The breakdown voltage can be varied by varying the diode material and construction. Zener diodes can be made with a breakdown voltage as low as 1 volt, up to breakdown voltages of several hundred volts. The current that can pass through any Zener diode before the diode will be damaged will depend upon the junction area and the methods used to keep the diode cool.

In a circuit where a Zener diode is used, it will be used as a voltage reference or a voltage regulator. As the reverse voltage across the diode

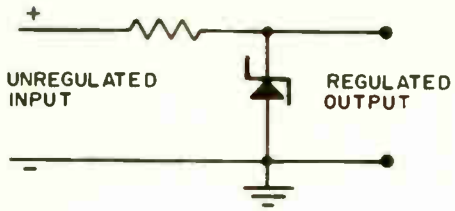

Fig. 16. Circuit using Zener diode as a voltage regulator.

increases, a very small reverse current will flow, and the value of this current will remain essentially constant until the breakdown voltage is reached. At that voltage, any further increase in voltage will result in a large increase in current across the junction. This large increase in current tends to produce a voltage drop in other components in the circuit so that the voltage across the diode will remain essentially constant. Thus a Zener diode can be used as a voltage regulator in a circuit such as shown in Fig. 16. If the input voltage tends to rise, the current through the diode will increase. This increase in current will increase the voltage drop across the resistor so that the output voltage will remain essentially constant. The fact that with even a very small increase in voltage the current through the diode will increase substantially means that the voltage across the diode will remain almost constant.

In some other applications the diode may be used as a reference voltage. This simply means that a Zener diode with a given breakdown voltage is used in a circuit like Fig. 16. The voltage applied to the diode will remain essentially constant. In some circuits, we may compare the voltage across a resistor or another part with the voltage across the Zener diode.

TUNNEL DIODES

A tunnel diode is a highly doped junction diode made either of germanium or gallium arsenite. Both the N region and the P region of the diode are very highly doped. As a result of the high doping, the depletion region around the junction is extremely narrow. Because of the narrow depletion region, holes and electrons can cross the junction by more or less tunneling from one atom to another. The exact action of the charges crossing the junction is somewhat difficult to visualize, but the characteristics of the tunnel diode are comparatively simple. With a reverse bias across the junction, current across the junction increases quite rapidly. If the reverse bias is dropped to zero the current will drop back to zero. If the forward bias, starting at zero and gradually increasing, is placed across the junction, current flow across the junction will increase at essentially the same rate as it increased with a negative bias. The current across the junction will increase quite rapidly as the forward bias is increased until a rather sharp peak is reached. If the forward bias is increased beyond this point, then the current begins to decrease.

As the forward bias is increased still further, the current across the junction decreases, forming a curve such as shown in Fig. 17. This decreasing current, with increasing voltage, results in a negative resistance characteristic. It might be difficult to visualize what a negative resistance is, but you will remember from Ohm's Law that re-

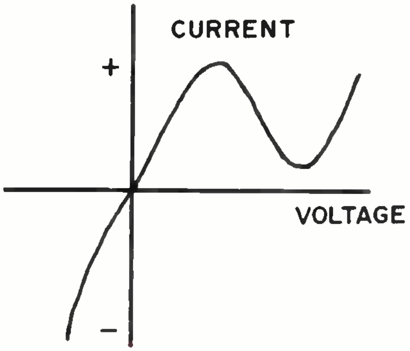

Fig. 17. Voltage-current relation in a tunnel diode.

sistance is equal to voltage divided by current. In a circuit where we have resistance, if the resistance is constant and the voltage increases, then the current must increase; and similarly if the voltage decreases, the current must decrease. Here in the tunnel diode we have a region where the opposite happens. If the voltage increases, the current decreases and if the voltage decreases, the current increases. Thus we have something in the circuit that is giving us the opposite effect of resistance; we call this negative resistance. You will remember that resistance in a circuit introduces losses. It is the resistance in a resonant circuit that prevents a resonant circuit from continuing to oscillate once it has been excited into oscillation. However, if we can put something with negative resistance in the circuit, for example a tunnel diode, since it has the opposite effect of resistance, then the circuit should continue to oscillate. Tunnel diodes can be used for this purpose.

At the present time, tunnel diodes have not appeared in the commercial entertainment-type equipment. However, it is probably just a matter of time until they are used; therefore you should at least have some basic knowledge of what the tunnel diode is.

P-I-N DIODES

The p-i-n diode, which is an abbreviation from positive-intrinsic-negative, is a new diode which is used in a somewhat different manner from the diodes you have studied previously. Rather than being used as a detector or rectifier, this diode is used primarily as a variable resistor. It is a special type of diode, and its resistance can be controlled by applying a dc bias to it. With a reverse bias across the diode, it has a very high resistance. With no bias, its resistance drops to about 7000 ohms, and with forward bias it drops to a comparatively low value.

The diode is particularly useful in circuits where the strength of a signal must be controlled. Its first commercial use has been in fm equipment and it is used in order to prevent extremely strong fm signals from causing overloading in the fm receiver. A dc bias is applied to the diode and the amplitude of the bias depends upon the strength of the signal. When a very strong signal is applied, the reverse bias applied to the diode increases so that the resistance of the diode increases. This reduces the strength of the signal fed to the mixer and i-f stages in the receiver and thus prevents overloading, particularly in the last stage of the receiver.

At this time p-i-n diodes are not widely used in commercial applications, but you should be aware of how the diode is used, because it is quite likely that it will be widely used in the future.

POINT-CONTACT DIODE

Another semiconductor diode is the diode detector used in many TV receivers. This detector is a point-contact diode. A cut-away view of a point-contact diode is shown in Fig. 18 along with the schematic symbol.

The point-contact diode is made of a small piece of either N-type or P-type germanium or silicon. N-type germanium or silicon is used more often than P-type. In manufacturing a diode of N-type material, a large contact is fastened to one side of the crystal. A thin wire, called a catswhisker, is attached to the other side of the crystal. When the catswhisker is attached to the N-type crystal, a small region of P-type material is formed around the contact as shown in Fig. 19. Thus we have a PN junction that performs in much the same way as the junctions we have already discussed.

The characteristics of the point-contact diode under forward and reverse bias are somewhat different from those of the junction diode. With forward bias the resistance of the diode is somewhat higher than that of a junction diode. With reverse bias the current flow through a point-contact diode is not as independent of the voltage applied to the crystal as it was in the junction diode. In spite of these disadvantages, the point-contact diode makes a better detector than the junction diode, particularly at high frequencies because the point-contact diode has a lower capacity than the junction diode.

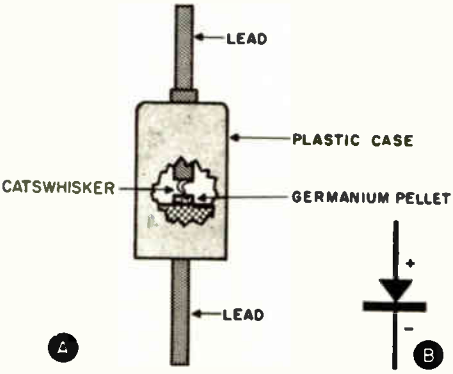

Fig. 18. (A) cut-away view of crystal rectifier. (B) schematic symbol of it.

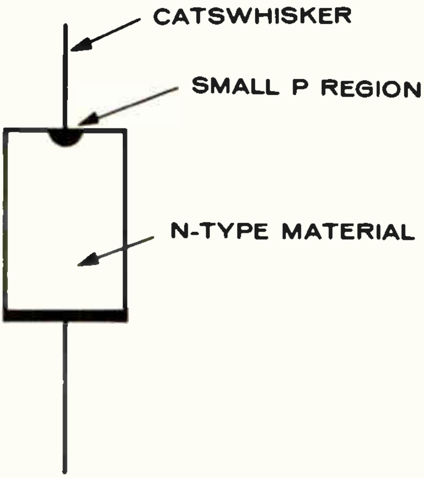

Fig. 19. Sketch of a point-contact diode showing where the P-type germanium is formed around the catswhisker.

SUMMARY

Again this is a very important section, so you should review it before going on to the next section. Make sure you understand what the depletion layer is and why it is formed. Also be sure you understand the movement of holes and electrons across a PN junction when no voltage is applied to the junction.

Current flow across the junction with both forward and reverse bias is important. With forward bias current flow across the junction is by majority carrier, and with reverse bias it is by minority carrier.

Semiconductor Triodes

Even though a junction diode will pass current in both directions, it passes current in one direction much better than it does in the other, and therefore it can be used as a detector. The tunnel diode can be used as an oscillator, and in some special circuits as an amplifier; however, its usefulness in these applications is limited. In most cases, the semiconductor diode is like the vacuum-tube diode; it is more or less useless insofar as amplifying a signal is concerned. In order to amplify a signal, a three element semiconductor is needed. Three element semiconductors that are capable of amplification are called transistors.

There are a number of different types of transistors in use today. The characteristics of the different types vary appreciably, but if you understand the operation of one type, you can understand how the others work without too much difficulty. We started our explanation of semiconductor devices with a junction diode, so we will start our study of triode semiconductors with a study of the junction transistor. You'll find that most of the transistors you will study operate in a manner similar to the basic junction transistor. The most notable exception to this is the field-effect transistor which you will study later in this lesson.

JUNCTION TRANSISTORS

Both germanium and silicon are used in the manufacture of junction transistors. A triode-junction transistor is made up of single semiconductor crystals with three different regions. The center region is made up of one type of germanium or silicon, and the two end regions are made up of the other type of germanium or silicon. In other words, in one type of junction transistor the center has had accepter-type region impurities added and the two end regions have had donor-type impurities added. In the other type of junction transistor, the center region has had donor-type of impurities added and the two end regions have had accepter-type impurities added.

The center region of the transistor is called the base. This is usually a comparatively thin region. One of the end sections is called the emitter and the other end section is called the collector.

If the center section of the crystal has been treated with donor-type impurities, then the center section becomes N-type germanium in the case of a germanium transistor or N-type silicon in the case of the silicon transistor. In this case, the two end sections will be treated with accepter-type impurities and they will both become P-type germanium or P-type silicon. We call this type of transistor a PNP transistor. We can have both germanium PNP and silicon PNP transistors. An example of this type of junction transistor is shown in Fig. 20A along with the schematic symbol used to identify it.

The other type of junction transistor is an NPN type. This type of transistor is produced by treating the center section with an accepter-

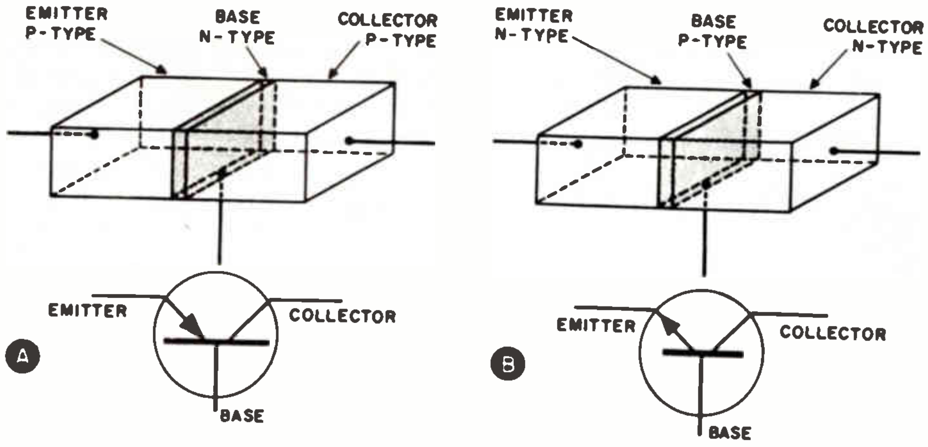

Fig. 20. (A) shows a PNP junction transistor and its schematic symbol. (B) shows an NPN junction transistor and its schematic symbol.

type impurity to produce P-type germanium or silicon, and the two end sections with a donor-type of impurity to produce N-type germanium or silicon. This is the type of junction transistor shown in Fig. 20B along with the schematic symbol for it. As in the case of the PNP transistor, we can have either an NPN germanium transistor or an NPN silicon transistor.

Notice that the schematic symbols for the PNP transistor and the NPN transistor are different. In the PNP transistor the arrow used to represent the emitter points down toward the base, whereas in the NPN transistor the arrow on the emitter points up away from the base. Thus on a schematic diagram of a piece of equipment using junction transistors, you can tell from the direction in which the arrow is pointing whether the transistor is a PNP or an NPN transistor.

There are several different ways of manufacturing junction transistors, and often you hear these transistors referred to by the manufacturing method used. For example a junction transistor might be called a grown junction, a fused junction, an alloy junction or a diffused junction. All these names simply describe the manufacturing process used to make the transistor. They are all junction transistors and all operate on the same basic principle. This does not mean to imply that the characteristics of all junction transistors are the same; they are not. There are wide differences in characteristics just as there are in various triode vacuum tubes.

To understand how junction transistors work, you must understand junction diodes. Because it is so important that you understand the formation of the depletion layers at the junctions we will review the explanation of what happens at the junctions in explaining the junction transistors. The big difference between the junction transistor and the junction diode is that in the transistor there are two junctions close together in the same crystal. One of these junctions is biased in the forward direction and the other in the reverse direction and the presence of one junction affects the operation of the other.

PNP TRANSISTORS

In transistor operation, the emitter-base junction is always biased in the forward direction and the collector-base junction is biased in the reverse direction. Each of the two junctions by itself behaves just like the PN junction already described.

Let us consider what happens in the PNP transistor before any voltages are applied to the transistor.

At the junctions, holes from the P-type emitter section and the P-type collector diffuse across the junctions into the base. At the same time, electrons from the base diffuse across the junctions into both the emitter and the collector. The holes diffusing into the base place a positive charge on the atoms near the junctions. Similarly the electrons diffusing from the base into the emitter on one side of the base and the collector on the other side of the base place a negative charge on the atoms on the emitter and collector sides of the junctions. These charged atoms, which are called ions, will repel electrons and holes from the region of the junctions. The positively charged ions in the base will repel holes in the P sections away from the junctions. Similarly, the negatively charged ions in the emitter and collector will repel electrons away from the junctions in the base. Thus we have two depletion layers formed, one at the emitter-base junction and the other at the base-collector junction.

