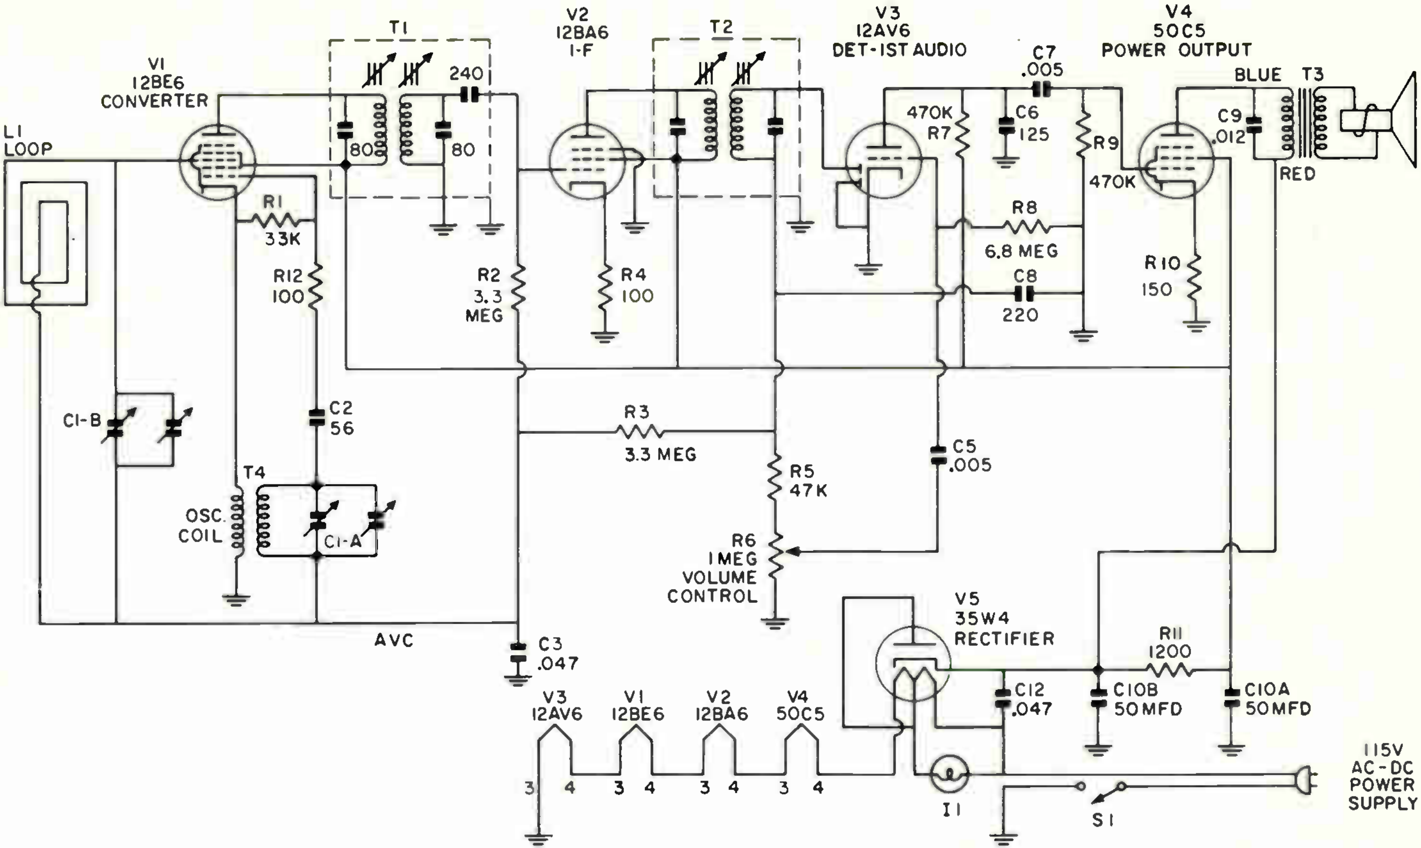

Fig. 23. Schematic diagram of a complete superheterodyne receiver.

two signals which will be the i-f signal, in addition to a signal equal to the sum of the frequencies of the two signals.

The primary winding of the transformer T1 and the capacitor connected across it form a parallel resonant circuit. This circuit is tuned to resonance at the difference frequency produced in the converter stage. Therefore it acts as a high resistance at this frequency, while at the same time it acts as a low impedance at the frequency of the incoming signal, the frequency of the local oscillator, and the frequency equal to the sum of the two frequencies. Thus in the parallel resonant circuit we will have a high circulating current having a frequency equal to the difference frequency. The other three frequencies appearing in the plate circuit of the mixer tube will produce little or no current flow in the resonant circuit.

THE I-F AMPLIFIERS

The secondary of T1 is inductively coupled to the primary. Thus a voltage will be induced in series with the secondary winding. The secondary winding of the transformer is tuned to resonance by the capacitor connected across it, and this coil and capacitor form a series resonant circuit. In a series resonant circuit there will be a high circulating current, and a resonant voltage step-up. This voltage is applied between the grid and cathode of the i-f amplifier.

The difference-frequency signal applied between the grid and cathode of the i-f amplifier is amplified by this stage. In the plate circuit of this tube, which is a conventional pentode rf amplifier, there is another parallel resonant circuit. This is made up of the primary winding of T2 plus the capacitor connected across it. Again, this transformer acts as a high resistance at the difference frequency and a low impedance at other frequencies.

Before leaving the i-f stage, notice the lead marked AVC. AVC is an abbreviation for automatic volume control. A variable voltage is applied to this lead, which in turn is connected to the grid of the i-f tube V2 through the 3.3-megohm resistor R2. The voltage is also applied to the grid of the mixer tube through the loop antenna.

The voltage that is fed to the grids of these tubes will depend upon the strength of the signal picked up from the station. If the signal is very strong, a fairly high negative voltage is fed to the grids of these tubes and this voltage reduces the gain of the stages. If the signal is weak, the negative voltage drops almost to zero so that the two stages operate at maximum gain. We will see how this voltage is developed when we study the second detector used in this receiver.

The tube used in the i-f stage of a modern superheterodyne receiver is usually what is called a remote cut-off type. A remote cut-off tube is a tube with a specially made control grid. The grid is designed so that it takes a very high negative voltage to completely cut-off the flow of plate current.

In the tubes we have discussed so far, the grid wires have been evenly and rather closely spaced. The plate current flow in a pentode tube that is made in this way can be cut off with a fairly low negative voltage applied to the grid of the tube. This type of tube is called a sharp cut-off tube. If however, instead of spacing the grid wires evenly, we space them so that they are close together at the ends but spaced quite widely apart in the middle as shown in Fig. 24, a much higher negative voltage must be applied to the grid of the tube before the plate current can be reduced to zero. As we begin to apply negative voltage to the grid of the tube to cut off the flow of plate current, the grid wires at the ends are able to cut off the flow of plate current through them, but because of the wide spacing in the center part of the grid, electrons will still travel from the cathode to the plate of the tube. In order to cut off the flow of plate current with this type of grid structure, a much higher negative grid voltage is required than with the sharp cut-off tube.

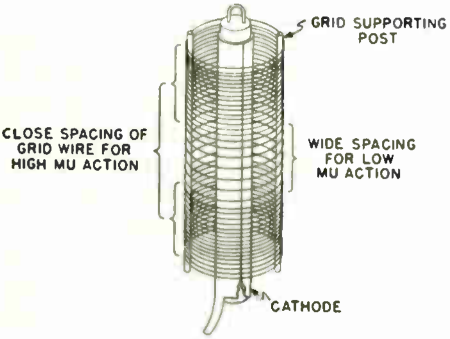

Fig. 24. The grid of a remote cut-off type pentode. Here the spacing between the grid wires is greater at the center of the grid than at the ends.

The remote cut-off tube is ideally suited for i-f amplifiers where avc is used. However, this type of tube usually does not have quite as high a gain as a sharp cut-off tube. A compromise between the sharp cut-off and the remote cut-off tubes is the semi-remote cut-off tube. In this type of tube, the spacing between the grid wires in the center of the tube is not quite as wide as the spacing between the grid wires in the remote cut-off tube.

THE DETECTOR - FIRST AUDIO STAGE

In our superheterodyne receiver the i-f signal is fed from the i-f stage to the second detector. The secondary of the i-f transformer forms a series resonant circuit with a capacitor connected across it. One end of the secondary is connected directly to the plate of the diode detector and the other end is connected to the diode load, which is made up of the 47K-ohm resistor R5 and 1-megohm volume control R6. These two resistors are in parallel with the diode load capacitor C8. You already know how a detector works and how an audio voltage will appear across the diode load resistors R5 and R6 and the diode load capacitor C8.

The i-f signal flowing through the detector can flow in only one direction with the result that there will be a series of pulses at the detector output which will charge the diode capacitor C8. The charge across this capacitor will depend upon two things, the audio signal and also the strength of the signal being received. By connecting a filter network consisting of a resistor and a capacitor such as R3 and C3 across this capacitor a dc voltage can be obtained across C3 that will depend upon the strength of the incoming signal. Now let's see where this voltage comes from.

We have a series of pulses flowing through the diode, charging capacitor C8. The amplitude of these pulses, and hence the voltage across C8, depends on the audio signal and the strength of the signal being received. C8 discharges through R5 and R6, producing a voltage having a polarity such that the junction of R5 and the i-f transformer is negative. This voltage also will depend on the audio signal and the strength of the signal being received.

This voltage also is across the combination of R3 and C3 in series. However, R3 and capacitor C3 form a voltage divider network. The resistance of R3 is much higher than the reactance of C3. Therefore most of the audio signal appearing across the two will be dropped across R3 so that the voltage across C3 will be almost pure dc and its strength will depend upon the strength of the incoming signal. This voltage is then fed to the avc line and used to control the gain of the mixer and i-f tubes. If the strength of the signal being picked up is strong, then a fairly high negative voltage is developed across C3, whereas, if the signal is weak, the voltage across C3 will be low. This voltage is used to control the gain of the mixer and i-f stages so they operate at maximum gain when a weak signal is being received, and at reduced gain when a strong signal is being received.

AVC is used in most modern radio receivers to regulate the gain of the set, so that as you tune across the broadcast band from one station to another, they all come in at approximately the same volume. Actually, this system is an automatic gain control rather than an automatic volume control, but when the scheme was first introduced manufacturers called it an automatic volume control because they felt that this would have more appeal to the public than the name automatic gain control. The name automatic volume has stuck, but the same system used in television receivers is called automatic gain control.

The tube used in the second detector-first audio stage is a combination tube. The tube contains two diodes and one triode. Only one of the diodes is used in the detector circuit; the other diode plate is unused and simply connected to ground and to the cathode. The triode section is used as the first audio stage. You will notice that the diode load is actually made up of two resistors. The 47K resistor R5 is only one twentieth of the size of R6 so most of the voltage will appear across R6. R6 is a potentiometer. The position at which the center tap connects to the resistor can be controlled by rotating the control shaft on the potentiometer. By moving this tap up and down the resistor, the amount of audio signal fed to the first audio stage can be varied. This control is called a volume control since it will vary the volume or output from the sound system in the receiver. The audio signal is then fed through coupling capacitor C5 to the grid of the first audio tube.

The first audio tube uses a bias system that we have not discussed previously. Notice that the cathode of the tube is connected directly to ground, and the grid resistor R8 is a 6.8-megohm resistor. You already know that some of the electrons leaving the cathode of the tube and travelling toward the plate will accidentally strike the grid of the tube. The number striking the grid is quite small, and these electrons flow through the grid resistor back to ground and from there back to the cathode of the tube. In most stages the grid resistor is kept low enough so the number of electrons flowing through it do not produce an appreciable voltage. However, by using a large value of grid resistor, a voltage can be developed across it to bias the tube. This type of bias is usually called "convection" bias and is frequently used in the first audio stage of modern radio receivers.

THE OUTPUT STAGE

The output stage in most modern receivers is either a pentode or a beam power tube. The tube is operated as a Class A amplifier.

In this receiver, the signal from the plate of the first audio stage is coupled to the grid of the output stage through capacitor C7. R9 is a grid leak resistor and R10 is the cathode bias resistor. The cathode bypass capacitor is omitted from this stage to improve the frequency response of the stage. You will see in a later lesson exactly why this happens.

The loudspeaker is a permanent-magnet dynamic speaker. This speaker is coupled to the output tube by means of transformer T3, which is called the output transformer. We have already studied output transformers and know that they are impedance-matching devices designed to match the low impedance speaker to the high impedance of the plate of the output tube in order to get as high a power transfer as possible.

There are a number of different types of tubes used as output tubes, but in general the circuit is similar to the one shown in Fig. 23, although the values of the components used in the circuit may vary slightly with different tubes.

THE POWER SUPPLY

The only section of the receiver left to discuss is the power supply. This is a universal ac-dc type of power supply using a half-wave rectifier similar to the one shown in Fig. 12.

The Plate Supply.

Notice that the plate voltage for the output tube is taken directly from the cathode of the rectifier tube through the primary of the output transformer instead of from the output of the filter network. We can do this because the plate current flowing in a pentode or beam power tube depends primarily on the screen voltage, and the plate voltage has little or no effect on it. Thus the ac ripple applied to the plate of the tube will not cause any appreciable hum current to flow through the tube and the primary of the output transformer. The output tube alone will draw as much current as all the rest of the tubes in the receiver. If we take the plate supply of the output tube directly from the cathode of the rectifier, we can use a resistor instead of a choke in the filter network, as we have done here-R11 in Fig. 23.

If we connected the plate of the output tube to the other side of the filter network, we would have to use a choke, because the high current drawn by the output tube through a resistor would cause such a high dc voltage drop that the output voltage for the rest of the plates would be too low. A choke has a high ac reactance, so it would filter any ripple voltage, but it has a low dc resistance, so the dc voltage drop across it would be lower.

The advantage of using a resistor in place of a choke is simply one of economy. A resistor is much cheaper than a filter choke. As long as the current through the resistor can be kept to a reasonably low value, the dc voltage drop across the resistor will not be too great. The resistor will form a voltage divider network with the output filter capacitor so that the hum voltage from the cathode of the rectifier will be reduced enough to provide suitably pure dc for the operation of the receiver. The plate and screen voltages for the rest of the tubes and the screen voltage for the output tube are obtained from the output of the filter network. These voltages will be much better filtered than the voltage supplied to the plate of the output tube. If these tubes, particularly the first audio tube or the screen of the output tube, were operated directly from the cathode of the rectifier tube there would be an extremely loud hum produced by the speaker.

The Heater Circuit.

The heaters of the various tubes in this receiver are connected in series, and the series circuit is connected directly across the power line. The tubes are designed so that they all require the same operating current. The voltage requirements for the various tubes are different. The 35W4 rectifier tube requires a heater voltage of 35 volts. The 50C5 output tube requires a heater voltage of 50 volts. Each of the other tubes requires a heater voltage of 12.6 volts. If you add these voltages together, you will find that the total is 122.8 volts. In actual practice, these tubes can be operated from a line voltage of anywhere between about 110 volts and 125 volts, and give satisfactory performance. Notice the pilot light marked I1 on the diagram. The heater of the 35W4 is tapped, and the pilot light is connected in parallel with part of the heater to get the voltage needed to operate the light.

Notice that 12-volt heaters are closer to the side of the power line that connects to B-, so that the voltage between these heaters and B- is maintained as low as possible.

The first audio tube is almost always connected at the end of the string so that one side of its heater is connected to B-. This keeps the potential between the cathode and heater of this tube as low as possible. This particular tube is more susceptible to hum pickup than are the other tubes in the receiver. The arrangement used in this receiver is pretty standard for this type of set. If you trace the heater circuit in an ac-dc receiver starting at the side of the power line that connects to B-, you will find the tubes connected in the following order: the first audio-second detector; the mixer oscillator; the i-f amplifier; the power output tube, and finally the rectifier.

Since the tube heaters in this receiver are connected in series, if any one of the heaters burns out, none of the tubes will light. This is probably the most common defect you will find in ac-dc receivers. Keep this point in mind. If you are asked to service a small ac-dc receiver and you find that none of the tubes light, look for a tube with an open heater. The chances are that replacing this tube will clear up the trouble.

SUMMARY

In this section of this lesson we have shown how the various stages that you have studied previously are put together to form a complete receiver. From this discussion you can see that a complete radio receiver is simply made up of a number of different stages, each performing the task for which it was designed. Complex electronic equipment is made up in the same way; it is made of a number of simple separate stages designed to work together.

There are a number of things that we have not discussed about these various stages, but we will discuss them in more detail in later lessons. At present you should have a general understanding of how each stage works and how they are put together to form a complete receiver.

SELF-TEST QUESTIONS

(an) To what stage is the signal from the antenna fed in a typical five-tube superheterodyne receiver?

(ao) In a modern superheterodyne receiver is the oscillator frequency higher or lower than the frequency of the incoming signal?

(ap) If you tune a superheterodyne receiver to a broadcast station operating on 1500kc, and the i-f amplifier operates on a frequency of 456kc, at what frequency must the local oscillator in the receiver be operating?

(aq) In the 12BE6 tube used in the circuit shown in Fig. 23, which grid acts as the plate of the oscillator tube?

(ar) In the i-f transformer T1 in Fig. 23, both the primary and secondary circuits are tuned to resonance. Are these circuits series-resonant circuits or are they parallel-resonant circuits?

(as) What is meant by a remote cut-off tube?

(at) In the second detector in the circuit shown in Fig. 23, across what part is the audio signal voltage developed?

(au) How is bias for the first audio stage in the circuit shown in Fig. 23 developed?

(av) What class of power amplifier is used in the circuit shown in Fig. 23?

(aw) In the circuit shown in Fig. 23, the heaters of all the tubes are connected in series across the power line. If you were called on to service a receiver of this type and saw that none of the tubes were lighting, what type of trouble would you look for?

Amplifier Variations

We have already mentioned that there are three basic types of amplifiers, the grounded-cathode, the grounded-grid, and the grounded-plate. All the amplifiers you have studied so far have been grounded-cathode amplifiers. Most of the amplifiers you will encounter will be the grounded-cathode amplifiers, but the other two types are also important. They have some special characteristics that are very useful in certain applications. The grounded-grid amplifier is widely used as the rf amplifier in VHF tuners of TV receivers. It is also quite widely used in transmitting equipment. The cathode-follower, which is the more frequently used name for the grounded-plate amplifier, is widely used in industrial applications, and also it has recently been used in a large number of color TV receivers. The cathode-follower is particularly useful as an impedance-matching device to match a high-impedance circuit to a low-impedance circuit.

In this section of this lesson you will study some of the important characteristics of all three types. You will see how these amplifiers differ from each other and see some examples of grounded-grid and grounded-plate amplifier circuits.

THE GROUNDED-CATHODE AMPLIFIER

As we mentioned, the amplifiers we have been studying have all been grounded-cathode amplifiers. We have repeated the basic grounded-cathode circuit shown in Fig. 1 as Fig. 25. Notice that the signal is applied between the grid and cathode of the tube; the cathode is operated at signal ground potential, and the load is placed in the plate circuit. The output signal is developed across the load, so in this circuit it is developed between the plate of the tube and ground. Remember that the end of the load that is connected to the B supply is at ground potential as far as the signal is concerned.

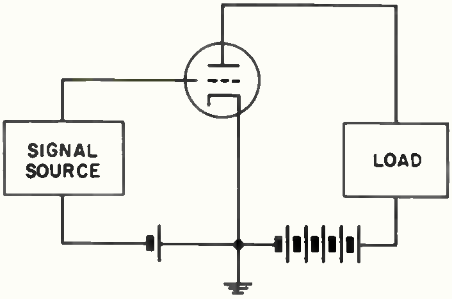

Fig. 25. The grounded-cathode amplifier shown in Fig. 1 is repeated here for your convenience.

Circuit Characteristics.

You already know how the grounded-cathode circuit amplifies a signal, so we will not go through an explanation of how this circuit works. Instead we will discuss some of the important characteristics of this type of circuit.

One important characteristic of this type of amplifier is that the output signal is greater than the input signal; in other words, the stage is capable of amplifying. The actual gain of the stage is equal to the ratio of the output voltage divided by the input voltage. The gain obtained from this type of stage may be quite low, sometimes as low as only two or three, or it may be quite high, sometimes as high as two hundred or more. The exact gain will depend on the tube used in the amplifier and the value of the components used with the tube.

Another important characteristic of this type of stage is that there is a phase shift of a half-cycle or 180° between the input and output signals. This means that when the input signal drives the grid in a positive direction, the output signal between the plate and ground will be going in a negative direction. Similarly if the grid is being driven negative, the output signal will be going positive.

Two other important characteristics are the input and output impedances of the stage. The input impedance is important because it tells you how the stage will load the signal source. The output impedance is important because it gives an indication of the type of load that must be connected in the output circuit in order to obtain proper results from the stage.

You will remember that in a Class A voltage amplifier the tube is biased so that it operates on the mid-point of its characteristic curve. The input signal is not strong enough to drive the grid positive, so there will be no grid current flow. Thus the input circuit of a Class A voltage amplifier is a high-impedance circuit. This is important because it tells us that this type of stage will take little or no power from the source driving the stage.

In a Class B or Class C power amplifier the grid is driven positive, so grid current will flow. Thus these stages have a comparatively low input impedance and will require power from the driving stage.

We can summarize the input characteristics of the grounded-cathode amplifier as follows: Voltage amplifiers and Class A power amplifiers draw no grid current, and hence have a high input impedance. Class B and Class C power amplifiers draw grid current, require power from the driver stage, and have a fairly low input impedance.

The grounded-cathode amplifier also has a fairly high output impedance. The load is placed in the plate circuit of the tube, and the output is developed across this load. If the load impedance is low, the output will be low.

THE GROUNDED-PLATE AMPLIFIER

The grounded-plate amplifier is more commonly called a cathode follower. The load in this type of circuit is connected in the cathode circuit between the cathode of the tube and ground. A block diagram of this type of amplifier is shown in Fig. 26.

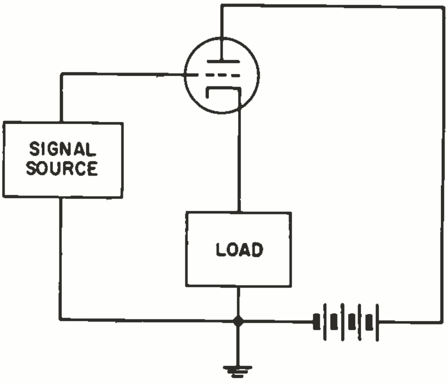

Fig. 26. A grounded-plate or cathode-follower circuit.

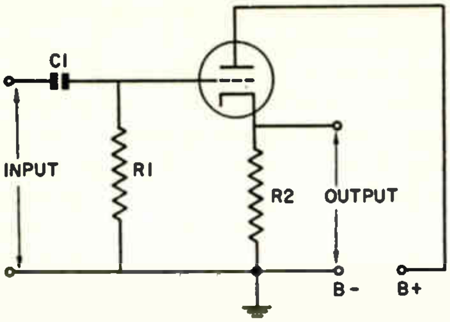

Fig. 27. Schematic diagram of a cathode follower stage.

Notice that the signal is applied between the grid of the tube and ground, as in the grounded-cathode amplifier, but the difference between the two is in the placement of the load.

Putting the load in the cathode circuit completely alters the characteristics of the amplifier. Let us study the operation of a typical cathode follower such as the one shown in schematic form in Fig. 27 to see why this type of amplifier is so different from the grounded-cathode type.

Capacitor C1 is used in the input circuit to isolate the grid circuit of the stage from the signal source and to keep any dc that may be present at the signal source away from the grid of the tube. Resistor R1 is the grid resistor and is placed in the grid circuit to act as a grid leak and provide a path back to the cathode for any electrons that accidentally strike the grid of the tube. The load is R2. It is placed in the cathode circuit of the tube between the cathode and B-. The plate of the tube is connected directly to B+, and since B+ is at ground potential insofar as the signal is concerned, the amplifier is a grounded-plate amplifier.

The operation of this type of amplifier is quite different from that of the grounded-cathode amplifier. When the input signal drives the grid in a positive direction, the current flowing from the cathode of the tube to the plate will increase. This will cause the voltage across the cathode resistor R2 to increase because the plate current flows through this resistor. However, notice that the input signal is applied between the grid of the tube and ground. The actual voltage that will control the flow of plate current through the tube is the voltage between the grid and cathode. If the grid voltage goes positive, the increase in plate current will cause the voltage between the cathode and ground to increase and become more positive. In other words, the positive voltage at the grid produces a more positive voltage at the cathode. This subtracts from the signal voltage so that it reduces the net grid-to-cathode voltage. This means that we have a situation where the output signal being produced by the stage subtracts from the input signal and reduces the input to the tube. Thus the output signal must always be less than the input signal in this type of amplifier. Technicians say that the gain of the stage is less than one. If the output signal were greater than the input signal, it would completely cancel the input signal producing it.

You might wonder why the cathode follower would be of any use at all if the output signal is less than the input. The stage is useful for two reasons. First, the output signal is in phase with the input. This means that when the input signal swings positive, the output signal swings positive; and when the input signal swings negative, the output signal swings negative. There are some applications where it is important not to change the phase.

Another and more important use of the cathode follower is as an impedance-matching device. The cathode follower has a high input impedance, but because the load is in the cathode circuit, it has a low output impedance. Thus, if we have a high-impedance generator and want to connect it to a low-impedance load, we can use a cathode follower to match the two impedances.

Cathode followers are very useful in any application where it is important to isolate the load from the signal source. They are often found in the input of a cathode ray oscilloscope, which is a test instrument used in servicing many kinds of electronic equipment. The cathode follower is used in the input circuit to provide isolation between the circuit under test and the test instrument so that connecting the test instrument to the equipment does not affect the performance of the equipment.