You will remember that when we discussed the junction diode, we mentioned that hole-electron pairs will be formed in the depletion region. The minority carriers formed in each section can cross over the junction. For example, the electrons released in both the emitter and the collector regions will cross the junctions into the base. These electrons will neutralize a few ions in the base region. When these ions are neutralized they will allow majority carriers from the emitter and collector to cross the junctions. In other words, there will be holes from the emitter and holes from the collector crossing the junctions into the base. Similarly, holes, which are the minority carriers in the base region (and are formed in the depletion layer) will cross the junctions into the emitter and collector. When these holes cross the junctions they will neutralize some of the nega-

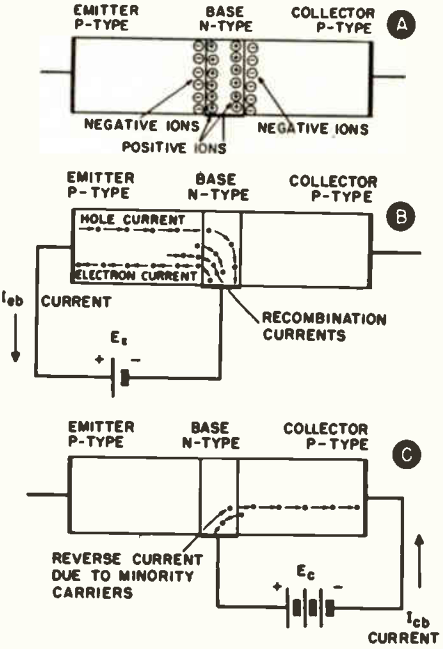

Fig. 21. (A) the formation of ions at the junctions of a PNP transistor. (B) the current flow in the emitter-base circuit and (C) in the collector-base.

tively charged ions in the emitter or collector region and allow some electrons to flow from the base into either the emitter or the collector. Thus, because of the intrinsic conduction due to hole-electron pairs being formed in the depletion region there will be some flow of carriers across the junction. However, the flow of majority carriers across the junction will be exactly equal to the flow of minority carriers across the junction so that the net current flow across each junction will be zero.

The potential barriers formed at the junction regions are shown in Fig. 21A. Notice that the charges formed at the junction are similar to those formed at a junction diode; we simply have two junctions to consider in a transistor.

Now when we place a forward bias between the emitter and the base we have an arrangement like that shown in Fig. 21B. Here the positive voltage applied to the end of the P-type emitter repels holes towards the junction. These holes tend to neutralize the negative charge on the ions on the emitter side of the junction. The holes are formed at the end of the P-type section by electrons being taken out of this section by the positive potential applied to it. At the same time the positive potential applied to the emitter attracts the electrons that have given the ions on the P side of the junction their negative charge. This also weakens the negative charge on the emitter side of the junction.

At the base, which is connected to the negative side of the battery, the holes will be attracted toward the negative terminal of the battery, and electrons will be pushed towards the depletion layer. The pulling of holes away from the depletion area and pushing electrons into the depletion area tends to neutralize the charge on the base side of the junction.

The net effect of biasing in a forward direction is to neutralize the charges on each side of the junction and allow current to flow across the junction. Current flow is by majority carriers: electrons from the N-type base region and holes from the P-type emitter region.

Thus in the emitter-base circuit we have electrons flowing from the negative terminal of the battery to the base, through the base, across the junction, and through the emitter to the positive terminal of the battery. At the same time we have holes being produced because electrons are being pulled out of the P-type emitter by the positive potential applied to it. The holes will move through the emitter, across the junction into the base and to the point where the base is connected to the negative terminal of the battery. At this point they will pick up electrons and disappear.

Not all the electrons going from the base to the emitter will reach the positive terminal of the battery. Some of these electrons will recombine with holes in the emitter. Similarly, some of the holes traveling from the emitter into the base will pick up an electron in the base. This current flow across the junction is called a recombination current, and the transistor is designed to keep this current as low as possible. In other words we want the holes and electrons crossing the junction to reach the terminals connected to the battery.

Now let us consider the other junction, the base-collector junction. This junction is reverse biased as shown in Fig. 21C. Here again we have a depletion layer at the junction. Also we have minority carriers being formed in the depletion layer. However, holes that are formed in the base will cross the junction and then instead of neutralizing a negatively charged atom near the junction in the collector, these holes will be attracted by the negative potential applied to the collector. Similarly, electrons formed in the depletion layer of the P-type collector will cross the junction and be attracted by the positive potential applied to the base. Thus we have a current flow due to the minority carriers. Electrons in the depletion layer of the collector section will cross the junction and flow through the base to the positive terminal of the battery. Meanwhile electrons from the negative terminal of the battery will fill holes that are moving from the base, across the junction, and through the collector to the negative terminal.

Thus you can see that while we have a current by majority carriers due to the forward bias applied between the emitter and the base, we also have a small current flowing through the base-collector circuit by minority carriers due to the reverse bias applied between the base and the collector. Now let us see how the two junctions affect each other.

A transistor with both biased junctions is shown in Fig. 22. Here we have a number of different currents flowing. In the emitter-base circuit we have current flowing due to the forward bias applied between these two. Electrons will flow from the negative terminal of the battery into the base, across the junction, and through the emitter to the positive terminal of the battery. We will also have some holes formed in the P-type emitter section due to electrons being pulled out of this section by the positive terminal of the battery. Some of these holes will cross the junction into the N-type base where they will pick up an electron and disappear. This current is called the recombination current.

Many of these holes will cross the base and flow through the collector, because the negative terminal of the battery connected between the base and collector will attract them. This movement of holes accounts for most of the current flow in the emitter and collector circuits. Remember that holes are being continually formed in the P-type emitter because electrons are

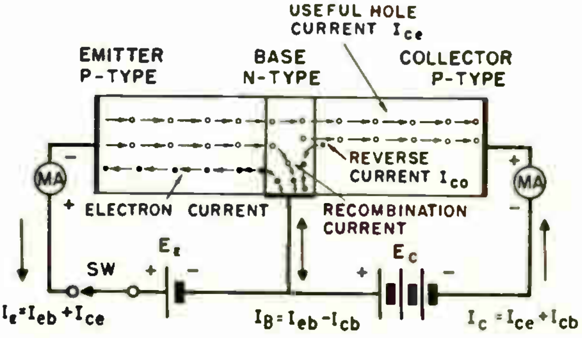

Fig. 22. Current flow and carrier movement in a PNP junction transistor.

being pulled out of the emitter by the positive potential applied to it. These holes will continually move through the emitter, and into the base. Here some of them will combine with electrons and disappear, but the majority of them will flow through the collector to the negative terminal of the collector where they will be filled by electrons and disappear.

Another current that will flow is reverse current I_{CO} that flows in the base-collector circuit. This is due to the formation of minority carriers in the depletion layer.

Thus we have four currents flowing in the PNP junction transistor. The largest of these currents is due to the movement of holes from the emitter through the base into the collector to the negative terminal of the battery connected to the collector. We have in addition to this current three small currents flowing. We have the current due to the electron movement from the negative terminal of the emitter-base battery into the base, across the junction and through the emitter to the positive terminal of this battery. We have the recombination current due to holes combining with electrons in the base, and we have the reverse current due to hole-electron pairs being formed in the depletion layer of the base-collector junction. The directions of the different movements of holes and electrons are marked in Fig. 22.

NPN TRANSISTORS

Although the operation of the NPN transistor is somewhat different from that of the PNP type, if you understand how the PNP transistor works, you should have no difficulty understanding the NPN. Again, we can start our study of this type of transistor by considering what happens at the junctions, remembering that the action at the junction is similar to the action we studied at the simple PN diode junction.

Let us first consider the action of the holes and electrons before any voltages are applied to the transistor. The charges that will be built up are shown in Fig. 23A. Remember that holes from the base will diffuse across both junctions into the emitter and the collector. Similarly electrons from the emitter and electrons from the collector will diffuse across the junctions into the base. The holes and electrons diffusing across the junctions will charge atoms near the junction. Holes crossing the junctions into the

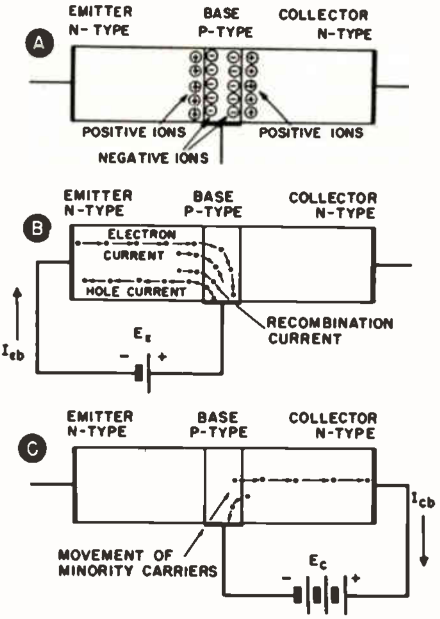

Fig. 23. (A) the formation of ions at the junctions of an NPN transistor. (B) the current flow in the emitter-base circuit and (C) in the collector-base circuit.

emitter and the collector will ionize the atoms on the emitter and collector sides of the junctions so that they will have positive charges. Similarly, electrons diffusing across the junctions into the base will ionize atoms in the base near the junctions so that they will have negative charges. Thus we will have potential barriers at the junctions. This is the same kind of potential barrier that we found existed across the PN junction in a diode.

The positively charged ions on the emitter and collector sides of the junctions will force holes in the base away from the junction. Similarly the negatively charged atoms on the base side of the junctions will force electrons in the emitter and collector away from the junction so that at the junctions we have a depletion layer.

Now let us consider what happens when we apply a forward bias between the emitter and the base by connecting a battery between the two as shown in Fig. 23B. Notice that the negative terminal of the battery is connected to the end of the emitter, and the positive terminal is connected to the base.

Now, several things happen. The negative potential applied to the emitter will force electrons toward the junction. At the same time the negative potential will attract holes away from the junction. Both of these actions tend to neutralize the positively charged ions on the emitter side of the junction. At the same time the positive terminal of the battery that is connected to the base will attract electrons away from the negatively charged atoms on the base side of the junction. In addition, the positive potential will repel holes towards the junction so that these two actions tend to neutralize the charge on the base side of the junction.

Once the potential barrier at the junction is weakened, electrons can flow from the negative side of the battery into the emitter, through the emitter, and across the junction into the base and from the base to the positive side of the battery. At the same time the positive terminal of the battery can extract electrons from the base, forming holes. Holes are then repelled toward the junction, across the junction, and through the emitter toward the end of the emitter that is connected to the negative terminal of the battery. Here the holes will pick up electrons and disappear. Thus we have a current flow through the emitter-base circuit as shown in Fig. 23B.

Now let us consider what happens when we apply a reverse bias between the base and the collector. Here the negative potential applied to the base will pull holes away from the junction, and the positive potential applied to the collector will pull electrons away from the junction. Thus the negative charge on the base side of the junction will be increased, and the positive charge on the collector side of the junction will be increased so that the potential barrier at the junction will be increased. This will prevent any current flow through the base-collector circuit due to the majority carriers.

At the same time electrons, which are minority carriers, will break loose from their nuclei in the depletion layer on the base side of the junction and will be attracted by the positive potential applied to the collector. They will cross the junction and flow through the collector to the terminal connected to the positive side of the battery, as shown in Fig. 23C. At the same time holes formed on the collector side of the junction in the layer will be attracted by the negative terminal of the battery, and hence will cross the junction and flow over into the base and toward the negative terminal of the battery. Here they will pick up an electron and disappear.

Thus we will have a current flow in the base-collector circuit due to the minority carriers. This is the same situation that we had in the reverse biased base-collector circuit of the PNP transistor.

Now let us see what happens when bias voltages are applied across both junctions of the complete NPN junction transistor as shown in Fig. 24. Considering first the emitter-base circuit, we have electrons flowing from the negative terminal of the battery to the N-type emitter. Here the electrons flow through the emitter, across the junction, and into the base. Some of these electrons reaching the base will recombine with holes in the base. This is called the recombination current. However, the majority of the electrons reaching the base will be attracted by the positive potential applied to the collector and hence will flow through the base across the base-collector junction and through the N-type collector to the positive terminal of the battery in the base-collector circuit.

At the same time the positive terminal of the battery in the emitter-base circuit is connected to the base, and this potential will pull electrons out of the P-type base, producing holes. These holes will then cross the junction into the emitter, and they will be attracted by the negative potential applied to the emitter and hence will flow through it to the end connected to the negative terminal of the battery. Here they will pick up an electron and disappear.

At the same time, in the base-collector circuit we will have a reverse current flowing due to the minority carriers. Holes appearing in the collector side of the depletion layer will cross the junction into the base and flow to the base terminal connected to the negative terminal of the battery, biasing the base-collector junction. Here each hole will pick up an electron and disappear. Electrons in the depletion layer on the base side of the junction will be attracted by the positive potential applied to the end of the collector. Hence they will cross the junction and flow toward the positive end of

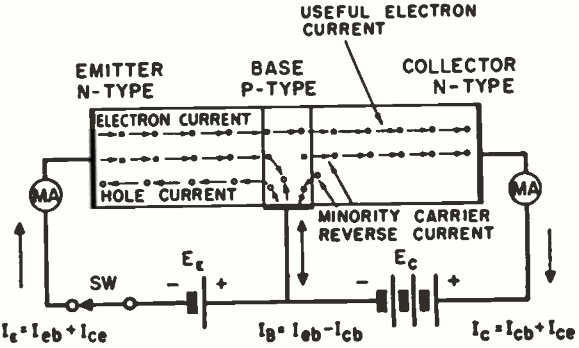

Fig. 24. Current flow and carrier movement in an NPN junction transistor.

the collector and from there to the positive terminal of the battery connected between the base and the collector.

Of these different currents flowing, the important and useful current flow is the flow of electrons from the emitter through the base to the collector. Since this is the useful current, we are interested in making this as large as possible in comparison to the other currents flowing across the emitter-base junction. Thus, the recombination current, which is due to electrons from the emitter crossing into the base and recombining with the holes, serves no useful purpose and should be kept as low as possible. This is accomplished by adding more donor atoms to the emitter than accepter atoms to the base. Thus there will be many more free electrons in the emitter than there will be holes in the base and the recombination current will be kept quite small.