THE GROUNDED-GRID AMPLIFIER

The grounded-grid amplifier is used in some special cases as a power amplifier. You will remember that we pointed out that when a triode tube is used as an rf amplifier, unless special precautions are taken, the tube will oscillate. This oscillation that occurred in a triode tube was one of the factors that led to the development of the tetrode tube. Remember that the screen grid was added to the tube in order to shield the grid from the plate and keep the energy fed from the plate back to the grid of the tube as low as possible.

In some circuits a triode tube will operate where a beam power tube or a pentode tube will not give satisfactory service. This situation is encountered at very high frequencies. It comes about because of the time it takes an electron to travel from the cathode of the tube to the plate. At very high frequencies a single cycle may take only a fraction of a millionth of a second. A half cycle will take only half this time. It could take the electrons longer than the time of one half cycle to travel from the cathode to the plate of the tube if the spacing between the cathode and plate were too great. The spacing between the cathode and plate in a beam power tube or a pentode is greater than in a triode because there must be room for the extra elements.

In higher-power amplifiers using beam power tubes with a high sensitivity, there will sometimes be oscillation because of energy getting through the screen from the plate of the tube to the grid. If the tube is a very sensitive tube, a small amount of energy getting through the screen may be enough to cause oscillation in the stage.

Oscillation in a triode stage or in a high-gain beam power stage can often be eliminated by using a grounded-grid circuit, because the grid is operated at ground potential. The signal is fed into the cathode circuit, and the grid, which is grounded, acts to shield the output circuit from the input circuit.

A simplified diagram of a grounded-grid amplifier is shown in Fig. 28. Notice that in this circuit the input is fed into the stage between the cathode and ground, and the grid

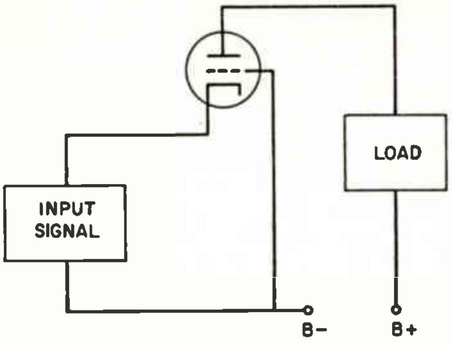

Fig. 28. Block diagram of a grounded-grid amplifier.

is operated at signal ground potential. The load is connected in the plate circuit of the tube as in the grounded-cathode amplifier.

The schematic diagram of a grounded-grid amplifier using a beam power tube is shown in Fig. 29. In this circuit the input signal is fed between the filament-type cathode and ground. The filament of the tube is isolated from ground by the two radio-frequency chokes, marked RFC1 and RFC2 on the diagram. These chokes are simply coils that have high inductive reactances at the operating frequency. Because they have high reactances, the filament cathode is isolated from ground insofar as the signal is concerned, while at the same time the chokes offer little or no opposition to the flow of dc or low-frequency ac used to heat the filament of the tube.

In this type of amplifier, if the incoming signal drives the cathode positive with respect to ground, it drives the cathode positive with respect to the grid, because the grid is connected to ground as far as the signal is concerned through capacitor C1, which has a low reactance at the signal frequency. If the cathode is driven positive with respect to the grid, it is the same as driving the grid negative with respect to the cathode, so the current flowing from the cathode to the plate of the tube will decrease. On the other hand, if the cathode is driven negative with respect to the grid, it is the same as driving the grid positive with respect to the cathode, so the plate current will increase.

Since both the grid and the screen grid of this tube are connected to ground as far as the signal is concerned, it will be almost impossible for any energy to get from the plate of the tube back into the input circuit. As long as energy cannot get from the plate circuit back into the input circuit, the stage will not oscillate.

It is not important to go into all the details of the grounded-grid amplifier at this time. The important thing for you to remember is the general configuration of the circuit. Remember that the signal is fed into the cathode circuit, and the load is connected into the plate circuit. Remember also that the big advantage of this type of circuit is that the energy fed from the plate circuit

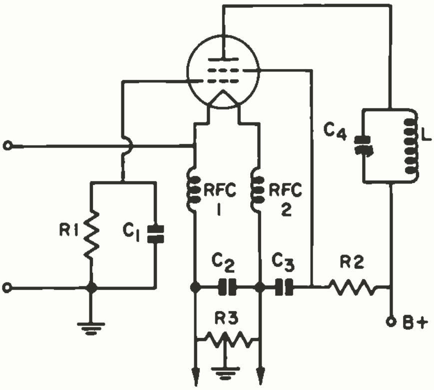

Fig. 29. Schematic diagram of a grounded-grid amplifier.

back into the input is low, so that the possibility of oscillation is remote.

SUMMARY

The important thing for you to remember from this section of the lesson is the general pattern of the circuit. Remember that there are three types of amplifier circuits: the grounded-cathode, the grounded-plate or cathode follower, and the grounded-grid amplifier. Most of the amplifiers that you will encounter will be grounded-cathode amplifiers, but the other types are found in some special applications.

The grounded-cathode amplifier is important because a high gain can be obtained from this type of circuit. This type of amplifier has a high input impedance and a high output impedance.

The cathode follower circuit always has a gain of less than one. This means that the output will be less than the input. This circuit is often used as an impedance-matching device; it has a high input impedance and a low output impedance.

The grounded-grid amplifier is often used as an rf power amplifier. It is particularly useful with triode tubes operating at very high frequencies and with beam power tubes having a high sensitivity. In conventional circuits, the screen may not offer enough isolation to prevent a beam power tube with a high sensitivity from oscillating.

SELF-TEST QUESTIONS

(ax) Where are the signal source and the load placed in a grounded-cathode amplifier?

(ay) Name two important characteristics of the grounded-cathode amplifier?

(az) What is the more common name by which the grounded-plate amplifier is known?

(ba) Where are the signal source and load placed in the cathode follower?

(bb) How does the amplitude of the output signal compare with the amplitude of the input signal in a cathode follower?

(bc) How does the phase of the output signal compare with the phase of the input signal in a cathode follower?

(bd) Name two important applications where a cathode-follower stage may be used?

(be) Where are the input signal and load placed in the grounded-grid amplifier?

(bf) How is oscillation prevented when a triode tube is used as an rf amplifier in a grounded-grid circuit?

(bg) How do the input impedances of the grounded-cathode and cathode-follower stages compare?

(bh) How do the output impedances of the grounded-cathode and cathode-follower stages compare?

LOOKING AHEAD

In later lessons many of the circuits you have studied in this lesson will be discussed in much more detail. The purpose of this lesson is to give you a look at some of the circuits in which tubes are used in order to help you better understand how tubes work. Later you will see that there are many other important things to be considered in the various stages that we have studied.

It is important for you to understand how all the various types of circuits commonly found in electronic equipment operate. You will remember that we have pointed out several times that complex electronic equipment is made up of a large number of simple circuits connected to work together. If you understand how the individual circuits work, you will be able to understand how they work together. If you understand how a piece of electronic equipment is supposed to work, you should have no difficulty locating a defect in the equipment.

Answers To Self-Test Questions

(a) A Class A amplifier is an amplifier that is biased to operate midway between zero bias and cut-off bias.

(b) A Class B amplifier is an amplifier operated with the bias approximately at cut-off.

(c) A Class C amplifier is an amplifier operated with a bias two to four times cut-off bias.

(d) Voltage amplifiers and power amplifiers.

(e) A voltage amplifier is an amplifier that is designed to take a small signal voltage and amplify it to a larger signal voltage.

(f) Voltage amplifiers are Class A amplifiers.

(g) The chief disadvantage of a Class A power amplifier is its relatively poor efficiency.

(h) The maximum theoretical efficiency that can be obtained from a Class A power amplifier is 50%. However, usually efficiencies in the order of 30% to 35% are all that is practical to obtain.

(i) A single Class B audio amplifier cannot be used because it produces only one half of an input cycle. However, two tubes can be used as a Class B power amplifier providing they are arranged so that one tube reproduces one half of the input cycle, and the other tube reproduces the other half of the input cycle.

(j) Class C power amplifiers are used to amplify radio-frequency signals.

(k) A Class AB amplifier is an amplifier operated with a bias between the value that would normally be used for a Class A amplifier and the value that would normally be used for a Class B amplifier. Sometimes Class AB amplifiers are designated as Class AB_1 or Class AB_2. A Class AB_1 amplifier does not draw any grid current and hence is very much like a Class A amplifier. A Class AB_2 amplifier does draw grid current and hence is operated closer to a Class B amplifier.

(l) Voltage amplifiers and power amplifiers.

(m) See Fig. 6.

(n) The grid-bias battery can be eliminated in a voltage amplifier by inserting a suitable resistor in the cathode circuit of the tube. Current flowing from B- through the resistor, to the cathode of the tube, then from the cathode to the plate and back to the B+ will develop a voltage drop across the cathode resistor. If the cathode resistor is of the correct size, the cathode will be sufficiently positive with respect to ground to provide the required bias. The grid will be essentially at ground potential and therefore negative with respect to the cathode. If the voltage between the cathode and ground is equal to the required grid bias, the tube grid will have the correct negative bias applied to it.

(o) Electrons accidentally striking the grid of the tube flow through the grid resistor back to ground and to the cathode of the tube. If the grid resistor is made too large, these electrons will develop an undesired voltage across this resistor. The size of the resistor is limited by the number of electrons striking the grid of the tube.

(p) The capacitor is used to hold the voltage across the cathode-bias resistor constant. The signal applied to the grid of the tube causes an ac current, which is superimposed on the dc current flowing through the tube, to flow in the cathode circuit. This ac current in effect flows through the bypass capacitor so that the voltage across the bias resistor does not vary.

(q) The output transformer is a step-down transformer. The transformer is primarily an impedance-matching device; it matches the low-impedance speaker to the higher impedance of the tube.

(r) The complete statement is as follows: a power amplifier using one tube such as shown in Fig. 8 is called a single-ended stage, whereas one using two tubes such as shown in Fig. 9 is called a double-ended stage.

(s) A voltage amplifier. The radio frequency amplifier used in a radio or television receiver is used to build up or amplify the voltage of a weak signal picked up by the antenna.

(t) C3 is a screen bypass capacitor. It is used to place the screen at signal ground potential so that the screen will provide maximum shielding between the plate and grid of the tube.

(u) A Class C power amplifier has the best efficiency; a Class A amplifier has the poorest efficiency.

(v) Both detectors and rectifiers work on the principle of allowing current to flow through them in only one direction.

(w) Sixty pulses per second. The rectifier will conduct once each cycle and therefore on a 60-cycle power line you will get 60 pulses per second.

(x) 120 pulses per second. A full-wave rectifier conducts on each half cycle. Since there are two half cycles in each cycle, on a 60-cycle power line you will get 120 pulses.

(y) The increased number of pulses per second from a full-wave rectifier makes it easier to filter the pulsating dc to pure dc. Thus smaller filter chokes and filter capacitors may be used with a full-wave rectifier rather than with a half-wave rectifier.

(z) See Fig. 14.

(aa) The variation in the strength of the signal being received causes the amplitude of the pulses flowing through a diode detector to vary. This variation in signal received is the modulation or intelligence signal that is placed on the rf carrier.

(ab) In the grid circuit. In a grid-leak detector the grid and cathode act like a diode tube. The grid acts like a plate, and when the input signal swings the grid positive, current flows from the cathode to the grid of the tube. When the input signal swings the grid negative, no current flows from the cathode to the grid.

(ac) We can compare the grid-leak detector to a diode detector followed by a triode amplifier stage.

(ad) Part of the signal from the output of the oscillator is fed back to the input circuit. This signal is called the feedback signal or simply feedback.

(ae) See Fig. 17.

(af) The grid bias is developed across the grid resistor, R1. This bias is self-regulating; in other words, if the output of the stage tends to increase, the bias will increase to hold the output down. If the output tends to decrease, the bias will decrease to permit the output signal to increase.

(ag) C3 and L1.

(ah) Feedback is controlled by the feedback capacitors C3 and C4. These capacitors form a voltage divider network to control the amount of signal fed from the output back to the grid-cathode, which forms the input circuit.

(ai) L1, C5, C3 and C4 control the oscillator frequency.

(aj) A sine-wave signal.

(ak) The output signal from a multivibrator is essentially a square wave.

(al) C1 - R2 and C2 - R3 control the multivibrator frequency.

(am) The multivibrator shown in Fig. 19 is called a plate-coupled multivibrator. It is given this name because the energy necessary for oscillation is fed between the tubes from the plate of each tube to the grid of the other tube.

(an) The mixer stage. This stage is sometimes referred to as the mixer-oscillator stage because the two functions of mixing and oscillation are performed in a single tube in a five-tube superheterodyne receiver.

(ao) The oscillator frequency is higher than the frequency of the incoming signal.

(ap) 1956kc. The i-f frequency in a receiver is equal to the difference between the local oscillator frequency and the frequency of the incoming signal. If the oscillator operates higher than the incoming signal, then the oscillator frequency must be equal to the frequency of the incoming signal plus the frequency at which the i-f amplifier operates. Therefore, in this case the oscillator frequency must be 1500 + 456 = 1956 kc.