Also, since there are a limited number of holes in the base compared to the number of electrons in the emitter, the number of holes crossing from the base to the emitter is also kept low in comparison to the number of electrons crossing from the emitter into the base. In a good transistor, over 95% of the electrons that cross the emitter-base junction flow to the collector.

Notice the differences and the similarities between the PNP and the NPN transistors. In both cases the emitter-base junction is forward biased and the base-collector junction is reverse biased. However, the battery connections must be reversed to provide the biases. In other words, with the PNP transistor the battery used to bias the emitter-base junction is connected with the positive terminal to the emitter and the negative terminal to the base. With the NPN transistor, the negative terminal of the battery is connected to the emitter and the positive terminal to the base. However, both are forward biased because in each case the positive terminal of the battery is connected to the P-type germanium and the negative terminal to the N-type germanium.

The base-collector junction of both transistors is reverse biased. In the PNP transistor, the positive terminal of this battery is connected to the base and the negative terminal to the collector; whereas in the NPN transistor, the negative terminal is connected to the base, and the positive terminal to the collector. Again, however, in both cases the positive terminal is connected to the N-type germanium and the negative terminal to the P-type germanium.

Also notice that in the PNP transistor the useful current flow is by means of holes, whereas in the NPN transistor the useful current flow is by means of electrons.

SELF-TEST QUESTIONS

(an) What is the base region of a transistor?

(ao) What two materials are widely used in the manufacture of transistors?

(at) Draw a diagram of a PNP transistor and show how the batteries are connected to place the correct bias across the two junctions.

(au) Draw a diagram of an NPN transistor and show how the batteries are connected to provide the correct bias across both junctions.

(av) What are the useful current carriers in a PNP transistor?

Semiconductor Types

There are two basic types of transistors that you will run into continuously. You are already familiar with these two types; they are the NPN transistor and the PNP transistor. However, these transistors are made in a number of different ways and the manufacturing processes result in transistors with different characteristics. In this section we are going to briefly discuss some of the important types and characteristics. We don't expect you to remember all these details; the important thing for you to remember is that they are basically either NPN or PNP transistors and operate in the same way as those we have discussed previously.

Also in this section of the lesson we'll discuss two other important semiconductor devices, the field-effect and unijunction transistors.

GROWN-JUNCTION TRANSISTORS

The first commercially available junction transistors were of the grown-junction type. This type of transistor is made from a rectangular bar cut from a germanium crystal that has been grown. Suitable impurities are added so that NPN regions such as those shown in Fig. 25 are formed. The base of the transistor is usually located midway between the two ends. Suitable contacts are then welded to the emitter, base and collector regions.

Of course, the actual bar of semiconductor material used is quite small. The emitter and the collector are considerably larger than the base; the base is kept as thin as possible and may have a thickness of less than .001".

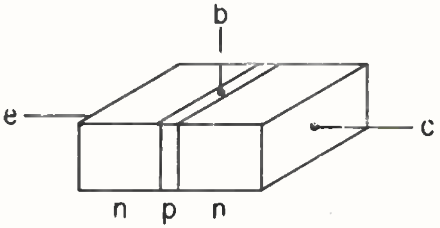

Fig. 25. A grown-junction transistor.

As mentioned the early germanium transistors were of the grown-junction type. The disadvantage of this type of transistor is that it is not particularly suitable for operations at high frequencies. In addition, it is quite temperature sensitive and can become quite unstable at higher temperatures.

ALLOY-JUNCTION TRANSISTORS

The alloy-junction transistor is made from a rectangular piece of

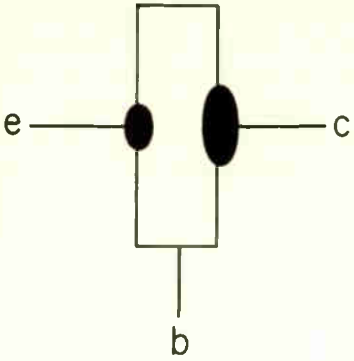

Fig. 26. An alloy-junction transistor.

semiconductor material to which suitable donor materials have been added. This results in an N-type piece of germanium or silicon. Small dots of indium are fused into the opposite sides of the wafer as shown in Fig. 26. The result is that P-type semiconductor material will be formed with the dots fused into the wafer so that we will have a PNP transistor.

An NPN-type alloy-junction transistor may be made by fusing a lead antimony alloy into each of the two opposite sides of a P-type semiconductor wafer. In this type of transistor it is possible to get a more uniform penetration of the lead antimony alloy into the semiconductor material, and this in turn leads to better junction spacing. This will cut down on the width of the space between the emitter and collector and give improved high-frequency performance. In addition, since the mobility of the electrons is more than twice that of holes, the NPN transistor will be better at high frequencies.

The general advantage of the alloy-type junction over the grown-type junction transistors is that they are usable at a somewhat higher frequency. In addition, they have a higher current gain, and the current gain remains stable as the temperature increases.

Surface-Barrier Transistor.

The surface-barrier transistor is similar to the alloy-type transistor except that depressions are etched into the N-type wafer. This permits smaller emitter and collector contacts and results in lower capacities between sections of the transistor which in turn results in better high-frequency performance.

In Fig. 27 we have shown a simplified sketch of a surface-barrier transistor. The sketch in Fig. 27B shows the carrier movement from the emitter across the base to the collector. Notice that in the sketch the emitter is shown smaller than the collector, we have shown it this way because this is the way the semiconductor is actually manufactured.

Various manufacturing techniques are used in the manufacture of the surface-barrier transistor. Both silicon and germanium types are made. In the manufacturing process different materials are evaporated or plated on to the etched depressions depending on the type of tran-

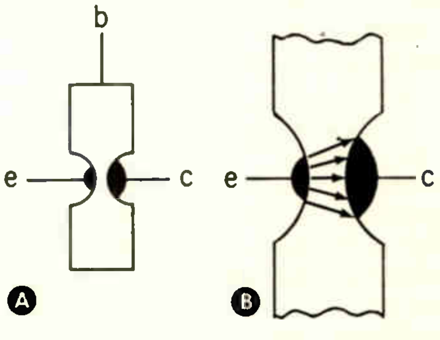

Fig. 27. Sketch of a surface barrier transistor is shown at A. Hole movement across the base is shown at B.

sistor being manufactured. However, regardless of the manufacturing technique used, which is of no interest to the technician, the surface-barrier transistors all have the characteristic of giving good performance at high frequencies.

DIFFUSION TRANSISTORS

To understand diffusion you have to understand a little about the molecular structure of materials. If you look at the wall of a glass jar, to the eye it appears solid with no space between the various molecules making up the jar. However, if you were to fill the jar with hydrogen and store it for any length of time, you would find that in a short while, the jar was no longer filled with hydrogen only, but contained a mixture of hydrogen and air. The reason is that the small hydrogen atoms are able to diffuse or pass right through the spaces between the molecules in the glass. At the same time, molecules of air will diffuse through the glass and pass on into the inside of the bottle. The hydrogen molecule is smaller than the air molecule; therefore the hydrogen will diffuse out of the jar faster than the air will diffuse in.

Diffusion can be used to add impurities to either silicon or germanium, and produce either N-type or P-type semiconductor material. The process can be controlled to provide either very uniform base, emitter, and collector regions, or it can be controlled to provide non-uniform base, emitter, and collector regions.

The Drift Type.

One of the most important uses of the diffusion technique is in the manufacture of transistors with a non-uniform base region. If the emitter and collector junctions are made by the alloy technique, but the base region is made by the diffusion technique and the impurities in the base region varied, we have what is known as a drift transistor. In a typical PNP-drift transistor, accepter impurities are added in the emitter and collector region. These impurities are controlled so that their concentration is uniform throughout the emitter and collector region. At the same time donor impurities are added to the base region. Their concentration is controlled so that it is highest in the region of the emitter-base junction and then drops off quickly and finally reaches a constant value which it maintains over to the base-collector junction, as shown in Fig. 28. This type of transistor is called a drift transistor, and its most important characteristic is its excellent performance at high frequencies. However, notice that it is still a PNP transistor and the basic theory of its operation is similar to that of any other PNP transistor. The improved performance is obtained by varying the concentration of donor impurities in the base region.

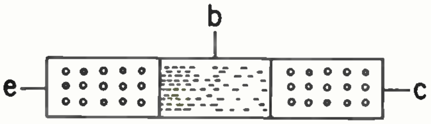

Fig. 28. Diagram showing how a large number of donor impurities increases the electron concentration in the base.

The Mesa Type.

It is also possible to manufacture a transistor using the diffusion technique entirely. An example of this type is the mesa transistor.

In this type of transistor a semiconductor wafer is etched down in steps so that the base and emitter regions appear as plateaus above the collector region as shown in Fig. 29. The advantages of the mesa transistor are good high-frequency performance and very good consistency. By this we mean that it is possible to control the manufacturing techniques quite closely so that the characteristics of mesa transistors of the same type number will be quite similar. This is not necessarily true of other transistors; often their characteristics vary over a wide range.

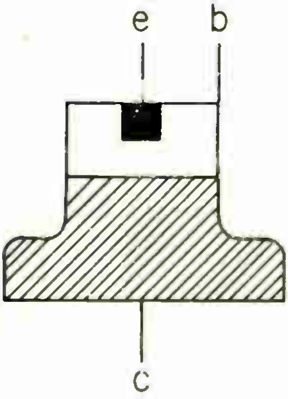

Fig. 29. A mesa transistor.

The Planar Type.

Another type of transistor manufactured by the diffusion technique is the planar type of diffused transistor. This type of transistor is shown in Fig. 30. Notice that each of the junctions is brought back to a common plane, whereas in the mesa type the various junctions are built up in plateaus. The importance of the planar-type transistor is that the junctions can be formed beneath a protective layer. As a result, many of the problems associated with other types of transistors having junctions exposed at the surface are avoided in this type of construction. Important characteristics of the planar transistor are generally very low reverse current and improved dc gain at low-current levels.

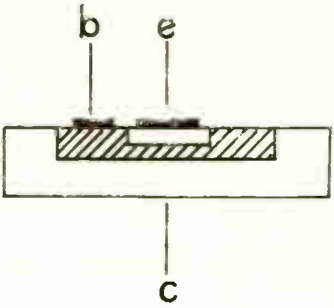

Fig. 30. A diffused planar-type transistor.

EPITAXIAL TRANSISTORS

One of the disadvantages of the diffusion-type transistor is the relatively high resistance of the collector region. This results in slow switching time; it limits the usefulness of the transistor in high-frequency applications. Reducing the resistance of the collector region reduces the collector breakdown voltage and this in turn again reduces the usefulness of the transistor. These problems can be overcome by the epitaxial technique. In this technique a thin high-resistance layer is produced in the collector region and the remainder of the collector region is controlled to keep its resistance low. This results in a transistor that looks something like the one shown in Fig. 31. The primary advantage of this transistor is that it provides good performance at very high frequencies. This technique can be combined with other techniques to produce transistors having varying characteristics. The epitaxial transistor can be referred to as a double-diffused epitaxial transistor. The thin high-resistance collector region is formed by the epitaxial technique and the base and the emitter are formed by the diffusion process - hence the term double diffusion.

All the transistors that we have discussed so far in this section of the lesson are either NPN or PNP transistors. The manufacturing techniques used to manufacture these transistors result in transistors of different characteristics, but the basic theory of operation of these transistors is the same. Now, we'll look at another semiconductor device which operates on a somewhat different principle.

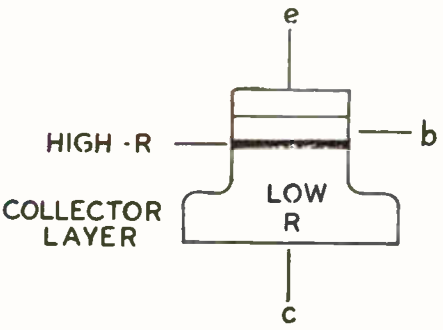

Fig. 31. A double-diffused epitaxial transistor.

THE JUNCTION FIELD-EFFECT TRANSISTOR

An interesting transistor that resembles a vacuum tube very closely in its characteristics and to some extent its operation is a field-effect transistor. One type of field-effect transistor can be made by taking a piece of N-type material as shown in Fig. 32. If the negative terminal of a battery is connected to one end of the material and the positive side of the terminal to the other end, electrons will flow through the material as shown. If we attach a piece of P-type material to one side so that the PN junction is formed and then place a negative voltage on the P-type material as shown in Fig. 32, there will be no current flow across the junction, because the battery biases the junction in such a way that electrons cannot flow from the N-type material to the P-type material nor can holes flow from the P-type material to the N-type.

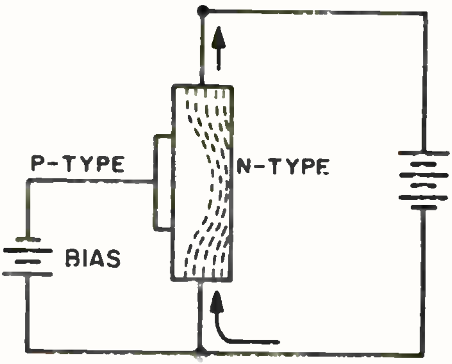

Fig. 32. Drawing showing the basic operation of a field-effect transistor.

However, the negative voltage applied to the P-type material sets up a field in the N-type material. This field opposes the electrons flowing through the N-type material and forces them to move over to one side so that the electron movement follows the path shown in Fig. 32. The negative voltage applied to the P-type material has the effect of increasing the resistance of the N-type material in the area in which the field is affected. It forms a depletion layer around the junction so there will be no free electrons in the N-type material near the junction. If the negative bias voltage is made high enough, it is able to prevent

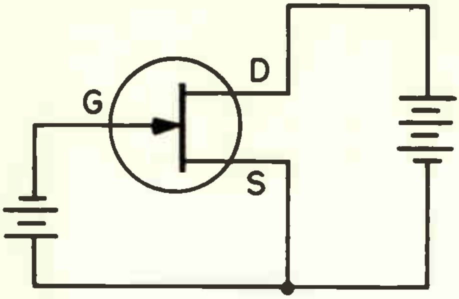

Fig. 33. Schematic representation of the circuit shown in Fig. 32.

the flow of electrons through the N-type material entirely so that the current flow will be cut off. We call this voltage where the bias voltage is high enough to stop the flow of current through the N-type material the "pinch-off" voltage. The N-type material is referred to as a channel, and the P-type material as a gate. This type of transistor is called a "junction field-effect transistor."