(aq) The second grid acts as the plate of the triode section of the tube which in turn is the oscillator section.

(ar) The primary winding along with the capacitor connected across it form a parallel-resonant circuit because the signal is fed to the coil and capacitor in parallel. The secondary circuit consisting of the coil and capacitor form a series-resonant circuit because the signal is induced in series with the turns of the coil.

(as) A remote cut-off tube is a tube with a grid specially constructed so that it takes a rather large negative bias to cut off the flow of plate current through the tube. This type of tube is normally used in i-f amplifier stages through which an automatic volume control voltage is fed.

(at) The audio signal voltage is developed by the second detector across a 220 pf capacitor C8.

(au) Bias for the first audio stage is developed across the 6.8 megohm resistor, R8. As you will remember, a few of the electrons leaving the cathode of the tube and travelling toward the plate will actually strike the grid of the tube. These few electrons flowing through R8, which has a high resistance, will develop a small voltage across this resistor having such a polarity that the grid end is negative. This voltage biases the stage.

(av) The power amplifier stage is a Class A power amplifier.

(aw) The chances are good that one of the tubes may have a burned-out heater. Since the tubes are connected in series, if any tube has a burned-out heater this will open the circuit and none of the tubes will light. However if all the tubes are good, there is a possibility that the on-off switch, the line cord, or the line-cord plug may be defective. In addition, the socket into which the receiver is plugged may be at fault. However, in most receivers of this type, when all the tubes fail to light, the heater of one of the tubes is burned out.

(ax) The signal source is placed between grid and cathode, and the load is placed in the plate circuit of the tube.

(ay) The output signal will be greater than the input signal, and the output signal will be 180° out of phase with the input signal.

(az) A cathode follower.

(ba) The signal source is placed between grid and ground, and the load is placed between the cathode and ground.

(bb) The output signal is always lower in amplitude than the input signal. We say that the gain of a cathode follower is less than one - in other words, there is a loss in signal amplitude in this stage.

(bc) In a cathode follower the output signal will be in phase with input signal.

(bd) Where it is important not to change the phase of the signal, and in impedance-matching applications.

(be) The input signal is placed between the cathode and ground, and the load is placed in the plate circuit.

(bf) In a grounded-grid amplifier the grid is grounded and acts to shield the output circuit from the input circuit and by so doing prevents feedback which could cause oscillation.

(bg) Input impedances of both types of stages are high.

(bh) The output impedance of a grounded-cathode stage is comparatively high, but the output impedance of a cathode-follower stage is low.

Lesson Questions

Be sure to number your Answer Sheet B111.

Place your Student Number on every Answer Sheet.

Most students want to know their grade as soon as possible, so they mail their set of answers immediately. Others, knowing they will finish the next lesson within a few days, send in two sets of answers at a time. Either practice is acceptable to us. However, don't hold your answers too long; you may lose them. Don't hold answers to send in more than two sets at a time, or you may run out of lessons before new ones can reach you.

1. Which element of a tube is operated at signal ground potential when the tube is used as a cathode follower?

2. Which class of amplifier is operated with a bias several times cut-off bias?

3. What will normally happen to the average plate current of a properly biased Class A amplifier when a symmetrical ac signal is applied to the amplifier?

4. What is the purpose of R2 in Fig. 6?

5. In the circuit shown in Fig. 11, what current develops bias for the stage?

6. Which type of rectifier, a half-wave or a full-wave, requires more filtering to get pure dc?

7. In which circuit does detection occur in the grid-leak detector?

8. On what basic principle do oscillators work?

9. What does avc found in modern receivers do?

10. What type of amplifier can be used to match a high impedance to a low impedance?

TOMORROW NEVER COMES

The fellow who coined the phrase, "Don't put off till tomorrow what you can do today," was one of the world's wisest men. As a sure-fire formula for success, this certainly hits the nail on the head.

Perhaps NRI men wonder why I repeat this warning so often. It is because I am convinced that of all the reasons for failure, this habit of "putting off" is the greatest. We can always find a good excuse for "putting off." We can easily convince ourselves that we are too tired (or lazy?), or that we don't feel well, or that it's too hot, or that we have too much to do. The reason we are "putting off" is not important; the fact that we are "putting off" is.

The best -- in fact, the only -- way to overcome this temptation is never to succumb to it. The first time you find yourself saying, "I'll skip studying tonight and do twice as much tomorrow," is the time to study twice as hard as usual. Soon you will no longer have to fight temptation; it will no longer exist. It won't occur to you to say, "I'll do it tomorrow." Instead, you will automatically say, "I'll do it now."

HOW TRANSISTORS WORK

B112

STUDY SCHEDULE

By dividing your study into the steps given below, you can get the most out of this part of your NRI Course in the shortest possible time. Check off each step when you finish it.

☐ 1. **Introduction** .... **Pages 1 - 2**
You learn some of the advantages and disadvantages of transistors compared to vacuum tubes.

☐ 2. **Semiconductor Fundamentals** .... **Pages 3 - 13**
You learn about conductors, insulators and semiconductors. You study important characteristics of germanium and silicon and how they are "doped" for use in transistors.

☐ 3. **Current Flow in Semiconductors** .... **Pages 14 - 18**
You study current flow in N-type and P-type semiconductor material.

☐ 4. **Semiconductor Diodes** .... **Pages 18 - 29**
You learn about current flow in diodes with forward bias and reverse bias. You study several important types of diodes.

☐ 5. **Semiconductor Triodes** .... **Pages 30 - 39**
In this section you study PNP and NPN transistors and how they are biased.

☐ 6. **Semiconductor Types** .... **Pages 39 - 52**
In this section you learn about a number of different types of transistors. You also study field-effect and unijunction transistors.

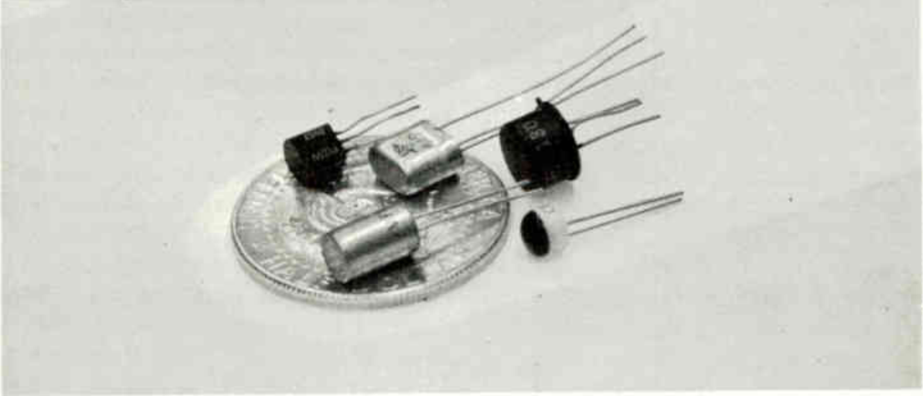
☐ 7. **Answers to Self-Test Questions** .... **Pages 52 - 56**

☐ 8. **Answer the Lesson Questions.**

☐ 9. **Start Studying the Next Lesson.**

PII3M375 1975 EDITION Litho in U.S.A.

HOW TRANSISTORS WORK



In the preceding lessons you studied tubes, and you saw how they are used in different circuits. In this lesson you will study semiconductor devices - these devices have already replaced tubes in many important applications and are rapidly moving into new areas that were once dominated entirely by tubes.

An example of the importance of semiconductor devices can be seen in entertainment-type equipment. Just a few years ago all the rectifiers used in this equipment were vacuum tubes. Today, however, the vacuum tube is no longer used for this purpose; rectifiers in the modern entertainment-type equipment are all semiconductor devices.

Semiconductor devices used as rectifiers have two elements and are called diodes just as two-element vacuum tubes are called diodes. Semiconductors used to amplify signals usually have three or more elements and are called transistors. There are a large number of different types of transistors available today, but for the most part these transistors can be classified into two types, the NPN transistor and the PNP transistor. If you understand how these two transistor types work, you should have little difficulty understanding how all others work and any new transistors that might be introduced in the future. You will run into many different types of transistors identified by different names, but these names usually refer to the method used in manufacturing the transistor rather than the manner in which it operates.

There are some similarities between tubes and semiconductors. A two-element vacuum tube can be used to change an alternating current to a direct current; a two-element semiconductor can be used for the same purpose. A triode vacuum tube can be used to amplify a signal; a transistor can be used for the same purpose. However, this is where the similarity ends. Most tubes are vacuum devices; in other words, all the air and gas have been evacuated from inside the tube. On the other hand, a semiconductor is a solid device and there is no space between the elements in it. We have a current flow through a vacuum in a tube, but we have a current flow through a solid in a semiconductor.

The importance of semiconductors cannot be overemphasized. They have completely supplanted the vacuum tube in portable radio receivers and in automobile receivers. Almost all high fidelity and stereo equipment manufactured today uses semiconductors exclusively - the only tube-operated equipment of this type you are likely to encounter is equipment that is several years old. Semiconductors are finding their way into television receivers and it is probably just a matter of time before they completely replace the vacuum tube.

Semiconductors have several advantages over the vacuum tube. Perhaps one of the most important advantages is that they do not require any heater or filament power. Not only is this a power saving in the operation of the equipment, but it also removes considerable heat from the equipment. Heat is probably the thing that causes the most damage to parts in electronic equipment. Thus with the removal of the heater or filament power from the equipment, other components such as capacitors, etc. will last longer.

Semiconductors are very rugged. They are solid devices and hence not subject to breakage from mechanical shock as tubes are. An important advantage of transistors is that they will operate on a comparatively low voltage, and this usually results in some reduction of the power required in the equipment.

Although semiconductors have many advantages over vacuum tubes, they do have some disadvantages. One disadvantage is that it is usually not possible to get as high a gain in an amplifier stage using a transistor as it is in a similar stage using a tube. Therefore to get the equivalent gain, more transistor stages are required than vacuum-tube stages. Another disadvantage of the transistor is that its characteristics are not as constant as those of a vacuum tube. In other words, you are more likely to run into difficulty replacing a transistor than you are in replacing a tube because the replacement transistor's characteristics might be considerably different from the characteristics of the original transistor. Another disadvantage of both diode semiconductors and transistors is that their characteristics can vary appreciably with changes in temperature. As a matter of fact, some semiconductor devices are easily destroyed by too much heat.

In spite of the fact that semiconductor devices have some disadvantages when compared to vacuum tubes, their advantages more than outweigh the disadvantages and their importance in the field of electronics is continually growing. Therefore it is important that the technician have a good understanding of semiconductor fundamentals, how they are used, and how they operate. Before going ahead to see how semiconductors are used as rectifiers and amplifiers, we need to know more about certain types of atoms, in order to understand how these devices work.

Semiconductor Fundamentals

You have already learned that certain materials will conduct electricity readily and that some materials will hardly pass any electric current at all. The materials that will conduct current readily are called conductors and those that will not conduct current are called insulators. Midway between the two types of materials is a group of materials called semiconductors. These materials are not good conductors, nor are they particularly good insulators. Two examples of semiconductor materials are germanium and silicon. These are the materials that we will be mostly concerned with in this section. Both diode semiconductors and transistors are made from germanium and silicon. A new material that shows promise for use in semiconductors is gallium arsenide. It's likely that this material will be used in semiconductors in the future. Before going ahead with our detailed study of semiconductor materials, let us review a few important facts about conductors and insulators.

CONDUCTORS AND INSULATORS

You will remember that all materials are made up of atoms. An atom is the smallest particle of a material that retains the characteristics of the material.

In the center of the atom is the nucleus. This nucleus contains a positive charge. The number of positive charges on the nucleus distinguishes one material from another. In other words, the nucleus of a copper atom does not have the same number of positive charges as the nucleus of an iron atom.

Each atom normally has enough electrons, which have a negative charge, to exactly neutralize the positive charge on the nucleus. Thus, the hydrogen atom which has a nucleus with one positive charge will have one electron, and the helium atom which has a positive charge of two in the nucleus will have two electrons. Another atom that has a nucleus with 30 positive charges will have 30 electrons to exactly neutralize the positive charge on the nucleus.

The electrons in an atom arrange themselves in shells around the nucleus. The total number of electrons will normally be just enough to neutralize the charge on the nucleus. However, there is a maximum number of electrons that can be forced into each shell. In the first shell around the nucleus, the maximum number of electrons is 2. In the second shell, the maximum number of electrons is 8, and in the next shell the maximum number of electrons is 18. A shell can have less than the maximum number of electrons, but not more than the maximum number.

Conductors.

An example of an atom in a conductor is shown in Fig. 1. We have drawn the shells in the form of rings, but remember that this atom actually has three dimensions, not two. Notice that in this atom there are two electrons in the first shell,

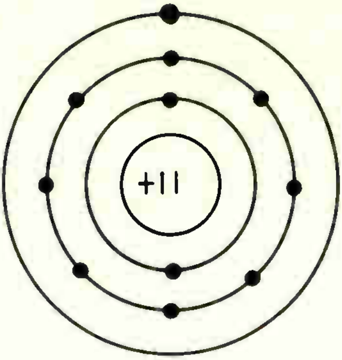


Fig. 1. An atom of a conductor.

8 electrons in the next shell and only one electron in the third shell. The outer shell is called a valence shell. The single electron in the third shell, which is called the valence electron, is not very closely bound to the nucleus; it can easily be removed from the atom. Thus a material of this type has a large number of electrons that can easily be removed from their atoms. When these electrons are forced to move in one direction we have a current flow. Thus a material that has only one or two electrons in an outer shell that could have many more, is a conductor, because the one or two electrons in the outer shell are not closely bound to the nucleus.

Insulators.

An atom of an insulator is shown in Fig. 2. Notice that in this atom there are two electrons in the first shell, and 8 electrons in the second shell. Both the shells are completely filled and will be closely bound to the nucleus. This means that it is very difficult to get one of these electrons out of an atom and therefore this material is an insulator or nonconductor.

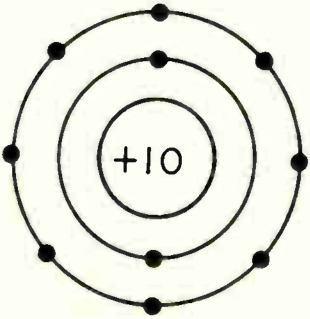

Fig. 2. An atom of an insulator.

Remember the important difference between conductors and insulators. A conductor is a material that has one or two electrons in the outer shell that are not closely bound to the nucleus, whereas an insulator is a material in which the outer shell of each atom is filled or almost filled so that the electrons are closely bound to the atom and cannot be easily removed. Because these electrons cannot be removed from the atom, this type of material normally will not conduct current, and hence is called an insulator.

SEMICONDUCTOR MATERIAL

A material that is classified as a semiconductor has electrical characteristics midway between those of a conductor and those of an insulator. The electrons in a semiconductor can be removed from their atoms when some type of external energy, such as voltage, heat, or light is applied to the material. Then the material acts like a conductor.

The most important semiconductor materials used for transistors are germanium and silicon. The first low-cost transistors were germanium transistors, but recent developments have lowered the cost of silicon transistors so that most of the new transistor types being introduced are silicon. Both germanium and silicon are very abundant elements, but neither is found in the pure state, and it is quite difficult to process them to the high state of purity required for use in transistors. The first transistors were made of germanium because techniques for getting pure germanium were developed first. However, now it is possible to refine silicon to the high degree of purity required, at a reasonable cost, and since silicon has several advantages over germanium for use in semiconductor devices it has in many ways replaced germanium.

In general, there is not too much difference between the operation of semiconductor devices made from germanium and those made from silicon. We will cover the important points of these devices made from both materials since you will run into semiconductor devices of both types.

The Germanium Atom.

The arrangement of electrons about the nucleus in a germanium atom is shown in Fig. 3A. The nucleus of the germanium atom has a positive charge of 32. Thus as you might expect, there will be 32 electrons revolving in the shells about the nucleus. There are two electrons in the first shell, eight in the second, eighteen in the third and four in the fourth shell. Thus, the first, second and third shells are filled, but there are only four electrons in the outer shell. However, these four electrons, which are called the valence electrons, are bound to the nucleus much more so than the one or two electrons found in the outer shell of a conductor.

The important electrons in the germanium atom, insofar as its use in semiconductors is concerned, are the four electrons in the outer shell because the shell is not filled. The other electrons are bound so closely to the nucleus that they cannot easily be removed. Therefore, germanium is often represented as shown in Fig. 3B.

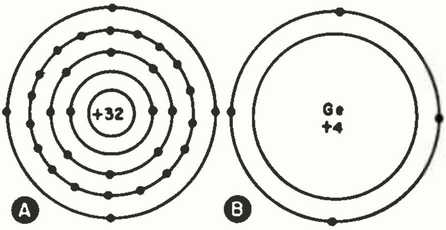

Fig. 3. (A) is the germanium atom with a charge of 32. (B) shows the simplified symbol.

The Silicon Atom.

The arrangement of electrons about the nucleus in a silicon atom is shown in Fig. 4A. The nucleus of the silicon atom has a positive charge of 14. Therefore, there will be fourteen electrons revolving about the nucleus. There are two electrons in the first ring, eight in the second and four in the third. Thus the first and second rings are filled, but there are only four electrons in the outer shell. These four

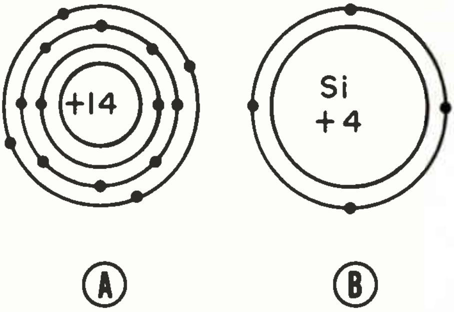

Fig. 4. (A) shows the silicon atom with a charge of 14. (B) shows the outer shell with four electrons.

electrons are the valence electrons like the four in the germanium atom and are bound fairly closely to the nucleus. As in the case of the germanium atom, the four electrons in the outer ring are the ones that are of importance in the use of silicon in semiconductors.

Notice the similarity between the silicon and germanium atoms. In both atoms, the outer shell or ring has four electrons, and all the other shells are filled.

The tendency of some materials like silicon and germanium, that do not have the outer shell completely filled with electrons, is to get additional electrons to fill up the outer shell. In pure germanium and silicon, the electrons in the outer shell of one atom are bound as closely to that atom as the four electrons in the outer shell of another atom. Therefore one atom cannot pull electrons away from another atom. Instead, two nearby atoms will share one outer electron from each atom. In other words, two atoms of germanium may share electrons as shown in Fig. 5A; and two atoms of silicon may share electrons as shown in Fig. 5B. By sharing electrons in this way, each atom will partly fill its outer shell. This pair of shared electrons, one from each of two atoms, is called "a covalent bond".

In order to try to fill its outer ring with electrons, a single germanium atom or a single silicon atom will establish covalent bonds with four other atoms. This arrangement of atoms in a piece of germanium is shown in Fig. 6A. A similar arrangement of atoms in a piece of silicon is shown in Fig. 6B. These pieces of silicon and germanium are called crystals and the way in which they are arranged is called a lattice structure. Each atom shares each of its four valence electrons with one valence electron of another atom to form these bonds.

INTRINSIC CONDUCTION

Even at comparatively low temperatures, there is heat energy in all materials. This energy is sufficient to cause a few of the electrons to move out of their proper place in the lattice structure of either the germanium crystal or the silicon crystal and become free electrons. These free electrons are available for conduction of electric current. The number of free electrons available is much higher in germanium than it is in silicon.

When one of these electrons moves out of its position in the lattice structure, it leaves an empty space in the crystal lattice. This empty space is called a hole. An electron from a

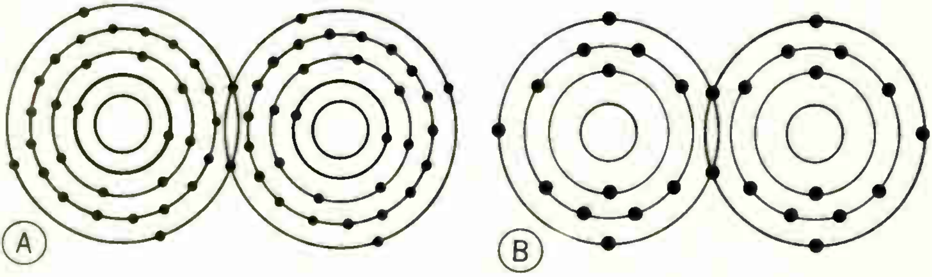

Fig. 5. The sharing of two electrons by two germanium atoms is shown at A; by two silicon atoms at B.

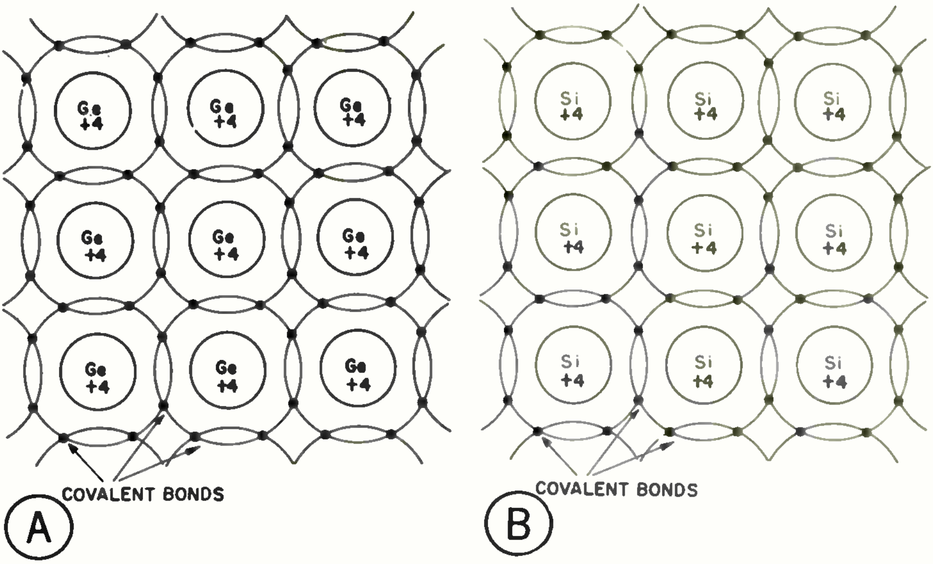

Fig. 6. The lattice structure of germanium is shown at A; of silicon at B.

nearby atom can move into this hole thus creating a new hole at the place it left. Another electron may move out of still another atom to fill this new hole, leaving behind it a hole. This movement of an electron to fill a hole thus creating a new hole in the place it left makes it look as if holes themselves move. Furthermore, since the hole represents a missing electron, it has a positive charge.

In a piece of germanium or silicon, the electrons are in a constant state of motion about their atoms. If in its movement an electron comes closer to a hole than to its own atomic nucleus, it will be strongly attracted to the hole and will leave its atom. When there is no voltage applied across the crystal, the movement of a hole or an electron is a random movement. Holes and electrons may move in any direction.

If heat or some other form of external energy is applied to the crystal, the resistance of the material is reduced. This happens because more electrons are freed by the energy applied to the crystal. In addition, the speed of the random movement is increased.

The movement of an electron out of an atom forms a hole in the atom. Thus, whenever an electron is freed from an atom a hole is formed. This free electron and the hole it forms are called a "hole-electron pair". The formation of hole-electron pairs is a continuous process. Also the filling of holes by electrons is a continuous process. In other words, the process of an electron leaving its atom and forming a hole, and another electron moving in to fill the hole and in so doing creating a new hole, is a continuous process. The conduction of electricity in pure germanium or pure silicon crystals due to the formation of hole-electron pairs is called the intrinsic conduction.

The conductivity of a germanium crystal or a silicon crystal, which is the ability of the material to conduct an electric current, depends on the average length of time an electron is free and on the number of free electrons. We mentioned previously that there are more electrons free if external energy, such as heat, is applied to the material. Therefore the conductivity rises as the temperature of the material is increased.

This type of conduction is much higher in germanium than it is in silicon. As an example, if we had a germanium crystal exactly one centimeter on each side and measured the resistance across two parallel surfaces, we would find the resistance to be approximately 60 ohms. The resistance of an equivalent piece of silicon would be approximately 60,000 ohms. Thus intrinsic conduction is much higher in germanium than it is in silicon.

Intrinsic conduction in transistors is undesirable. It is kept as low as possible by holding the operating temperature of the material down. Transistors are also shielded from light because light is a form of energy and light striking the crystal will increase the intrinsic conduction. Since silicon has a much lower intrinsic conduction than germanium, semiconductors made from silicon are less affected by heat than are semiconductors made from germanium. This is one of the chief advantages of silicon over germanium as a semiconductor material.

In their pure forms, neither germanium nor silicon are useful in semiconductor devices. In fact, in spite of intrinsic conduction, neither material is a good conductor at room temperature; they are both fairly good insulators. To use these materials in semiconductors, controlled amounts of other selected elements called impurities are added to the crystals to alter their characteristics. By adding these materials we can produce two types of silicon and two types of germanium. They are called N-type and P-type. Now, let us study the characteristics of these two types of materials.

N-TYPE MATERIAL

N-type silicon or germanium can be produced by adding as an impurity an element that has five electrons in its outer ring. An example of this type of material is arsenic. Arsenic has a positive charge of 33 on the nucleus and has 33 electrons in the shells surrounding the nucleus. There are two electrons in the first shell, eight in the second, eighteen in the third and five in the fourth or outer shell. In other words, arsenic is just like germanium except that the nucleus has one more positive charge and there is one additional electron in the outer shell.

If a small amount of arsenic is added to the germanium, the arsenic atoms will form covalent bonds with the germanium atoms as shown in Fig. 7. However, to form the covalent bonds with its neighboring germanium atoms, the arsenic atom needs only four of the electrons in its outer shell. Therefore there will be one electron left over when the arsenic atom forms covalent bonds with the four neighboring germanium atoms. This electron is free to move about within the crystal in exactly the same manner as a single valence electron in a good metal conductor. The addition of arsenic, which produces these free electrons, greatly reduces the resistance of the material.