The schematic representation of the circuit shown in Fig. 32 is shown in Fig. 33. Notice that the end of the N-type channel at which the electrons from the battery enter is called the "source". The other end, the end from which the electrons leave and flow to the positive terminal of the battery, is called the "drain". The P-type material is called the gate, as we mentioned previously. The transistor is called a field-effect transistor because it is the field produced by the bias voltage applied to the gate that controls the flow of current through the channel. This particular type of transistor is called a junction transistor because a junction is formed between the P and N-type materials. It is called an N-channel transistor because the material in the channel through which current flows has been treated in such a way as to produce an N-type semiconductor material. Thus the complete name for this type of transistor is an N-channel, junction-gate, field-effect transistor. We usually abbreviate field-effect transistor FET, so you will see that this type of transistor is abbreviated JFET to indicate it is a junction-gate type.

An amplifier using a field-effect transistor of this type is shown in Fig. 34. In this circuit we have eliminated the bias battery by means of a resistor connected between the negative terminal of the battery and the source. This resistor might be compared to the cathode-bias re-

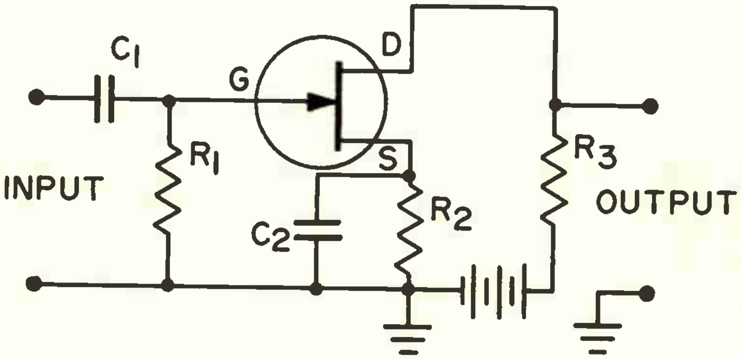

Fig. 34. An amplifier using an N-channel junction gate FET.

sistor in a triode vacuum tube amplifier stage. In the amplifier circuit, electrons flow from the negative terminal of the battery through the resistor R_2 to the source. In so doing they set up a voltage drop across R_2 having a polarity such that the source is positive with respect to ground. Since the gate connects back to ground through R_1, the gate will be at ground potential and this will make the source positive with respect to the gate, or in other words, the gate negative with respect to the source. Therefore none of the electrons in the N channel will flow to the gate, because the gate is negative.

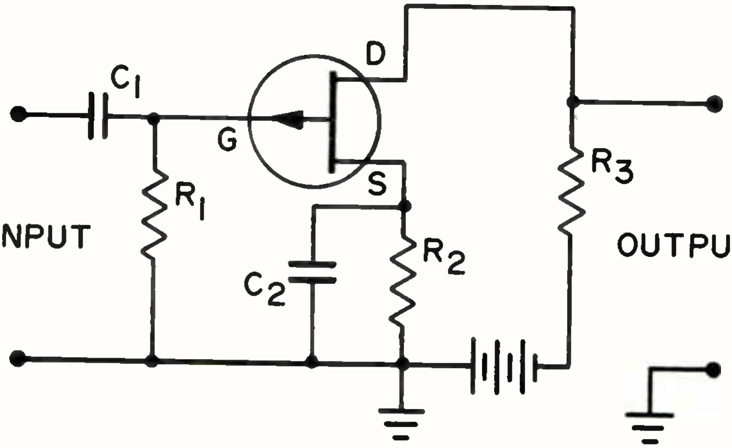

Fig. 35. An amplifier using a P-channel junction gate FET.

Electrons will flow through the N channel to the drain and then through the load resistor R_3 back to the positive terminal of the battery. As the input voltage applied across the input terminals causes the voltage between the gate and the source to vary, the current flow from the source to the drain will vary because the controlling action of the gate on the current through the channel depends upon the voltage between the gate and the source. Thus we have a varying current, which will vary as the input signal varies, flowing from the source to the drain of the transistor and through the load resistor R_3. This varying current flowing through R_3 will produce an amplified signal voltage across R_3.

It is interesting to note the similarity between the circuit shown in Fig. 34 and a triode amplifier. When the input signal swings the gate in a positive direction, current flowing through the transistor will increase; this will cause the voltage drop across R_3 to increase and therefore the voltage between the drain and ground will decrease. Thus a positive-going signal applied to the gate will cause a negative-going signal at the drain. In other words, this transistor inverts the signal phase just as the triode vacuum tube amplifier stage does.

P-Channel JFET.

It is possible to make a P-channel junction-gate field-effect transistor by using a P-type material between the source and drain. The gate is then made of an N-type material. The bias polarity is reversed so that once again the PN junction is biased and no current flows across the junction.

A schematic diagram of an amplifier using a P-channel junction-gate effect is shown in Fig. 35. Notice the schematic symbol for the P-channel unit: we have turned the direction of the arrow around just as we did to distinguish between NPN and PNP transistors. Also notice that in this circuit the battery polarity is reversed. This is because the carriers in the channel in the P-channel unit will be holes. The positive terminal of the battery which connects to the source through R_2 repels the holes and they travel through the channel to the drain where they are attracted by the negative potential connected to the drain. Meanwhile, holes arriving at the drain terminal are filled by electrons which flow from the negative terminal of the battery through R_3 to the drain. At the same time, the positive terminal of the battery attracts electrons from the source creating new holes. These electrons flow from the source through R_2 to the positive terminal of the battery.

The operation of the P-channel, junction-gate effect is the same as with the N-channel unit, except that in one case the majority carriers are electrons, and in the other case they are holes.

In discussing the action of the junction-gate field-effect transistor, we often refer to the reverse bias across the junction creating a depletion layer in the conducting channel. In the case of an N-channel unit, the negative voltage on the P-type gate will repel electrons at the junction so that the electrons have been depleted from that area around the junction. The higher the negative voltage the further the electrons are depleted in the area around the junction, and as we pointed out previously if the voltage is made high enough, all of the electrons will be depleted so that there will be no current flow through the channel. The transistor is referred to as a depletion-type transistor because the bias depletes the number of majority carriers from the channel around the junction region. Remember what we mean by a depletion type of FET; you'll see later there is another type.

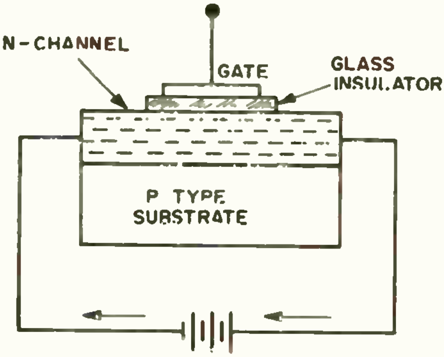

Fig. 36. Current flow through an insulated-gate, N-channel field-effect transistor with no bias applied.

INSULATED-GATE FIELD-EFFECT TRANSISTORS

The transistors we have been discussing so far are called junction-gate field-effect transistors. There is another type of field-effect transistor that is called an insulated-gate field-effect transistor. We usually abbreviate this IGFET.

In the insulated-gate field-effect transistor, the gate is completely insulated from the channel by a thin insulating material. For example, a very thin piece of glass might be placed between the conducting channel and the gate. Thus there is no actual junction formed between the semiconductor materials in the channel and the gate. In an N-channel, insulated-gate field-effect transistor, construction such as shown in Fig. 36 is often used. Here we have an N channel between the source and drain. The substrate on which the channel material is mounted is P-type material and the gate is placed along the channel as shown in the figure. The thin layer of glass prevents any actual contact between the channel and the gate.

In operation, the source and the substrate are connected to the negative terminal of the battery and the drain is connected to the positive terminal. This will permit current to flow from the negative terminal of the battery to the source, through the channel to the drain and then back to the positive terminal of the battery.

When a negative voltage is applied to the gate, it has the effect of repelling electrons away from the gate as before. In addition, the negative potential applied to the gate attracts holes in the P-type material so that the width of the channel is reduced as shown in Fig. 37. Thus the current flow through the channel is restricted by the narrowing of the channel. In effect, the resistance of the channel is increased. We refer to this type of channel as a depletion channel. The transistor is called an insulated-gate-field-effect transistor and it is also referred to as a depletion type because the flow of current through the transistor is controlled by producing a depletion layer in the channel as in the case of the junction transistors discussed previously.

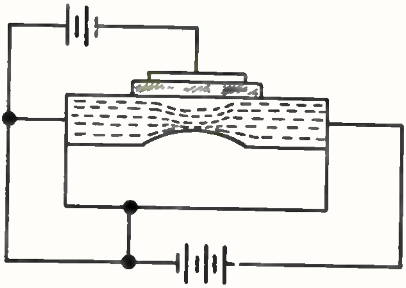

Fig. 37. Current flow through an N-channel IGFET with bias applied.

Both N-channel and P-channel IGFET's are manufactured. The schematic symbols used to represent the two different types are shown in Fig. 38A and B. In A, we have shown the symbol used for an N-channel type, and in B the schematic symbol used for a P-channel type. In operation, the units perform in essentially the same way as the junction-gate units with the exception that there will be no current

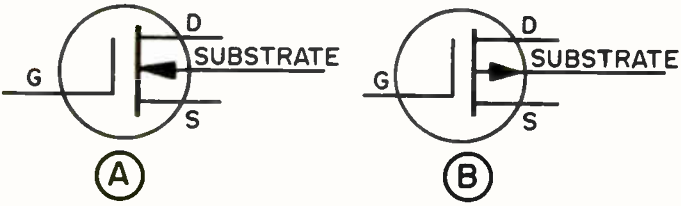

Fig. 38. Insulated-gate field-effect transistors. (A) shows the schematic symbol for an N-channel unit and (B) the symbol for a P-channel unit.

flow at all from the channel to the gate or from the gate to the channel. In the JFET, there may be very small leakage current across the junction. However, a JFET has a high input resistance because this leakage current is low. The IGFET has an even higher input resistance because there is no current flow at all from the gate to the channel or from the channel to the gate. Thus the input resistance of an IGFET is almost infinite.

Enhancement Type.

So far the field-effect transistors we have been discussing are all what are known as depletion types. In the depletion type of FET, the channel is formed and a bias is placed on the gate so as to reduce the size or width of the channel. In the enhancement-type of field-effect transistor, there is no channel present until the bias is applied to the gate. Thus, there is no current flow from the source to the drain through the transistor, unless there is a bias applied to the gate. The polarity of the bias applied to the gate is reversed from what it is in the depletion type, and this bias forms the channel through which current can flow. The operation of the units is the same as with the depletion type with the single exception of the reverse bias. In other words, in the case of an N-channel enhancement-type field-effect transistor, instead of placing a negative bias on the gate to reduce the width of the channel, as we do in the depletion-type transistor, in the enhancement-type we place a positive bias on the gate and produce the N channel.

The enhancement-type field-effect transistor is always an insulated gate type. In the case of a junction FET, if we produced an enhancement type, we would have current flow across the junction because the voltage required to produce the channel would forward bias the junction. However, in the insulated-gate FET, no current can flow across the junction because we have an insulating material between the gate and the channel. Thus we can put any type of bias we want, either forward or reverse bias, on the gate and we still will not get a current flow from the gate to the channel or from the channel to the gate.

The schematic symbol of an N-type IGFET of the enhancement type is shown in Fig. 39A. Notice that we have indicated there is no channel by breaking the channel into three parts. When the correct bias is applied to the gate, an N channel between the source and the drain will be formed. The schematic symbol for the P-channel unit of an enhancement-type IGFET is shown in Fig. 39B.

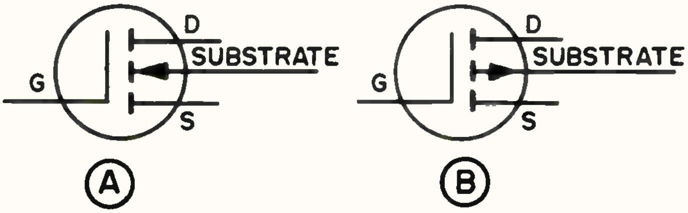

Fig. 39. A shows the schematic symbol for an N-channel enhancement-type IGFET. B shows the P-channel unit.

The operation of the enhancement-type IGFET is basically the same as with the depletion type. It could be used in a circuit similar to the circuits shown in Fig. 34 and Fig. 35.

One of the problems with IGFET's is the very high resistance between the gate and the channel. In shipping these units the manufacturer usually wraps the leads in tin foil to keep them connected together. If he doesn't do this, static charges can build up on the gate because of the very high resistance between the gate and the channel. These static charges may become high enough to actually puncture the insulation between the gate and the channel and thus ruin the unit.

In soldering an IGFET into a circuit, there might be enough leakage from the power line through the tip of your soldering iron to ruin the FET. To prevent this from happening, ground leads should be used on the various connections to the transistor and these leads should be left in place until the transistor is installed in the circuit. Once the transistor is soldered in place, you do not have to be concerned about static charges destroying the unit because the resistance in the circuit will be low enough to prevent static charges from building up to a high enough value to destroy the transistor.

Field-effect transistors are finding their way into commercial equipment, and you should therefore be sure you understand how they operate. You should review the sections on field-effect transistors several times if necessary because you can be sure they are going to be widely used in the future. They offer the advantages of the transistor as well as many of the advantages of the vacuum tube.

THE UNIJUNCTION

Another important semiconductor device is the unijunction. The unijunction is different from a conventional two-junction transistor in that it has only a single junction.

Most unijunctions are made of a bar of N-type silicon. There are two base contacts made to this bar called base 1 and base 2. These contacts are made at the ends of the bar. Between the two bases is a single rectifying contact called the emitter. The schematic symbol of the unijunction is shown in Fig. 40.

In Fig. 41 we have an equivalent circuit showing how the unijunction operates. We have referred to the resistance between base 1 and the emitter as R_{B1} and the resistance between base 2 and the emitter contact as R_{B2}. When a dc voltage is applied to the unijunction between B_1 and B_2, a current will flow through the base as shown. As long as the voltage drop across R_{B1} is greater than the emitter voltage, the emitter will be reverse biased so that there will be no current flow across the junction between the emitter and the base. The voltage across the resistance representing base 1 and the voltage across the resistance representing base 2 will remain constant. The two bases more or less act like two resistors

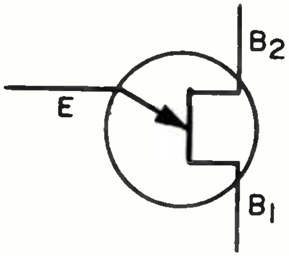

Fig. 40. Schematic symbol of a unijunction.

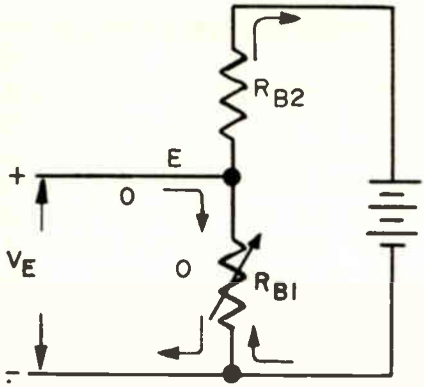

Fig. 41. Equivalent circuit showing the operation of the unijunction.

in series. The positive voltage at the emitter junction prevents any electrons from leaving the base and crossing the junction to the emitter and also prevents holes from traveling from the emitter to the base. There will be a small leakage current across the junction, but this is of no importance insofar as the operation of the unijunction is concerned.

If the voltage, V_E, exceeds the voltage across R_{B1}, then holes will enter the base and flow through R_{B1} as shown by the arrows on the diagram. These holes will cause the number of electrons flowing in R_{B1} to increase. The net result will be that you will have a drop in voltage across R_{B1} but at the same time an increase in current.

You will remember from Ohm's Law that the current flowing in a circuit is equal to the voltage divided by the resistance. If the voltage drops, the current must drop. However, in this device we have a situation where the voltage drops, but the current increases. We refer to this as "negative resistance". Devices that have this characteristic can be used in various types of amplifier circuits.

The unijunctions made for a number of years always made use of an N-type base material and a P-type emitter. However, recently some unijunctions using a P-type base material and an N-type emitter have been developed. The schematic symbol is the same, except that the direction of the arrow is reversed.

Unijunctions have not been widely used in commercial radio and TV equipment; however, they have been used in various pieces of test equipment. It is quite likely that as more transistorized television receivers are manufactured, the unijunction may be used in the sweep circuits since they are quite readily adapted to this type of application.

The important thing for you to remember at this time about the unijunction is that the device has a single junction and that the resistance of the two bases remains essentially constant until the emitter voltage exceeds the voltage across base 1. Then the voltage drop across base 1 decreases while the current flow through it increases, resulting in the negative resistance characteristic of base 1.

SUMMARY

There are too many details in this section to try to summarize them. The important thing for you to do is to realize that the different names assigned to the conventional two-junction transistors indicate the manufacturing process used to make the transistor. Typical two-junction transistors are either NPN or PNP transistors, and the basic theory of operation of the two-junction transistors is the same regardless of the manufacturing technique used. Different manufacturing techniques result in transistors with different characteristics, but the theory of operation is the same.

The field-effect transistor is a transistor that very closely resembles a vacuum tube in many of its characteristics. Remember that there are two basic types: the junction field-effect transistor and the insulated-gate field-effect transistor. In the insulated-gate type, the gate is insulated so that the leakage current to and from the gate is practically zero. This type of transistor has a very high input resistance.

You should also remember that field-effect transistors can be made in both N-channel types and P-channel types. You'll recall that by depletion type we are referring to a transistor where a channel is present. The input voltage to this type of transistor controls its channel width. JFET transistors are all of the depletion type. The IGFET may be either the depletion type or the enhancement type.

The unijunction is a semiconductor device with a single junction. Its use in commercial equipment is somewhat limited at this time, but you should understand the basic fundamentals of the device because it is quite likely that it will be used in the future.

One important point about all types of transistors that we must emphasize is that they are all easily damaged by excessive heat. This is true particularly of germanium transistors, but silicon transistors can also be destroyed by excessive heat. Whenever you have to replace a transistor in a circuit, you should make sure that the point at which you have to solder the transistor in the circuit is clean so that the solder will melt and flow over the connection quickly. Also make sure that the transistor leads are clean. It is a good idea to use a heat sink between the point at which you are soldering and the semiconductor device. A good heat sink is a pair of longnose pliers; simply hold the lead securely in the jaws of the pliers while you are soldering the lead in place. Much of the heat developed at the joint will flow through the pliers and keep the semiconductor device itself from becoming excessively hot. The joint should be soldered as quickly as possible; get the iron off the joint just as soon as the solder has melted and flowed smoothly over the connection.

Semiconductor devices can be damaged by storing them in excessively warm places. Again, this is particularly true of germanium transistors which are more heat sensitive than silicon transistors. Storing semiconductor devices at room temperature will prevent this type of damage. You should avoid storing them in any place where they can become excessively hot.

Now to check yourself on this important section you should answer the following self-test questions.

SELF-TEST QUESTIONS

(aw) Into what two basic types can the grown-junction transistor be divided?

(ax) What type of transistor can the surface-barrier transistor be classified as?

(ay) What is the most important characteristic of the surface-barrier transistor?

(az) What do we mean by a diffussion transistor?

(ba) What is an important use of the diffusion technique in manufacturing transistors?

(bb) What is the difference between a junction-gate field-effect transistor and an insulated-gate field-effect transistor?

(bc) What is a depletion-type field-effect transistor?

(bd) What is an enhancement-type FET?

(be) What is a unijunction?

Answers to Self-Test Questions

(a) Four.

(b) Germanium and silicon.

(c) A covalent bond is the sharing of two electrons by two atoms, one from each atom.

(d) Four. A single atom of germanium or silicon will share an electron from its outer ring and an electron from the outer ring of a nearby atom to form a covalent bond. It will do this with four electrons to establish four covalent bonds.

(e) Intrinsic conduction is conduction due to the formation of hole-electron pairs throughout a germanium or silicon crystal.

(f) No.

(g) Germanium.

(h) Heat.

(i) Silicon.

(j) An N-type material is a material that has been doped so that electrons are the majority carriers. This is brought about by using an impurity that has five electrons in the valence ring so that when it forms covalent bonds with nearby germanium or silicon atoms there will be an electron left over.

(k) A donor material is an impurity which when added to silicon or germanium will form covalent bonds with four nearby atoms and have an electron left over. When a donor material is added to germanium or silicon, N-type material is formed.

(l) Arsenic, antimony, and phosphorous.

(m) P-type semiconductor material is a material that has been doped with an impurity having three electrons in the valence ring. This will leave a covalent bond that is short one electron so there will be a hole in the bond. The hole is in effect a positive charge and hence the majority carriers in the P-type material are the holes or positive charges.

(n) An accepter-type impurity is an impurity with three electrons in the valence ring or shell. It is an accepter-type material because it leaves a hole in the covalent bond which can accept an electron.

(o) Indium, boron and aluminum.

(p) Electrons are the majority carriers in N-type material.

(q) Holes.

(r) When the arsenic loses an electron it will be short one electron to completely neutralize the charge on the nucleus, and therefore the atom will have a positive charge. Meanwhile the atom of silicon or germanium that has received the extra electron will have a negative charge on it.

(s) There is no charge on the crystal, it is neutral. Although some regions may have a positive charge, other regions may have a negative charge; the crystal itself neither gains nor loses electrons and therefore it does not have any charge.

(t) Holes are produced.

(u) Diffusion is a random motion of the carriers in a semiconductor material. It goes on at all times in the crystal and every effort is made to keep diffusion as low as possible since it contributes nothing insofar as the usefulness of the material in semiconductor devices is concerned.

(v) Drift.

(w) Electrons are the majority carriers in an N-type material and they move from the end to which the negative potential is applied towards the end to which the positive potential is applied.

(x) Holes are the majority carriers in a P-type material and they move from the end to which the positive potential is applied to the end to which the negative potential is applied.

(y) No - the crystal will remain electrically neutral. In the case of N-type material, exactly the same number of electrons will leave the positive end of the crystal and enter the negative end of the crystal. In the case of the P-type material, electrons will leave the end to which the positive potential is connected creating holes. Exactly the same number of electrons will enter the end to which the negative potential is connected to fill holes arriving at the negative end.

(z) No. For a given potential and given size of crystal, electrons will move at approximately twice the rate through an N-type crystal as the holes will through a P-type crystal.

(aa) The N-type material will have the lower resistance. This is due to the higher mobility of the electrons in the N-type material than the holes in the P-type material.

(ab) Detectors and rectifiers.

(ac) The depletion layer is an area on both sides of the junction. On the P-side of the junction there is a shortage of holes and on the N-side of the junction there is a shortage of electrons. The shortage is caused by a few of the majority carriers crossing the junction in each way building up a charge at the junction so that the majority carriers are repelled away from the junction.

(ad) The potential barrier is the voltage built up across the junction by the diffusion of majority carriers across the junction. The holes that diffuse across the junction into the N-side of the junction create an area that has a negative charge in the P-side of the junction. Similarly, the electrons diffusing across the junction into the P-side create an area on the N-side of the junction that has a positive charge. This charge across the junction eventually becomes high enough to prevent any further diffusion of holes and electrons across the junction.

(ae) No. The net charge on the crystal will remain zero. There may be areas on the crystal that have a positive charge, and other areas that have a negative charge, but since the crystal itself neither gains nor loses electrons, the net charge on the crystal will remain zero.

(af) Yes. Minority carriers crossing the junction tend to weaken the potential barrier established across the junction by majority carriers diffusing across the junction. When the potential barrier is weakened, additional majority carriers can cross the junction. Thus we end up with carriers crossing the junction in both directions. This adds nothing to the useful current that the diode can handle, but it does contribute to heating and thus limits the useful current that can cross the junction.

(ag) When a junction is forward biased we have a positive potential applied to the P-side and a negative potential applied to the N-side. This permits electrons to freely cross the junction from the N region to the P region. Similarly holes can cross the junction from the P region to the N region.

(ah) When a junction is reverse biased we have a negative potential connected to the P region and a positive potential connected to the N region. The positive potential connected to the N region repels holes in the P region away from the junction so that they cannot cross the junction. Similarly, the negative potential applied to the P region repels electrons in the N region away from the junction so that they cannot cross the junction. When a junction is reverse biased, majority carriers normally cannot cross the junction.

(ai) When there is no voltage applied to a semiconductor diode, the net current flow across the junction is zero. However, in the case of a vacuum tube where there is no voltage applied between plate and cathode, some electrons will leave the cathode with sufficient energy to travel over to the plate. As a result, there will be a small current through the tube even though there is no voltage applied between the plate and cathode.

(aj) When a semiconductor diode is reverse biased, there will be a small current flow across the junction due to minority carriers. As long as the breakdown voltage of the diode is not exceeded, this current will be quite small. In the case of a vacuum tube, when the plate is made negative with respect to the cathode, the plate will repel electrons so that there will be no current flow through the vacuum tube.

(ak) A Zener diode is a diode used in applications where a reverse bias is placed across the junction. The diode is designed to break down at a certain voltage and then maintain a constant voltage. If the voltage tries to increase above this constant value, the current flow through the Zener diode will increase so that the diode can be used in voltage regulating circuits and also can be used as a voltage reference source.

(al) A tunnel diode is a diode where the electrons cross the junction by a process similar to tunneling across the junction. The tunnel diode has a characteristic of introducing negative resistance into the circuit when a certain voltage is applied across the junction. In other words, when the voltage across the diode increases, the current flow through the diode decreases. Similarly, when the voltage decreases the current increases. Because of this negative resistance characteristic, the tunnel diode can be used as an oscillator.

(am) A p-i-n diode is a diode that is primarily used as a variable resistance. The resistance of the diode varies as the voltage across it is varied. The p-i-n diode is used in automatic gain control circuits to vary the strength of the signal reaching amplifier stages.

(an) The base region is the center region of the transistor. On one side of the base region is the emitter, and on the other side is the collector.

(ao) Germanium and silicon.

(ap) PNP transistors and NPN transistors.

(aq) Forward bias.

(ar) Reverse bias.

(as) The base region is usually comparatively thin.

(at) See Fig. 22.

(au) See Fig. 24.

(av) Holes are useful current carriers in a PNP transistor.

(aw) NPN and PNP transistors.

(ax) An alloy-type transistor.

(ay) Good high-frequency performance.

(az) A diffusion transistor is a transistor which has been made by diffusing the impurities into the emitter, base and collector regions.

(ba) One of the most important uses of the diffusion technique is in the manufacture of non-uniform base regions.

(bb) In a junction-gate field-effect transistor there is an actual contact between the channel material and the gate. There will be some current flow across the contact at all times due to minority carriers crossing the junction. In addition, if the junction is forward biased there will be a high current flow across the junction. In an insulated-gate field-effect transistor a glass or similar insulating material is used between the material in the channel and the gate. Since there is an insulator between the gate and the channel, there will be little or no current flow across the insulator either due to minority carriers when there is a reverse bias applied, or due to majority carriers with a forward bias applied.

(bc) A depletion-type FET is a unit in which the channel is present at all times. The transistor works by depleting or reducing the size of the channel.

(bd) An enhancement FET is a unit in which there is no channel present until the operating bias is applied between the gate and the material in which the channel is formed.

(be) A unijunction is a semiconductor device having two base connections but only a single junction. The junction is called the emitter. The single junction makes the unijunction quite different from the conventional two-junction transistor.

Lesson Questions

Be sure to number your Answer Sheet B112.

Place your Student Number on every Answer Sheet.

Most students want to know their grades as soon as possible, so they mail in their answers immediately. Others, knowing they will finish the next lesson within a few days, send in two sets of answers at a time. Either practice is acceptable. However, don't hold your answers too long; you may lose them. Don't hold answers to more than two sets of lessons at any time, or you may run out of lessons before new ones can reach you.