When a small amount of arsenic

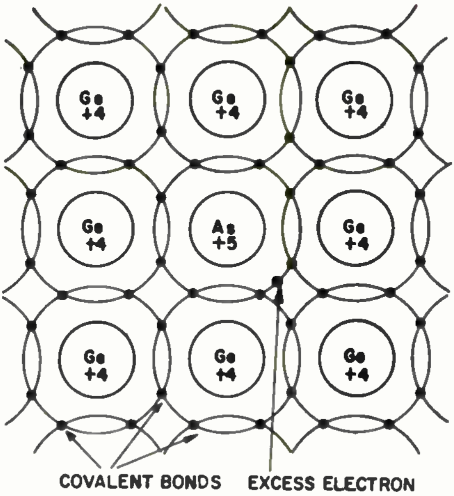

Fig. 7. Germanium with arsenic added.

is added to a silicon crystal exactly the same thing happens. The arsenic atom forms covalent bonds with the silicon atoms. As in the case of the germanium atom, only four of the electrons in the outer shell of the arsenic atom are used in forming these covalent bonds so there will be one electron left over.

When germanium or silicon have had an impurity added to them we say they have been doped. When semiconductor material has been doped with a material such as arsenic that results in there being excess electrons, we call it an N-type material. The N refers to the negative carriers, which are the free electrons. Arsenic is called a donor impurity because it donates an easily freed electron.

In addition to arsenic, other materials have been used as donors. Phosphorus, which has a total of fifteen electrons, can be used. The phosphorus atom has two electrons in the first shell, eight in the second and five in the third. Four of the electrons in the valence shell or ring will form covalent bonds with germanium or silicon atoms leaving a fifth electron free. Antimony, which has 51 electrons, also has been used as a donor. Antimony has two electrons in the first shell, eight in the second, eighteen in the third, eighteen in the fourth and five in the fifth or valence shell.

P-TYPE MATERIAL

If instead of adding a material with five electrons in its valence shell, we add a material with only three electrons in the valence shell, we have a situation where the impurity added to the silicon or germanium has one less electron than it needs to establish covalent bonds with four neighboring atoms. Thus, in one covalent bond there will be only one electron instead of two. This will leave a hole in that covalent bond.

A material that is frequently used for this purpose is indium. Indium has 49 electrons, two in the first shell, eight in the second, eighteen in the third, eighteen in the fourth and three in the fifth or valence shell.

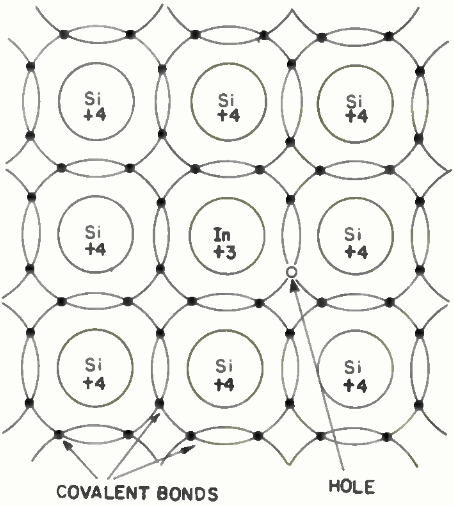

Fig. 8. Silicon with indium added.

The manner in which indium forms covalent bonds with neighboring silicon atoms is shown in Fig. 8. It forms covalent bonds with germanium atoms in the same way.

We mentioned previously that even at comparatively cold temperatures there is some heat energy within the crystal and thus there will be a few free electrons moving about the crystal. These free electrons are strongly attracted to the holes in the covalent bond produced where an indium atom has replaced a silicon or a germanium atom. Thus an electron will move into a hole in the covalent bond producing a new hole in another atom and giving the effect that the hole is moving as shown in Fig. 9.

Since a hole in the crystal actually represents a shortage of an electron, it is an area with a positive charge. Therefore when a semiconductor material has been doped with a material such as indium that produces holes in the lattice structure, we call it a P-type material.

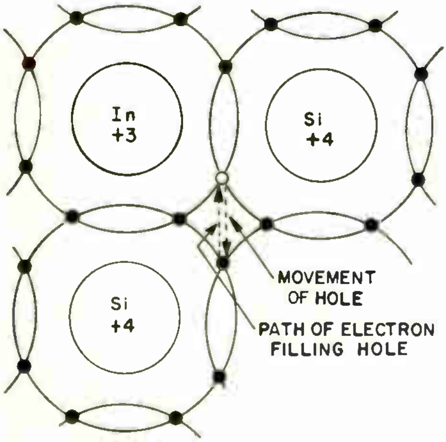

Fig. 9. When an electron fills a hole, another hole will apparently move to where the electron was.

P stands for positive; since holes represent a shortage of an electron we say they act as positive carriers. The indium is called an accepter impurity because its atoms leave holes in the crystal structure that are free to accept electrons. In addition to indium, boron and aluminum are also used as accepter impurities. Boron has 5 electrons, two in the first shell and three in the second which is the valence shell. Aluminum has 13 electrons, two in the first shell, eight in the second and three in the third or valence shell.

CHARGES IN N-TYPE AND P-TYPE MATERIAL

When a donor material such as arsenic is added to germanium or silicon, the fifth electron in the valence ring of the arsenic atom does not become part of a covalent bond. This extra electron may move away from the arsenic atom to one of the nearby germanium or silicon atoms.

The arsenic atom has a charge of +33 on the nucleus and normally has 33 electrons to neutralize this charge. When the electron moves away from the atom there will be only 32 electrons to neutralize the charge on the nucleus, and as a result there will be a small region of positive charge around the arsenic atom. Similarly, the excess electron that has moved into a nearby germanium or silicon atom will provide an excess electron in the atom. In the case of the germanium atom there will be a total of 33 electrons around a nucleus requiring only 32 electrons to completely neutralize it, and in the case of the silicon atom there will be 15 electrons around the nucleus requiring only 14 electrons to neutralize it. This means that the atom will have an extra electron so that there will be a region of negative charge around this atom.

It is important to notice that although there is a region of positive charge around the arsenic atom after the electron has moved away, and a region of negative charge around the germanium or silicon atom taking up the extra electron, the total charge on the crystal remains the same. In other words, a given crystal will have a net charge of zero. This means that there will be exactly enough electrons to neutralize the positive charges on the nuclei on the various atoms. But because some of the electrons may move about in the crystal, there will be regions in the crystal where there are negative charges and other regions where there are positive charges, even though the net charge on the crystal is zero.

In a P-type material to which material such as indium has been added we will have a similar situation. You will remember that the indium atom has only three electrons in its valence ring. These are all that were needed to neutralize the positive charge on the nucleus. However, with only three electrons in the valence ring, there is a hole in one of the covalent bonds formed between the indium atom and the four adjacent germanium or silicon atoms. If an electron moves in to fill this hole, then there is one more electron in the indium atom than is needed to neutralize the charge on the nucleus. Thus there will be a region of negative charge around the indium atom. Similarly, if one of the germanium or silicon atoms has given up an electron to fill the hole in the covalent bond, then the atom which has given up the electron will be short an electron so that there will be a region of positive charge around this atom. Again, while this giving up of an electron by a germanium atom and the acceptance of an electron by the indium atom ionizes or charges both atoms involved, the net charge on the crystal is still zero. We simply have one atom that is short an electron and another atom that has one too many. The crystal itself does not take on any charge.

These ionized atoms produced in both the N-type and the P-type germanium and the N-type and the P-type silicon are not concentrated in any one part of the crystal, but instead are spread uniformly about the crystal. If any region within the crystal were to have a very large number of positively charged atoms, these atoms would attract free electrons from other parts of the crystal to neutralize part of the charged atom, so that the charge would be spread uniformly about the crystal. Similarly, if a large number of atoms within a small region have had an excess of electrons, these electrons would repel each other and spread throughout the crystal.

Both holes and electrons are involved in conduction at all times. Holes are called positive carriers and electrons negative carriers. The one present in greatest quantity is called the majority carrier; the other is the minority carrier. In an N-type material, electrons are the majority carriers and holes are the minority carriers, whereas in a P-type material, holes are the majority carriers and electrons the minority carriers.

SUMMARY

This is a very important section of this lesson. You have covered many of the fundamentals of semiconductors on which we will build the remainder of the lesson. It is important that you understand the basic theory of semiconductors in order to be able to understand how semiconductor diodes and transistors work. We will summarize the important points that were covered in the preceding section.

If any of these points are not clear, you should go back and study the lesson again until they are clear. If you understand the first section of the lesson, you should be able to understand the material following without too much difficulty. However, if you do not understand what has been covered previously, you will have difficulty understanding what is to follow.

Pure semiconductor material such as germanium or silicon is a very poor conductor. In fact, it is an insulator if it is protected from all outside sources of energy. However, even at room temperature there is enough heat present in germanium and silicon to produce some electron and hole movement. The movement is much greater in germanium than it is in silicon.

An electron movement out of a covalent bond in a germanium or silicon atom leaves a hole in that bond. The hole will attract an electron from a nearby atom, producing a hole in that atom. Thus, both the hole and the electron appear to move. The holes are positive carriers and the electrons negative carriers of electricity. This formation of hole-electron pairs is undesirable in transistors and steps are taken to keep it as low as possible. The formation of hole-electron pairs increases as the temperature increases and is a much more serious problem in germanium-type semiconductor material than in silicon-type semiconductor material.

Semiconductor materials can be doped by adding small amounts of impurities. If a material with five electrons in the valence ring is added, the material is called a donor-type impurity. This type of material has one electron left over after it forms covalent bonds with four neighboring germanium or silicon atoms. Thus there will be an excess of electrons. We then refer to this kind of material as an N-type material.

If the germanium or silicon is doped with an impurity, called an accepter impurity, having three electrons in the valence shell, the impurity forms covalent bonds with the four neighboring germanium or silicon atoms. However, there will be a hole in one of the covalent bonds because the impurity has only three electrons available to form covalent bonds with four neighboring germanium and silicon atoms. This type of germanium or silicon is called P-type because there will be holes in the material, and these holes act as positive carriers.

Another point to remember is that when an electron is freed or when a hole captures an electron, the atoms involved become charged, or ionized. Thus throughout both N-type and P-type germanium or N-type and P-type silicon we have small regions of charge. However, the net charge on the crystal is zero and the charged regions are evenly distributed throughout the material.

SELF-TEST QUESTIONS

(a) How many electrons are there in a valence shell or ring in a silicon atom?

(b) What are the two types of material most widely used in semiconductor devices?

(c) What is meant by a covalent bond?

(d) How many covalent bonds will a single germanium or silicon atom establish?

(e) What is intrinsic conduction?

(f) Is intrinsic conduction desirable?

(g) In which type of conductor material, germanium or silicon, is intrinsic conduction the greatest?

(h) What is the greatest cause of an increase in intrinsic conduction in germanium?

(i) Which semiconductor material, silicon or germanium, has greater resistance?

(j) What is an N-type material?

(k) What is a donor material?

(l) Name two materials used as donors.

(m) What is P-type material?

(n) What is an accepter impurity?

(o) Name three types of accepter material.

(p) In N-type material what is the majority carrier?

(q) What are the majority carriers in the P-type material?

(r) When a donor impurity such as arsenic loses an electron in a semiconductor material, what happens to the arsenic and to a nearby atom that gains the electron insofar as their relative charge is concerned?

(s) Although there are small areas that have positive and negative charges in a doped semiconductor, what is the overall charge on the crystal?

Current Flow in Semiconductors

In order to understand how transistors operate, there are several new ideas that you must master. First, you must understand how current flows through both N-type and P-type semiconductor materials. Current flow through an N-type material is not too different from current flow through metals, which you have already studied. However, there is quite a difference in the way current flows through a P-type material.

When a P-type material is placed next to an N-type material, we have what is called a junction. The action that occurs at the point of contact between these two different types of materials is extremely important. It is this action that makes the transistor possible.

In this section of the lesson we will study how current flows through N-type and P-type materials. We need to understand current flow through both types of germanium or silicon to be able to understand how a junction works. In a later section we will see how a junction works. Later, we will see what happens in a transistor, which has two junctions.

This section is extremely important, and you should be sure that you understand it completely. Once you understand this material, it will be a simple step to see how transistors can be used to amplify signals.

DIFFUSION

As we have mentioned, adding impurities to pure germanium or silicon adds free electrons or holes. You might at first think that when there is no voltage applied there would be no motion of the free holes and electrons. However, this is not true--as you learned when we discussed intrinsic conduction, there is a certain amount of energy present in the crystal. This energy might be due to the temperature of the crystal, because as we pointed out before, even at room temperature the crystal does have heat energy. Motion of the free holes or electrons due to energy of this type is at random; in other words there is no net movement in any one direction. Holes move one atom at a time, and any hole may move from its starting location to any of the surrounding atoms. This means that a hole may start off in one direction as it moves from one atom to another, and then may move in almost the opposite direction as it moves to still a third atom. Similarly, electron movement is in a random direction; a given electron may move in first one direction and then in another.