1. Name the two most important semiconductor materials used for transistors.
2. When a donor type of material is added to a silicon or a germanium crystal, what type of semiconductor material is produced? Does this type have free electrons or free holes?
3. What effect do the two layers of ionized atoms at the junction in a PN diode have on the majority carriers in the vicinity of the junction?
4. To which side of a PN junction diode do you connect the positive battery terminal if you wish to place a forward bias on the junction?
5. If a reverse bias is applied to a junction diode, what effect will a small increase in bias have on the current flowing, provided the reverse voltage does not exceed the breakdown voltage?
6. What is a Zener diode?
7. In a PNP transistor, what happens to a hole that crosses the emitter and the base and moves into the collector?
8. What is a drift transistor?
9. What is an N-channel, junction-type field-effect transistor?
10. What do we mean when we refer to a field-effect transistor as an enhancement type?

CASHING IN ON DISCONTENT

Discontent is a good thing--if it makes you want to do something worthwhile. If you had not been discontented, you would never have enrolled for the NRI course.

Practically everyone is discontented. But some of us are "floored" by discontent. We develop into complainers. We find fault with anything and everything. We end up as sour and dismal failures.

Those of us who are wise use our discontent as fuel for endeavor. We keep striving toward a goal we have set for ourselves. We are happy in our work. We face defeat, and we come out the victors.

At this minute you may be discontented with many things--your progress with your course, your earning ability, yourself.

Make that discontent pay you dividends. Don't let it throw you down. If you do, you may never be able to get up again. Keep striving to remove the cause of your discontent. Remember that it's always darkest before the dawn. And a real NRI man works hardest and accomplishes most when he is face to face with the greatest discouragements.

HOW TRANSISTORS WORK

B112

STUDY SCHEDULE

☐ **1. Introduction . . . . Pages 1-2**
You learn some of the advantages and disadvantages of transistors compared to vacuum tubes.

☐ **2. Semiconductor Fundamentals . . . . Pages 3-13**
You learn about conductors, insulators and semiconductors. You study important characteristics of germanium and silicon and how they are "doped" for use in transistors.

☐ **3. Current Flow in Semiconductors . . . . Pages 14-18**
You study current flow in N-type and P-type semiconductor material.

☐ **4. Semiconductor Diodes . . . . Pages 18-29**
You learn about current flow in diodes with forward bias and reverse bias. You study several important types of diodes.

☐ **5. Semiconductor Triodes . . . . Pages 30-39**
In this section you study PNP and NPN transistors and how they are biased.

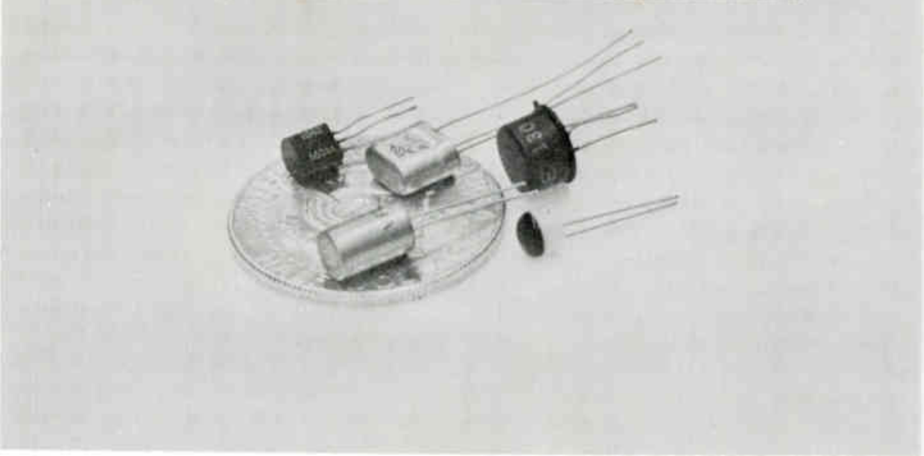
☐ **6. Semiconductor Types . . . . Pages 39-52**
In this section you learn about a number of different types of transistors. You also study field-effect and unijunction transistors.

☐ **7. Answer the Lesson Questions.**

☐ **8. Start Studying the Next Lesson.**

JD4M168 **1968 EDITION** Printed in U.S.A.

HOW TRANSISTORS WORK



In the preceding lessons you studied tubes, and you saw how they are used in different circuits. In this lesson you will study semiconductor devices - these devices have already replaced tubes in many important applications and are rapidly moving into new areas that were once dominated entirely by tubes.

An example of the importance of semiconductor devices can be seen in entertainment-type equipment. Just a few years ago all the rectifiers used in this equipment were vacuum tubes. Today, however, the vacuum tube is no longer used for this purpose; rectifiers in the modern entertainment-type equipment are all semiconductor devices.

Semiconductor devices used as rectifiers have two elements and are called diodes just as two-element vacuum tubes are called diodes. Semiconductors used to amplify signals usually have three or more elements and are called transistors. There are a large number of different types of transistors available today, but for the most part these transistors can be classified into two types, the NPN transistor and the PNP transistor. If you understand how these two transistor types work, you should have little difficulty understanding how all others work and any new transistors that might be introduced in the future. You will run into many different types of transistors identified by different names, but these names usually refer to the method used in manufacturing the transistor rather than the manner in which it operates.

There are some similarities between tubes and semiconductors. A two-element vacuum tube can be used to change an alternating current to a direct current; a two-element semiconductor can be used for the same purpose. A triode vacuum tube can be used to amplify a signal; a transistor can be used for the same purpose. However, this is where the similarity ends. Most tubes are vacuum devices; in other words, all the air and gas have been evacuated from inside the tube. On the other hand, a semiconductor is a solid device and there is no space between the elements in it. We have a current flow through a vacuum in a tube, but we have a current flow through a solid in a semiconductor.

The importance of semiconductors cannot be overemphasized. They have completely supplanted the vacuum tube in portable radio receivers and in automobile receivers. Almost all high fidelity and stereo' equipment manufactured today uses semiconductors exclusively - the only tube-operated equipment of this type you are likely to encounter is equipment that is several years old. Semiconductors are finding their way into television receivers and it is probably just a matter of time before they completely replace the vacuum tube.

Semiconductors have several advantages over the vacuum tube. Perhaps one of the most important advantages is that they do not require any heater or filament power. Not only is this a power saving in the operation of the equipment, but it also removes considerable heat from the equipment. Heat is probably the thing that causes the most damage to parts in electronic equipment. Thus with the removal of the heater or filament power from the equipment, other components such as capacitors, etc. will last longer.

Semiconductors are very rugged. They are solid devices and hence not subject to breakage from mechanical shock as tubes are. An important advantage of transistors is that they will operate on a comparatively low voltage, and this usually results in some reduction of the power required in the equipment.

Although semiconductors have many advantages over vacuum tubes, they do have some disadvantages. One disadvantage is that it is usually not possible to get as high a gain in an amplifier stage using a transistor as it is in a similar stage using a tube. Therefore to get the equivalent gain, more transistor stages are required than vacuum-tube stages. Another disadvantage of the transistor is that its characteristics are not as constant as those of a vacuum tube. In other words, you are more likely to run into difficulty replacing a transistor than you are in replacing a tube because the replacement transistor's characteristics might be considerably different from the characteristics of the original transistor. Another disadvantage of both diode semiconductors and transistors is that their characteristics can vary appreciably with changes in temperature. As a matter of fact, some semiconductor devices are easily destroyed by too much heat.

In spite of the fact that semiconductor devices have some disadvantages when compared to vacuum tubes, their advantages more than outweigh the disadvantages and their importance in the field of electronics is continually growing. Therefore it is important that the technician have a good understanding of semiconductor fundamentals, how they are used, and how they operate. Before going ahead to see how semiconductors are used as rectifiers and amplifiers, we need to know more about certain types of atoms, in order to understand how these devices work.

Semiconductor Fundamentals

You have already learned that certain materials will conduct electricity readily and that some materials will hardly pass any electric current at all. The materials that will conduct current readily are called conductors and those that will not conduct current are called insulators. Midway between the two types of materials is a group of materials called semiconductors. These materials are not good conductors, nor are they particularly good insulators. Two examples of semiconductor materials are germanium and silicon. These are the materials that we will be mostly concerned with in this section. Both diode semiconductors and transistors are made from germanium and silicon. A new material that shows promise for use in semiconductors is gallium arsenide. It's likely that this material will be used in semiconductors in the future. Before going ahead with our detailed study of semiconductor materials, let us review a few important facts about conductors and insulators.

CONDUCTORS AND INSULATORS

You will remember that all materials are made up of atoms. An atom is the smallest particle of a material that retains the characteristics of the material.

In the center of the atom is the nucleus. This nucleus contains a positive charge. The number of positive charges on the nucleus distinguishes one material from another. In other words, the nucleus of a copper atom does not have the same number of positive charges as the nucleus of an iron atom.

Each atom normally has enough electrons, which have a negative charge, to exactly neutralize the positive charge on the nucleus. Thus, the hydrogen atom which has a nucleus with one positive charge will have one electron, and the helium atom which has a positive charge of two in the nucleus will have two electrons. Another atom that has a nucleus with 30 positive charges will have 30 electrons to exactly neutralize the positive charge on the nucleus.

The electrons in an atom arrange themselves in shells around the nucleus. The total number of electrons will normally be just enough to neutralize the charge on the nucleus. However, there is a maximum number of electrons that can be forced into each shell. In the first shell around the nucleus, the maximum number of electrons is 2. In the second shell, the maximum number of electrons is 8, and in the next shell the maximum number of electrons is 18. A shell can have less than the maximum number of electrons, but not more than the maximum number.

Conductors.

An example of an atom in a conductor is shown in Fig. 1. We have drawn the shells in the form of rings, but remember that this atom actually has three dimensions, not two. Notice that in this atom there are two electrons in the first shell,

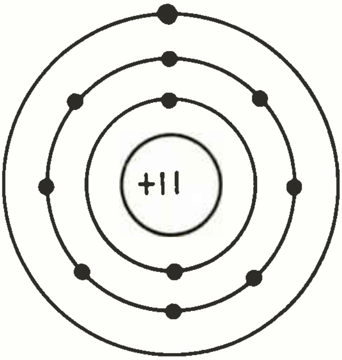


Fig. 1. An atom of a conductor.

8 electrons in the next shell and only one electron in the third shell. The outer shell is called a valence shell. The single electron in the third shell, which is called the valence electron, is not very closely bound to the nucleus; it can easily be removed from the atom. Thus a material of this type has a large number of electrons that can easily be removed from their atoms. When these electrons are forced to move in one direction we have a current flow. Thus a material that has only one or two electrons in an outer shell that could have many more, is a conductor, because the one or two electrons in the outer shell are not closely bound to the nucleus.

Insulators.

An atom of an insulator is shown in Fig. 2. Notice that in this atom there are two electrons in the first shell, and 8 electrons in the second shell. Both the shells are completely filled and will be closely bound to the nucleus. This means that it is very difficult to get one of these electrons out of an atom and therefore this material is an insulator or nonconductor.

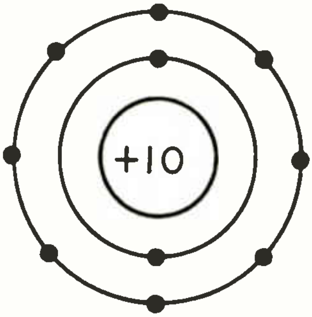

Fig. 2. An atom of an insulator.

Remember the important difference between conductors and insulators. A conductor is a material that has one or two electrons in the outer shell that are not closely bound to the nucleus, whereas an insulator is a material in which the outer shell of each atom is filled or almost filled so that the electrons are closely bound to the atom and cannot be easily removed. Because these electrons cannot be removed from the atom, this type of material normally will not conduct current, and hence is called an insulator.

SEMICONDUCTOR MATERIAL

A material that is classified as a semiconductor has electrical characteristics midway between those of a conductor and those of an insulator. The electrons in a semiconductor can be removed from their atoms when some type of external energy, such as voltage, heat, or light is applied to the material. Then the material acts like a conductor.

The most important semiconductor materials used for transistors are germanium and silicon. The first low-cost transistors were germanium transistors, but recent developments have lowered the cost of silicon transistors so that most of the new transistor types being introduced are silicon. Both germanium and silicon are very abundant elements, but neither is found in the pure state, and it is quite difficult to process them to the high state of purity required for use in transistors. The first transistors were made of germanium because techniques for getting pure germanium were developed first. However, now it is possible to refine silicon to the high degree of purity required, at a reasonable cost, and since silicon has several advantages over germanium for use in semiconductor devices it has in many ways replaced germanium.

In general, there is not too much difference between the operation of semiconductor devices made from germanium and those made from silicon. We will cover the important points of these devices made from both materials since you will run into semiconductor devices of both types.

The Germanium Atom.

The arrangement of electrons about the nucleus in a germanium atom is shown in Fig. 3A. The nucleus of the germanium atom has a positive charge of 32. Thus as you might expect, there will be 32 electrons revolving in the shells about the nucleus. There are two electrons in the first shell, eight in the second, eighteen in the third and four in the fourth shell. Thus, the first, second and third shells are filled, but there are only four electrons in the outer shell. However, these four electrons, which are called the valence electrons, are bound to the nucleus much more so than the one or two electrons found in the outer shell of a conductor.

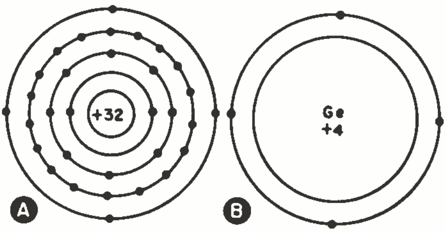

Fig. 3. (A) is the germanium atom with a charge of 32. (B) shows the simplified symbol.

The important electrons in the germanium atom, insofar as its use in semiconductors is concerned, are the four electrons in the outer shell because the shell is not filled. The other electrons are bound so closely to the nucleus that they cannot easily be removed. Therefore, germanium is often represented as shown in Fig. 3B.

The Silicon Atom.

The arrangement of electrons about the nucleus in a silicon atom is shown in Fig. 4A. The nucleus of the silicon atom has a positive charge of 14. Therefore, there will be fourteen electrons revolving about the nucleus. There are two electrons in the first ring, eight in the second and four in the third. Thus the first and second rings are filled, but there are only four electrons in the outer shell. These four

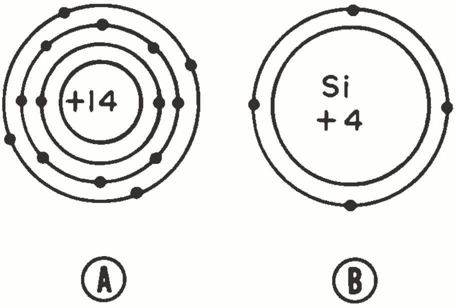

Fig. 4. (A) shows the silicon atom with a charge of 14. (B) shows the outer shell with four electrons.

electrons are the valence electrons like the four in the germanium atom and are bound fairly closely to the nucleus. As in the case of the germanium atom, the four electrons in the outer ring are the ones that are of importance in the use of silicon in semiconductors.

Notice the similarity between the silicon and germanium atoms. In both atoms, the outer shell or ring has four electrons, and all the other shells are filled.

The tendency of some materials like silicon and germanium, that do not have the outer shell completely filled with electrons, is to get additional electrons to fill up the outer shell. In pure germanium and silicon, the electrons in the outer shell of one atom are bound as closely to that atom as the four electrons in the outer shell of another atom. Therefore one atom cannot pull electrons away from another atom. Instead, two nearby atoms will share one outer electron from each atom. In other words, two atoms of germanium may share electrons as shown in Fig. 5A; and two atoms of silicon may share electrons as shown in Fig. 5B. By sharing electrons in this way, each atom will partly fill its outer shell. This pair of shared electrons, one from each of two atoms, is called "a covalent bond".

In order to try to fill its outer ring with electrons, a single germanium atom or a single silicon atom will establish covalent bonds with four other atoms. This arrangement of atoms in a piece of germanium is shown in Fig. 6A. A similar arrangement of atoms in a piece of silicon is shown in Fig. 6B. These pieces of silicon and germanium are called crystals and the way in which they are arranged is called a lattice structure. Each atom shares each of its four valence electrons with one valence electron of another atom to form these bonds.

INTRINSIC CONDUCTION

Even at comparatively low temperatures, there is heat energy in all materials. This energy is sufficient to cause a few of the electrons to move out of their proper place in the lattice structure of either the germanium crystal or the silicon crystal and become free electrons. These free electrons are available for conduction of electric current. The number of free electrons available is much higher in germanium than it is in silicon.

When one of these electrons moves out of its position in the lattice structure, it leaves an empty space in the crystal lattice. This empty space is called a hole. An electron from a

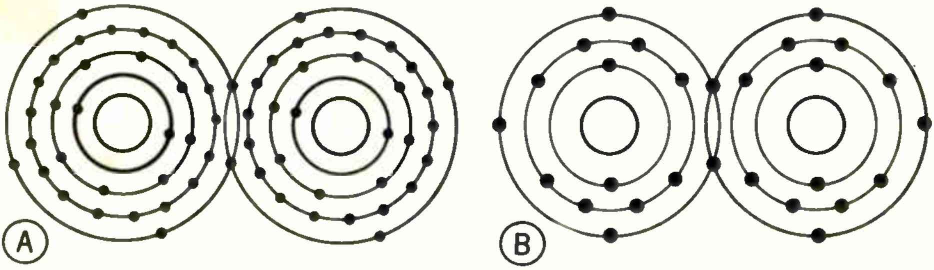

Fig. 5. The sharing of two electrons by two germanium atoms is shown at A; by two silicon atoms at B.

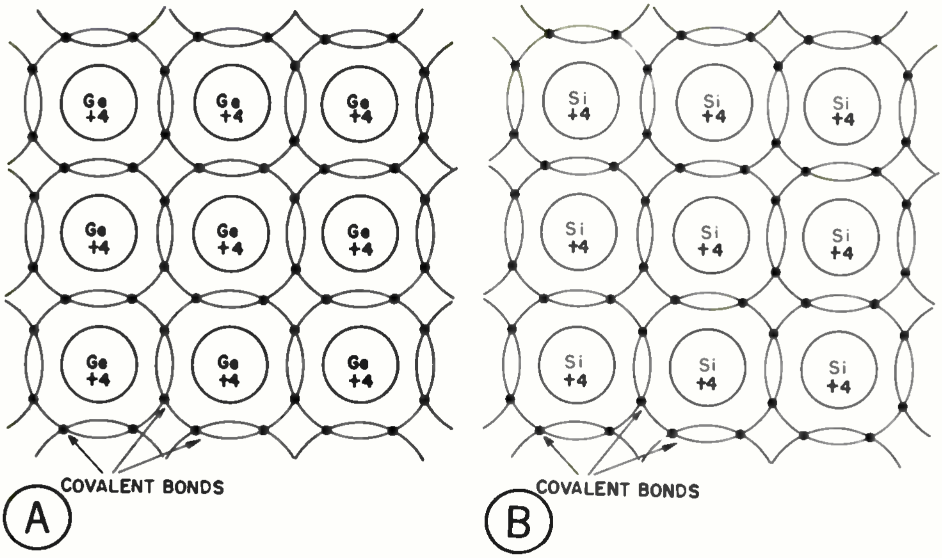

Fig. 6. The lattice structure of germanium is shown at A; of silicon at B.

nearby atom can move into this hole thus creating a new hole at the place it left. Another electron may move out of still another atom to fill this new hole, leaving behind it a hole. This movement of an electron to fill a hole thus creating a new hole in the place it left makes it look as if holes themselves move. Furthermore, since the hole represents a missing electron, it has a positive charge.

In a piece of germanium or silicon, the electrons are in a constant state of motion about their atoms. If in its movement an electron comes closer to a hole than to its own atomic nucleus, it will be strongly attracted to the hole and will leave its atom. When there is no voltage applied across the crystal, the movement of a hole or an electron is a random movement. Holes and electrons may move in any direction.

If heat or some other form of external energy is applied to the crystal, the resistance of the material is reduced. This happens because more electrons are freed by the energy applied to the crystal. In addition, the speed of the random movement is increased.

The movement of an electron out of an atom forms a hole in the atom. Thus, whenever an electron is freed from an atom a hole is formed. This free electron and the hole it forms are called a "hole-electron pair". The formation of hole-electron pairs is a continuous process. Also the filling of holes by electrons is a continuous process. In other words, the process of an electron leaving its atom and forming a hole, and another electron moving in to fill the hole and in so doing creating a new hole, is a continuous process. The conduction of electricity in pure germanium or pure silicon crystals due to the formation of hole-electron pairs is called the intrinsic conduction.

The conductivity of a germanium crystal or a silicon crystal, which is the ability of the material to conduct an electric current, depends on the average length of time an electron is free and on the number of free electrons. We mentioned previously that there are more electrons free if external energy, such as heat, is applied to the material. Therefore the conductivity rises as the temperature of the material is increased.

This type of conduction is much higher in germanium than it is in silicon. As an example, if we had a germanium crystal exactly one centimeter on each side and measured the resistance across two parallel surfaces, we would find the resistance to be approximately 60 ohms. The resistance of an equivalent piece of silicon would be approximately 60,000 ohms. Thus intrinsic conduction is much higher in germanium than it is in silicon.

Intrinsic conduction in transistors is undesirable. It is kept as low as possible by holding the operating temperature of the material down. Transistors are also shielded from light because light is a form of energy and light striking the crystal will increase the intrinsic conduction. Since silicon has a much lower intrinsic conduction than germanium, semiconductors made from silicon are less affected by heat than are semiconductors made from germanium. This is one of the chief advantages of silicon over germanium as a semiconductor material.

In their pure forms, neither germanium nor silicon are useful in semiconductor devices. In fact, in spite of intrinsic conduction, neither material is a good conductor at room temperature; they are both fairly good insulators. To use these materials in semiconductors, controlled amounts of other selected elements called impurities are added to the crystals to alter their characteristics. By adding these materials we can produce two types of silicon and two types of germanium. They are called N-type and P-type. Now, let us study the characteristics of these two types of materials.

N-TYPE MATERIAL

N-type silicon or germanium can be produced by adding as an impurity an element that has five electrons in its outer ring. An example of this type of material is arsenic. Arsenic has a positive charge of 33 on the nucleus and has 33 electrons in the shells surrounding the nucleus. There are two electrons in the first shell, eight in the second, eighteen in the third and five in the fourth or outer shell. In other words, arsenic is just like germanium except that the nucleus has one more positive charge and there is one additional electron in the outer shell.

If a small amount of arsenic is added to the germanium, the arsenic atoms will form covalent bonds with the germanium atoms as shown in Fig. 7. However, to form the covalent bonds with its neighboring germanium atoms, the arsenic atom needs only four of the electrons in its outer shell. Therefore there will be one electron left over when the arsenic atom forms covalent bonds with the four neighboring germanium atoms. This electron is free to move about within the crystal in exactly the same manner as a single valence electron in a good metal conductor. The addition of arsenic, which produces these free electrons, greatly reduces the resistance of the material.

When a small amount of arsenic

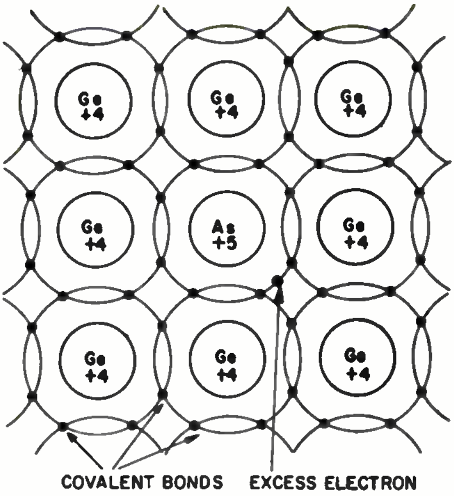

Fig. 7. Germanium with arsenic added.

is added to a silicon crystal exactly the same thing happens. The arsenic atom forms covalent bonds with the silicon atoms. As in the case of the germanium atom, only four of the electrons in the outer shell of the arsenic atom are used in forming these covalent bonds so there will be one electron left over.

When germanium or silicon have had an impurity added to them we say they have been doped. When semiconductor material has been doped with a material such as arsenic that results in there being excess electrons, we call it an N-type material. The N refers to the negative carriers, which are the free electrons. Arsenic is called a donor impurity because it donates an easily freed electron.

In addition to arsenic, other materials have been used as donors. Phosphorus, which has a total of fifteen electrons, can be used. The phosphorus atom has two electrons in the first shell, eight in the second and five in the third. Four of the electrons in the valence shell or ring will form covalent bonds with germanium or silicon atoms leaving a fifth electron free. Antimony, which has 51 electrons, also has been used as a donor. Antimony has two electrons in the first shell, eight in the second, eighteen in the third, eighteen in the fourth and five in the fifth or valence shell.

P-TYPE MATERIAL

If instead of adding a material with five electrons in its valence shell, we add a material with only three electrons in the valence shell, we have a situation where the impurity added to the silicon or germanium has one less electron than it needs to establish covalent bonds with four neighboring atoms. Thus, in one covalent bond there will be only one electron instead of two. This will leave a hole in that covalent bond.

A material that is frequently used for this purpose is indium. Indium has 49 electrons, two in the first shell, eight in the second, eighteen in the third, eighteen in the fourth and three in the fifth or valence shell.

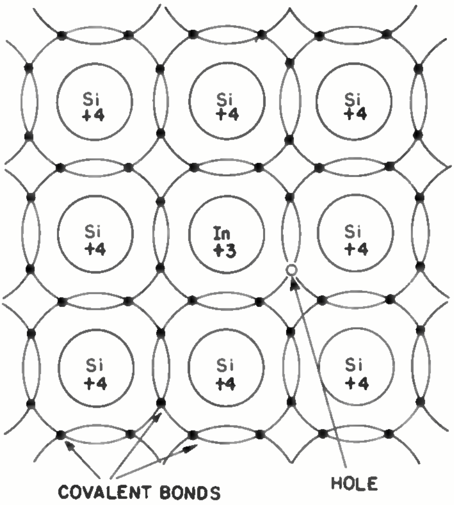

Fig. 8. Silicon with indium added.

The manner in which indium forms covalent bonds with neighboring silicon atoms is shown in Fig. 8. It forms covalent bonds with germanium atoms in the same way.

We mentioned previously that even at comparatively cold temperatures there is some heat energy within the crystal and thus there will be a few free electrons moving about the crystal. These free electrons are strongly attracted to the holes in the covalent bond produced where an indium atom has replaced a silicon or a germanium atom. Thus an electron will move into a hole in the covalent bond producing a new hole in another atom and giving the effect that the hole is moving as shown in Fig. 9.

Since a hole in the crystal actually represents a shortage of an electron, it is an area with a positive charge. Therefore when a semiconductor material has been doped with a material such as indium that produces holes in the lattice structure, we call it a P-type material. P stands for positive; since holes represent a shortage of an electron we say they act as positive carriers. The indium is called an accepter impurity because its atoms leave holes in the crystal structure that are free to accept electrons. In addition to indium, boron and aluminum are also used as accepter impurities. Boron has 5 electrons, two in the first shell and three in the second which is the valence shell. Aluminum has 13 electrons, two in the first shell, eight in the second and three in the third or valence shell.

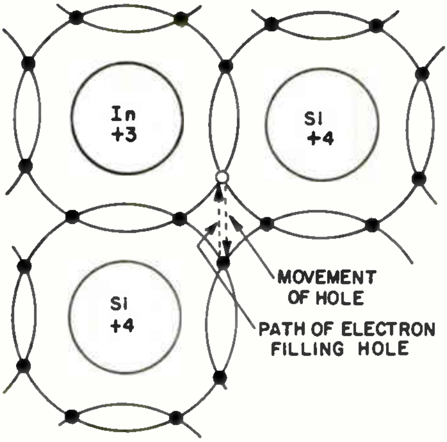

Fig. 9. When an electron fills a hole, another hole will apparently move to where the electron was.

CHARGES IN N-TYPE AND P-TYPE MATERIAL

When a donor material such as arsenic is added to germanium or silicon, the fifth electron in the valence ring of the arsenic atom does not become part of a covalent bond. This extra electron may move away from the arsenic atom to one of the nearby germanium or silicon atoms.