When electrons and holes are in motion, the different carriers are moving in different directions. Remember that when there is a hole in one atom, and an electron moves from another atom to fill that hole, a new hole appears in the second atom. In other words, the electron has moved from the second atom to the first, whereas the hole has moved in the opposite direction from the first atom over to the second atom that gave up the electron. The result is that the effective current flow of any one carrier is cancelled by the movement of the other carrier and the resulting current flow in any direction is zero.

This random motion of carriers is called diffusion. It goes on at all times in a crystal whether there is a voltage applied to the crystal or not. Every effort is made in the design of transistors to keep this diffusion as low as possible.

DRIFT

Another type of carrier movement in semiconductors is known as "drift". This is the type of movement that is obtained when a voltage is applied across the crystal. Since the manner in which current flows through N-type and P-type material is different, let's consider them separately.

N-Type Material.

In Fig. 10 we have shown an N-type crystal with a voltage applied to it. The voltage difference supplied by the battery provides a force which makes it easier for the electrons to move in one direction than in the other. In an N-type material, the electrons will be attracted by the positive terminal of the battery. Because in the N-type material the electrons greatly outnumber the holes, they will carry the current.

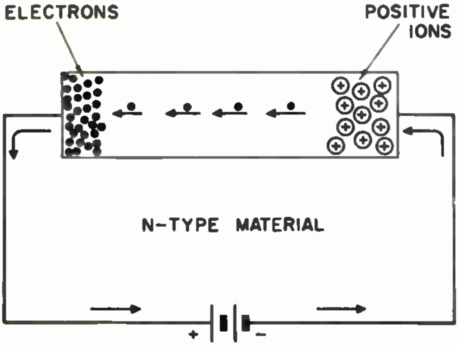

Fig. 10. N-type crystal with voltage applied to it.

When the electrons are attracted by the voltage applied to the positive terminal, they will move towards the positive terminal. When an electron moves away from the covalent bond that produced this free electron, it will leave behind an atom with a positive charge, which we call a positive ion. The electrons moving towards one end of the crystal set up a region that has a local negative charge, as shown in Fig. 10. This negative charge sets up a potential difference between that part of the crystal and the positive terminal of the battery. In other words the attraction of the positive battery terminal causes electrons to bunch up near the end of the crystal connected to the positive terminal. The electrons are drawn from the crystal into the wire connecting the crystal to the positive terminal of the battery by this potential difference.

Meanwhile, the electrons that have left the atoms at the other end of the crystal have left behind positive ions. This sets up a region of positive charge around the end of the crystal connected to the negative terminal of the battery so there will be a potential difference between the negative terminal of the battery and this region of positive charge. This potential difference will pull electrons from the wire into the crystal. These electrons replace the free electrons that were attracted to the positive terminal of the battery.

The number of electrons leaving the crystal at the end connected to the positive terminal of the battery will be exactly equal to the number of electrons entering the crystal at the end connected to the negative terminal of the battery. Since the crystal was electrically neutral be-

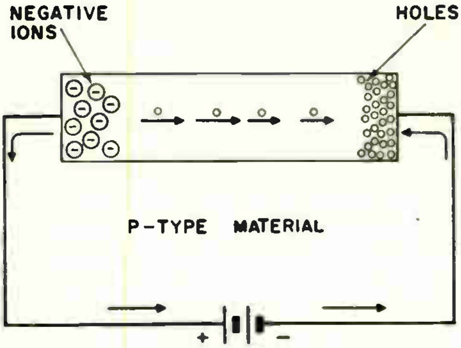

Fig. 11. P-type crystal with voltage applied to it.

fore the battery was connected and the number of electrons in it are constant, the crystal remains electrically neutral.

P-Type Material.

Conduction through P-type material is quite different from conduction through N-type material. In the P-type semiconductor, nearly all of the current is carried by holes. When a battery is applied to a P-type semiconductor, as shown in Fig. 11, the voltage causes the holes to drift towards the negative terminal. They are repelled by the positive potential applied to the one end of the material and attracted by the negative potential applied to the other end. When a hole starts moving away from the end of the material connected to the positive terminal of the battery, it moves because it is filled by an electron attracted from a nearby germanium atom.

When the hole in an accepter type atom is filled with an electron, the atom actually has one electron more than it needs to neutralize the charge on the nucleus. Thus, the atom has a negative charge, or in other words it becomes a negative ion. Negative ions that are formed near the end of the semiconductor that is connected to the positive terminal of the battery build up a region of negative charge at this end of the material. The extra electrons are drawn from these ions by the positive terminal of the battery, and a new hole is formed. These holes then drift towards the end of the semiconductor that is connected to the negative terminal of the battery, and build up a positive charge at this end of the semiconductor. This positive charge attracts free electrons from the external circuit. As a hole is filled with an electron, it disappears.

Thus in the P-type material, we have an electron flow in the external circuit from the negative terminal of the battery to the semiconductor, and from the semiconductor to the positive terminal of the battery. However, in the semiconductor itself, current flow is by means of holes, which drift from the end of the semiconductor that is connected to the positive terminal to the end that is connected to the negative terminal of the battery. Keep this point in mind, that even in the P-type material where conduction within the material is by holes (which are positive carriers) the current flow in the external circuit is by means of electrons and is in the conventional direction from the negative terminal towards the positive terminal of the battery in the external circuit.

There are several important differences between conduction in N-type semiconductors and conduction in P-type semiconductors. In both cases electrons flow from the external circuit into the crystal and then out of the crystal into the external circuit. However, in the N-type crystals, the excess electron produced when a donor atom forms covalent bonds with four germanium atoms is a free electron that can move about in the crystal. However, in the P-type material, the electrons are not free, but can move only to holes. Since a hole can capture an electron from any of its surrounding atoms, it is the hole that is free to move in any direction.

Another important difference between the N-type and the P-type materials is that a free electron moves approximately twice as fast as a hole. This affects the conductivity of the two types of semiconductor material. If we have two crystals, one an N-type and the other a P-type, if the N-type material has the same number of free electrons as the P-type has holes, the N-type will have a lower resistance because the free electrons can move approximately twice as fast as the holes in the P-type material.

SUMMARY

The important thing to remember from this section is that there are two types of carrier movement in semiconductors. The first is called diffusion and is simply a random movement of the carriers in the semiconductor material. The current flow produced by one carrier is cancelled by the movement of the other, and the resultant current flow in any direction is zero. Diffusion is the random motion of electrons or holes in a doped semiconductor due to the energy of the material.

The other type of movement we discussed is called drift. This type of conduction is produced when a potential is connected across a semiconductor. This potential can cause either electrons or holes to move within the semiconductor. In an N-type semiconductor, current flows through the semiconductor because of the movement of the free electrons produced by the donor atoms that have been added to the semiconductor material. In the P-type semiconductor, current flow through the crystal is by means of holes which are produced when an accepter-type impurity is added to the crystal.

In both cases current flow in the external circuit is from the negative terminal of the battery to the crystal and from the crystal to the positive terminal of the battery. In the N-type material, electron flow through the crystal is from the end connected to the negative terminal of the battery to the end connected to the positive terminal of the battery. In the P-type semiconductor, the holes flow from the end of the semiconductor connected to the positive terminal of the battery to the end of the semiconductor connected to the negative terminal of the battery.

The speed with which electrons move through N-type material is about twice the speed with which holes move through P-type material. Thus N-type material has better conductivity than P-type material, which means that N-type germanium will have a lower resistance than P-type germanium.

SELF-TEST QUESTIONS

(t) When an accepter-type impurity is added to a silicon or a germanium crystal, what type of carrier is produced in the crystal?

(u) What is diffusion?

(v) What is the name given to the movement of carriers in a semiconductor material when a voltage is applied across the material?

(w) What are the majority carriers in an N-type material and in what direction do they move when a voltage is applied across the material?

(x) What are the majority carriers in a P-type material and in what direction do they move through the material when a potential is applied across the material?

(y) When current is flowing through a crystal, will the crystal be charged?

(z) Is the rate of travel of electrons through N-type material the same as the rate of travel of holes through P-type material?

(aa) If you had two identical pieces of silicon and one was doped so that it was N-type material and the other doped so that it was P-type material, which would have the lower resistance?

Semiconductor Diodes

Just as there are diode tubes, there are also diode semiconductors. Some diode semiconductors are used as detectors: others are used as rectifiers in power supplies to change ac to pulsating dc. Diodes used as detectors are often referred to as signal diodes. Both germanium and silicon signal diodes are widely used. Diodes used for power rectification are almost exclusively silicon diodes. Relatively small silicon diodes can often handle considerably more current than a large rectifier tube.

A semiconductor diode is made by taking a single crystal and adding a donor impurity to one region and an accepter impurity to the other. This will give us a single crystal with a P section and an N section. Where the two sections meet, we have what is called a junction. Contacts are fastened to the two ends of the crystal so that a simple PN junction diode like the one shown in Fig. 12 is formed. For simplicity in the diagram we have represented the crystal as a box-like structure with one half being P-type material and the other half N-type material with a junction between the two sections.

This type of diode is called a junction diode. The action that takes place at the junction of the P-type crystal and the N-type crystal is what we will be most concerned with now. In order to understand how a junction diode works, you must learn something about the movement of electrons and holes near the junction. The movement of holes and

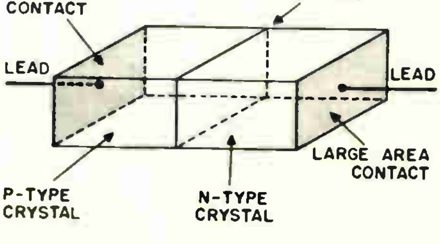

Fig. 12. Simple PN junction.

electrons will form what is called a depletion layer at the junction. Now let us see what the depletion layer is and how it is formed.

DEPLETION LAYER

Remember that in an N-type crystal there are free electrons, and in a P-type crystal there are free holes. Also remember that the electrons and holes are moving about the crystal with a random motion, called diffusion. In the PN junction diode, holes will be moving about in the P section and electrons in the N section. Some of the holes will cross over the junction from the P section into the N section and be filled by a free electron. Similarly, some of the electrons in the N-type material will diffuse across the junction and fill a hole in the P section.

When an atom in the N section loses an electron the atom becomes charged or ionized. It will have a positive charge because it will have one less electron than is needed to completely neutralize the charge on the nucleus. Thus electrons diffusing across the junction to fill a hole on the P side of the junction will leave behind atoms with a positive charge. At the same time, when an electron fills a hole on the P side, the atom will have one more electron than it needs to completely neutralize the charge on its nucleus, and therefore that atom will have a negative charge. Similarly, holes diffusing from the P side of the junction over into the N side will leave behind atoms with a negative charge. When the hole moves over to the N side, it will mean the atom into which it moves will have an electron missing and therefore it will assume a positive charge. When the hole leaves the P side of the junction because it has been filled by an electron, the atom that gains the extra electron will have a negative charge.

As a result of this diffusion across the junction, a region will build up around the junction called the depletion area. On the P side of the junction there will be an area where the holes are missing. On the N side of the junction there will be an area where electrons are missing; thus we get the name depletion layer.

The missing holes on the P side of the junction will result in a negative charge on the P side and the missing electrons on the N side will produce a positive charge on the N side of the junction. The negative charge on the P side of the junction will build up until it has sufficient amplitude to prevent any further electrons from the N side from crossing the junction to the P side. Remember that the negative charge built up on the P side of the junction will repel electrons from the negative side. Similarly, the positive charge built up on the N side of the junction will prevent holes from the P side from crossing the junction into the N-type material. Thus this area, which is called the depletion layer because it is short holes on one side and electrons on the other side, is also sometimes called the barrier layer, because the charges built up form barriers to prevent any further diffusion of holes or electrons across the junction. It is also sometimes called a potential barrier because a negative potential is built up on the P side of the junction and a positive potential is built up on the N side of the junction.

The action taking place at the junction is quite important and is illus-

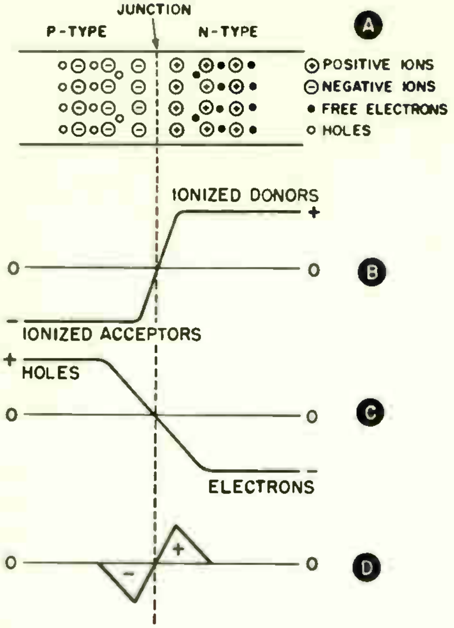

Fig. 13. (A) locations of ions and carriers at a PN junction; (B) charges at junction due to ionized impurity atoms; (C) carrier charges available; (D) resultant charges.

trated in Fig. 13A. On the P side of the junction we have shown ionized atoms that have a negative charge because the holes in these atoms have been filled by electrons. The holes have escaped and travelled or diffused across the junction into the N-type material. On the N side of the junction we have shown atoms that are ionized and have a positive charge. These atoms have a positive charge because they have lost electrons. These electrons have diffused across the junction into the P-type material. Thus we have a charged area at the junction. The negative charge on the P side of the junction prevents any further movement of electrons from the N-type material across the junction into the P-type material, and the positive charge on the N side of the junction prevents any further movement of holes from the P-type material across the junction into the N-type material.

The charge on the ions is shown in Fig. 13B. Notice that on the P side of the junction the atoms that have lost holes by gaining electrons have a negative charge. At the junction the potential drops to zero and then reverses on the N side where the ionized atoms have a positive charge because they have lost electrons.

In Fig. 13C we see the carrier charges which are available to neutralize the ionized atoms. At some distance from the junction there are holes with a positive charge. However, as we approach the junction, the concentration of these holes decreases because they are repelled away from the junction by the positive ions on the N side of the junction. On the N side of the junction at some distance from the junction we have many electrons available, but as we approach the junction, the charge drops to zero because these electrons are repelled away from the junction by the negative ions on the P side of the junction.

The resultant charges on the crystal are shown in Fig. 13D. As before, the crystal will have a tendency to remain neutral, or in other words not to have any charge. Some distance from the junction the atoms will have exactly the correct number of holes and electrons so that the net charge on the atoms is zero. As we approach the junction, the negative ions on the P side will result in an area in the crystal that has a negative charge. As we move closer to the junction, the charge will drop to zero so that at the junction itself the net charge on the atoms is zero. Then the charge builds up in a positive direction on the N side of the junction due to the ionized atoms that have lost electrons. As we move away from the junction we again reach a region where the atoms have exactly the correct number of electrons to neutralize the charges on the nucleus so the net charge in that area will be zero.

So far we have been discussing only the action of the majority carriers at the PN junction. However, there is one other important point we must consider in order to completely understand what happens at the junction. You will remember some time ago that we mentioned that holes and electrons are in a continuous state of motion in the crystal due to the energy of the crystal. For example, even at room temperature, the crystal contains a certain amount of heat energy and this energy is sufficient to cause motion of both electrons and holes. In the N-type material an electron will leave an atom creating a hole. This hole will be filled by an electron from another atom. Thus we have the continual formation of hole-electron pairs. Away from the junction, this formation of hole-electron pairs does not have any effect on the carrier concentration in the crystal. In other words, the holes will remain the majority carriers in the P-type region, and the electrons will remain the majority carriers in the N-type side of the crystal.

However, as we mentioned previously, both holes and electrons are involved in conduction at all times. There are minority carriers in both regions - holes in the N region and electrons in the P region. The holes produced in the N region near the junction will be attracted by the negative ions on the P side of the depletion layer at the junction and pass across the junction. These holes will tend to neutralize the ions on the P side of the junction. Similarly, free electrons produced on the P side of the junction will pass across the junction, and neutralize positive ions on the N side of the junction. This is an example of intrinsic conduction, conduction due to the formation of hole-electron pairs, and as we mentioned, this type of conduction is undesirable.

Now let us consider what happens due to the minority carriers crossing the junction. Holes crossing the junction from the N-type material to the P-type material tend to neutralize the negative ions on the P side of the junction. Similarly, electrons traveling from the P side of the junction to the N side of the junction tend to neutralize the positive ions on the N side of the junction. This flow of minority carriers across the junction weakens the potential barrier in the region around the atoms they neutralize. When this happens, the majority carriers are able to cross the junction at the location of the neutral atom. This means that the holes from the P side will cross over to the N side, and electrons from the N side will cross over to the P side.

The result is that we have both holes and electrons crossing the junction in both directions. The hole that crosses from the N side to the P side due to intrinsic conduction permits a hole to cross from the P side to the N side by diffusion. Similarly, an electron that crosses the junction from the P side to the N side due to intrinsic conduction permits another electron to go from the

N side to the P side by diffusion. The result of the holes and electrons crossing the junction in both directions is that these movements cancel each other, and the charge on the atoms at the junction remains the same. This movement of holes and electrons in both directions contributes nothing towards the net charge or current flow through the junction. However, the flow across the junction will produce a certain amount of heating; it will in effect use up a percentage of the total capacity of the junction to pass current so that the net result is to reduce the amount of useful current the diode can pass.

BIASED JUNCTIONS

If a battery is connected to the ends of a PN junction diode, the battery potential will bias the junction. If we connect the battery so that its polarity aids the flow of current across the junction, we call it a "forward-biased junction", whereas if we connect the battery so that the polarity opposes the flow of current across the junction, we say that it is a "reverse-biased junction". In both cases there will be some current flow through the junction, but as you might expect, with forward bias the current flow will be higher.

In order to understand how transistors work, you must understand both conditions of bias. You will study each condition separately, because the action that occurs at the junction is quite different in the two cases. In the operation of transistors both types of bias are used, and therefore it is important that you understand what happens in each case.

Forward Bias.

When we connect a battery to a junction diode with the polarity such that it aids the movement of majority carriers across the junction, we say that the diode is forward biased. A forward-biased junction is shown in Fig. 14. Here the positive terminal of the battery is connected to the P-type section and the negative terminal of the battery is connected to the N-type section. Now let us consider what happens to the depletion layer at the junction of the P and N-type material when the battery voltage is applied.

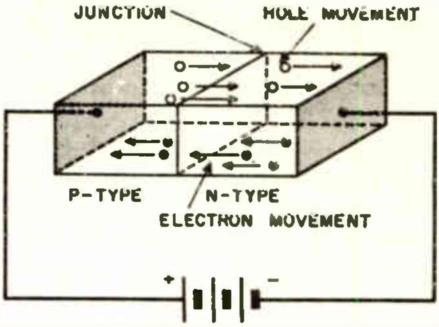

Fig. 14. Forward-biased junction.

The positive voltage connected to the end of the P-type crystal will repel holes towards the junction and attract electrons from the negative ions near it. The combination of holes moving towards the junction to neutralize charged negative ions on the P side of the junction and electrons being taken from the negatively charged ionized accepter atoms tends to neutralize the negative charge on the P side of the junction.

On the N side of the crystal, the negative terminal of the battery repels electrons towards the junction. These electrons tend to neutralize the positive charge on the donor atoms at the N side of the junction. At the same time the negative potential at the N side of the crystal attracts holes away from the charged positive ions on the N side of the junction. Both of these actions tend to neutralize the positive charge on the donor atoms at the junction.

The effect of the battery voltage is to reduce the potential barrier at the junction and allow more majority carriers to cross the junction. This means that we will have more electrons flowing from the N-type material across the junction to the P-type material and to the positive terminal of the battery and more holes traveling from the P-type material across the junction to the N-type material and towards the end of the crystal connected to the negative terminal of the battery. You know that we already had a certain number of intrinsic minority carriers crossing the junction, but now the majority carriers outnumber them, so there will be a steady current flow from the negative battery terminal, through the N-section, across the junction and through the P-section, to the positive battery terminal.

Placing a forward bias on a junction diode drives majority carriers back into the depletion layer and allows conduction across the junction. If the battery voltage is increased, more carriers will arrive at the junction and the current flow will increase. Eventually, if we continue to increase the battery voltage, we will reach a point where all the charges at the junction are neutralized. When this happens, the holes will fill the P-type region right up to the junction; electrons will fill the N-type region up to the junction; and the only limit to current flow through the diode will be the resistance of the material on the two sides of the junction.

It is important for you to remember that in a forward biased junction conduction through the crystal will be by the majority carriers. Any intrinsic conduction across the junction will be by minority carriers and this will subtract from the total current flow across the junction. Increasing the forward bias will increase the current flow across the junction until the point is reached where all the charges at the junction are neutralized, at which time the potential barrier will disappear, and current flow across the junction will be unhindered by any potential across the junction.

Reverse Bias.

If we reverse the battery connections we will have what is known as reverse bias. This condition is shown in Fig. 15.

With a reverse bias applied to a junction diode, the negative terminal of the battery will be connected to the P-type section, and will attract holes away from the junction, and increase the shortage of holes on the P side of the junction. At the same time the positive terminal of the battery is connected to the N-type section of the crystal and this

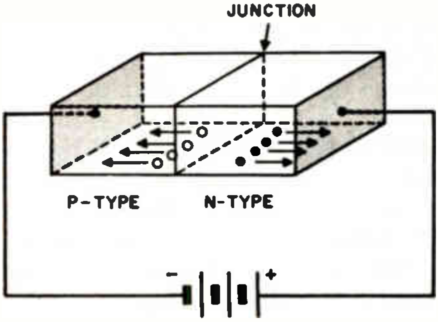

Fig. 15. Reverse-biased junction.

terminal will attract electrons away from the junction and increase the shortage of electrons on the N side of the junction. This movement of holes and electrons away from the junction will in effect result in an increased potential barrier at the junction. The increase in potential barrier occurs because there will be fewer holes on the P side of the junction to neutralize the negative ions and fewer electrons on the N side to neutralize the positive ions formed on this side of the junction. The increase in potential barrier will help prevent any further current flow across the junction due to majority carriers.

The current flow across the barrier, however, is not zero because we will still have minority carriers crossing the junction. Holes forming in the N side of the depletion layer will be attracted by the negative potential applied to the end of the P-type section of the crystal, and electrons breaking loose from their nuclei in the P side of the depletion layer will be attracted by the positive voltage applied to the end of the N-type section of the crystal.

We had this situation when there was no bias applied to the junction. Holes from the N side would cross over to the P section, and electrons from the P side would cross over to the N section. However, when there was no bias applied to the crystal, these minority carriers would neutralize ions near the junction and allow the majority carriers to cross the junction. However, since the minority carriers are now attracted away from the junction by the potential applied to the crystal, all of the minority carriers do not remain near the junction to neutralize charged atoms so they no longer allow the passage of an equal number of majority carriers in the opposite direction. This means that the flow of minority carriers across the junction is not fully offset by a flow of majority carriers in the opposite direction. Therefore, there will be a small current flow across the junction due to the minority carriers crossing the junction. This current flow is very small and nearly constant at all normal operating voltages in signal diodes and power rectifier diodes. However, as you will see later, there are certain types of diodes where this reverse current can increase quite rapidly even at low voltages.

It is important to realize that when a reverse bias is applied to a junction diode, the bias increases the potential difference across the junction and makes it more difficult for majority carriers to cross the junction. However, some minority carriers will still cross the junction with the result that there will be a small current flow across the junction due to the minority carriers.

COMPARISON OF JUNCTION DIODES AND VACUUM TUBES

Although the operation of junction diodes designed for use as rectifiers is quite different from the operation of vacuum tubes, they can perform identical tasks and therefore some comparison of the most important characteristics of both is in order.

When there is no voltage applied to a junction diode, the net current flow across the junction is zero. On the other hand, in a vacuum tube, even though there may be no voltage applied to the plate of the tube, some of the electrons will leave the cathode with sufficient velocity to travel across the space between the cathode and the plate and strike the plate. This will result in a small current flow from the cathode to the plate of the tube even though there may be no voltage applied to the plate of the tube.

We can consider applying a positive voltage to the plate of a vacuum tube and a negative voltage to the cathode as being similar to placing a forward bias on a junction diode. Under both circumstances there will be a current flow through the diode. In this respect the two are similar.

When the voltages applied to the diode vacuum tube are reversed so that there is a negative voltage applied to the plate and a positive voltage to the cathode, there will be no current flow at all through the tube. The negative potential on the plate of the tube will repel electrons from the plate. This reverse voltage situation is similar to a reverse bias across a junction diode. However, when we place a reverse bias across a junction diode, there will be some current flow across the junction due to the conduction by minority carriers. As long as the breakdown voltage of the junction diode is not exceeded, this current will be very small and almost constant. In a good diode, it is so small it can be ignored.

We can summarize the characteristics of diode vacuum tubes and junction diodes as follows: with forward bias both the tube and junction diodes will conduct. With reverse bias, the tube will not pass current; the junction diode will pass a small current. With no bias, the tube will pass a small current; the junction diode will not.

ZENER DIODES

In junction diodes designed for use as rectifiers we must be careful not to exceed the rated reverse voltage of the diode. In other words, if we place too high a reverse bias across the junction, the junction will break down, a very high current will flow across the junction for a short while, and the diode will be destroyed. However, in some diodes we make use of this reverse current due to minority carriers. In diodes of this type both the P section and the N section are doped quite heavily. The junction between the P section and the N section is considerably larger than the junction of the rectifier-type diode, so that when the diode begins to pass current in the reverse direction, it can pass it over a larger area and thus avoid destroying the diode. This type of diode is used as a voltage reference and is referred to as a voltage-reference diode or a Zener diode.

In the Zener diode, the current remains small with low reverse voltages. At a certain voltage, called the breakdown voltage, the current will increase rapidly with any further increase in voltage.