The arsenic atom has a charge of +33 on the nucleus and normally has 33 electrons to neutralize this charge. When the electron moves away from the atom there will be only 32 electrons to neutralize the charge on the nucleus, and as a result there will be a small region of positive charge around the arsenic atom. Similarly, the excess electron that has moved into a nearby germanium or silicon atom will provide an excess electron in the atom. In the case of the germanium atom there will be a total of 33 electrons around a nucleus requiring only 32 electrons to completely neutralize it, and in the case of the silicon atom there will be 15 electrons around the nucleus requiring only 14 electrons to neutralize it. This means that the atom will have an extra electron so that there will be a region of negative charge around this atom.

It is important to notice that although there is a region of positive charge around the arsenic atom after the electron has moved away, and a region of negative charge around the germanium or silicon atom taking up the extra electron, the total charge on the crystal remains the same. In other words, a given crystal will have a net charge of zero. This means that there will be exactly enough electrons to neutralize the positive charges on the nuclei on the various atoms. But because some of the electrons may move about in the crystal, there will be regions in the crystal where there are negative charges and other regions where there are positive charges, even though the net charge on the crystal is zero.

In a P-type material to which material such as indium has been added we will have a similar situation. You will remember that the indium atom has only three electrons in its valence ring. These are all that were needed to neutralize the positive charge on the nucleus. However, with only three electrons in the valence ring, there is a hole in one of the covalent bonds formed between the indium atom and the four adjacent germanium or silicon atoms. If an electron moves in to fill this hole, then there is one more electron in the indium atom than is needed to neutralize the charge on the nucleus. Thus there will be a region of negative charge around the indium atom. Similarly, if one of the germanium or silicon atoms has given up an electron to fill the hole in the covalent bond, then the atom which has given up the electron will be short an electron so that there will be a region of positive charge around this atom. Again, while this giving up of an electron by a germanium atom and the acceptance of an electron by the indium atom ionizes or charges both atoms involved, the net charge on the crystal is still zero. We simply have one atom that is short an electron and another atom that has one too many. The crystal itself does not take on any charge.

These ionized atoms produced in both the N-type and the P-type germanium and the N-type and the P-type silicon are not concentrated in any one part of the crystal, but instead are spread uniformly about the crystal. If any region within the crystal were to have a very large number of positively charged atoms, these atoms would attract free electrons from other parts of the crystal to neutralize part of the charged atom, so that the charge would be spread uniformly about the crystal. Similarly, if a large number of atoms within a small region have had an excess of electrons, these electrons would repel each other and spread throughout the crystal.

Both holes and electrons are involved in conduction at all times. Holes are called positive carriers and electrons negative carriers. The one present in greatest quantity is called the majority carrier; the other is the minority carrier. In an N-type material, electrons are the majority carriers and holes are the minority carriers, whereas in a P-type material, holes are the majority carriers and electrons the minority carriers.

SUMMARY

This is a very important section of this lesson. You have covered many of the fundamentals of semiconductors on which we will build the remainder of the lesson. It is important that you understand the basic theory of semiconductors in order to be able to understand how semiconductor diodes and transistors work. We will summarize the important points that were covered in the preceding section.

If any of these points are not clear, you should go back and study the lesson again until they are clear. If you understand the first section of the lesson, you should be able to understand the material following without too much difficulty. However, if you do not understand what has been covered previously, you will have difficulty understanding what is to follow.

Pure semiconductor material such as germanium or silicon is a very poor conductor. In fact, it is an insulator if it is protected from all outside sources of energy. However, even at room temperature there is enough heat present in germanium and silicon to produce some electron and hole movement. The movement is much greater in germanium than it is in silicon.

An electron movement out of a covalent bond in a germanium or silicon atom leaves a hole in that bond. The hole will attract an electron from a nearby atom, producing a hole in that atom. Thus, both the hole and the electron appear to move. The holes are positive carriers and the electrons negative carriers of electricity. This formation of hole-electron pairs is undesirable in transistors and steps are taken to keep it as low as possible. The formation of hole-electron pairs increases as the temperature increases and is a much more serious problem in germanium-type semiconductor material than in silicon-type semiconductor material.

Semiconductor materials can be doped by adding small amounts of impurities. If a material with five electrons in the valence ring is added, the material is called a donor-type impurity. This type of material has one electron left over after it forms covalent bonds with four neighboring germanium or silicon atoms. Thus there will be an excess of electrons. We then refer to this kind of material as an N-type material.

If the germanium or silicon is doped with an impurity, called an accepter impurity, having three electrons in the valence shell, the impurity forms covalent bonds with the four neighboring germanium or silicon atoms. However, there will be a hole in one of the covalent bonds because the impurity has only three electrons available to form covalent bonds with four neighboring germanium and silicon atoms. This type of germanium or silicon is called P-type because there will be holes in the material, and these holes act as positive carriers.

Another point to remember is that when an electron is freed or when a hole captures an electron, the atoms involved become charged, or ionized. Thus throughout both N-type and P-type germanium or N-type and P-type silicon we have small regions of charge. However, the net charge on the crystal is zero and the charged regions are evenly distributed throughout the material.

SELF-TEST QUESTIONS

(a) How many electrons are there in a valence shell or ring in a silicon atom?

(b) What are the two types of material most widely used in semiconductor devices?

(c) What is meant by a covalent bond?

(d) How many covalent bonds will a single germanium or silicon atom establish?

(e) What is intrinsic conduction?

(f) Is intrinsic conduction desirable?

(g) In which type of conductor material, germanium or silicon, is intrinsic conduction the greatest?

(h) What is the greatest cause of an increase in intrinsic conduction in germanium?

(i) Which semiconductor material, silicon or germanium, has greater resistance?

(j) What is an N-type material?

(k) What is a donor material?

(l) Name two materials used as donors.

(m) What is P-type material?

(n) What is an accepter impurity?

(o) Name three types of accepter material.

(p) In N-type material what is the majority carrier?

(q) What are the majority carriers in the P-type material?

(r) When a donor impurity such as arsenic loses an electron in a semiconductor material, what happens to the arsenic and to a nearby atom that gains the electron insofar as their relative charge is concerned?

(s) Although there are small areas that have positive and negative charges in a doped semiconductor, what is the overall charge on the crystal?

Current Flow in Semiconductors

In order to understand how transistors operate, there are several new ideas that you must master. First, you must understand how current flows through both N-type and P-type semiconductor materials. Current flow through an N-type material is not too different from current flow through metals, which you have already studied. However, there is quite a difference in the way current flows through a P-type material.

When a P-type material is placed next to an N-type material, we have what is called a junction. The action that occurs at the point of contact between these two different types of materials is extremely important. It is this action that makes the transistor possible.

In this section of the lesson we will study how current flows through N-type and P-type materials. We need to understand current flow through both types of germanium or silicon to be able to understand how a junction works. In a later section we will see how a junction works. Later, we will see what happens in a transistor, which has two junctions.

This section is extremely important, and you should be sure that you understand it completely. Once you understand this material, it will be a simple step to see how transistors can be used to amplify signals.

DIFFUSION

As we have mentioned, adding impurities to pure germanium or silicon adds free electrons or holes. You might at first think that when there is no voltage applied there would be no motion of the free holes and electrons. However, this is not true--as you learned when we discussed intrinsic conduction, there is a certain amount of energy present in the crystal. This energy might be due to the temperature of the crystal, because as we pointed out before, even at room temperature the crystal does have heat energy. Motion of the free holes or electrons due to energy of this type is at random; in other words there is no net movement in any one direction. Holes move one atom at a time, and any hole may move from its starting location to any of the surrounding atoms. This means that a hole may start off in one direction as it moves from one atom to another, and then may move in almost the opposite direction as it moves to still a third atom. Similarly, electron movement is in a random direction; a given electron may move in first one direction and then in another.

When electrons and holes are in motion, the different carriers are moving in different directions. Remember that when there is a hole in one atom, and an electron moves from another atom to fill that hole, a new hole appears in the second atom. In other words, the electron has moved from the second atom to the first, whereas the hole has moved in the opposite direction from the first atom over to the second atom that gave up the electron. The result is that the effective current flow of any one carrier is cancelled by the movement of the other carrier and the resulting current flow in any direction is zero.

This random motion of carriers is called diffusion. It goes on at all times in a crystal whether there is a voltage applied to the crystal or not. Every effort is made in the design of transistors to keep this diffusion as low as possible.

DRIFT

Another type of carrier movement in semiconductors is known as "drift". This is the type of movement that is obtained when a voltage is applied across the crystal. Since the manner in which current flows through N-type and P-type material is different, let's consider them separately.

N-Type Material.

In Fig. 10 we have shown an N-type crystal with a voltage applied to it. The voltage difference supplied by the battery provides a force which makes it easier for the electrons to move in one direction than in the other. In an N-type material, the electrons will be attracted by the positive terminal of the battery. Because in the N-type material the electrons greatly outnumber the holes, they will carry the current.

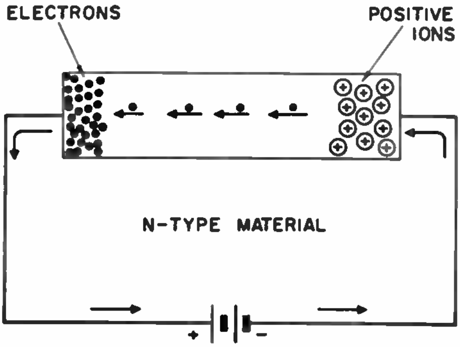

Fig. 10. N-type crystal with voltage applied to it.

When the electrons are attracted by the voltage applied to the positive terminal, they will move towards the positive terminal. When an electron moves away from the covalent bond that produced this free electron, it will leave behind an atom with a positive charge, which we call a positive ion. The electrons moving towards one end of the crystal set up a region that has a local negative charge, as shown in Fig. 10. This negative charge sets up a potential difference between that part of the crystal and the positive terminal of the battery. In other words the attraction of the positive battery terminal causes electrons to bunch up near the end of the crystal connected to the positive terminal. The electrons are drawn from the crystal into the wire connecting the crystal to the positive terminal of the battery by this potential difference.

Meanwhile, the electrons that have left the atoms at the other end of the crystal have left behind positive ions. This sets up a region of positive charge around the end of the crystal connected to the negative terminal of the battery so there will be a potential difference between the negative terminal of the battery and this region of positive charge. This potential difference will pull electrons from the wire into the crystal. These electrons replace the free electrons that were attracted to the positive terminal of the battery.

The number of electrons leaving the crystal at the end connected to the positive terminal of the battery will be exactly equal to the number of electrons entering the crystal at the end connected to the negative terminal of the battery. Since the crystal was electrically neutral be-

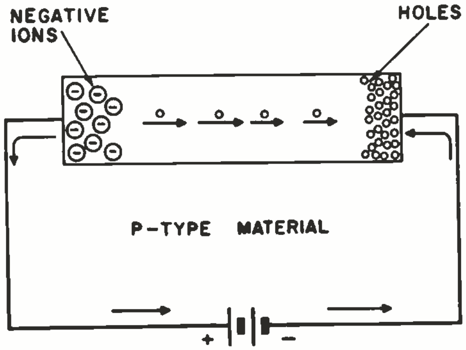

Fig. 11. P-type crystal with voltage applied to it.

fore the battery was connected and the number of electrons in it are constant, the crystal remains electrically neutral.

P-Type Material.

Conduction through P-type material is quite different from conduction through N-type material. In the P-type semiconductor, nearly all of the current is carried by holes. When a battery is applied to a P-type semiconductor, as shown in Fig. 11, the voltage causes the holes to drift towards the negative terminal. They are repelled by the positive potential applied to the one end of the material and attracted by the negative potential applied to the other end. When a hole starts moving away from the end of the material connected to the positive terminal of the battery, it moves because it is filled by an electron attracted from a nearby germanium atom.

When the hole in an accepter type atom is filled with an electron, the atom actually has one electron more than it needs to neutralize the charge on the nucleus. Thus, the atom has a negative charge, or in other words it becomes a negative ion. Negative ions that are formed near the end of the semiconductor that is connected to the positive terminal of the battery build up a region of negative charge at this end of the material. The extra electrons are drawn from these ions by the positive terminal of the battery, and a new hole is formed. These holes then drift towards the end of the semiconductor that is connected to the negative terminal of the battery, and build up a positive charge at this end of the semiconductor. This positive charge attracts free electrons from the external circuit. As a hole is filled with an electron, it disappears.

Thus in the P-type material, we have an electron flow in the external circuit from the negative terminal of the battery to the semiconductor, and from the semiconductor to the positive terminal of the battery. However, in the semiconductor itself, current flow is by means of holes, which drift from the end of the semiconductor that is connected to the positive terminal to the end that is connected to the negative terminal of the battery. Keep this point in mind, that even in the P-type material where conduction within the material is by holes (which are positive carriers) the current flow in the external circuit is by means of electrons and is in the conventional direction from the negative terminal towards the positive terminal of the battery in the external circuit.

There are several important differences between conduction in N-type semiconductors and conduction in P-type semiconductors. In both cases electrons flow from the external circuit into the crystal and then out of the crystal into the external circuit. However, in the N-type crystals, the excess electron produced when a donor atom forms covalent bonds with four germanium atoms is a free electron that can move about in the crystal. However, in the P-type material, the electrons are not free, but can move only to holes. Since a hole can capture an electron from any of its surrounding atoms, it is the hole that is free to move in any direction.

Another important difference between the N-type and the P-type materials is that a free electron moves approximately twice as fast as a hole. This affects the conductivity of the two types of semiconductor material. If we have two crystals, one an N-type and the other a P-type, if the N-type material has the same number of free electrons as the P-type has holes, the N-type will have a lower resistance because the free electrons can move approximately twice as fast as the holes in the P-type material.

SUMMARY

The important thing to remember from this section is that there are two types of carrier movement in semiconductors. The first is called diffusion and is simply a random movement of the carriers in the semiconductor material. The current flow produced by one carrier is cancelled by the movement of the other, and the resultant current flow in any direction is zero. Diffusion is the random motion of electrons or holes in a doped semiconductor due to the energy of the material.

The other type of movement we discussed is called drift. This type of conduction is produced when a potential is connected across a semiconductor. This potential can cause either electrons or holes to move within the semiconductor. In an N-type semiconductor, current flows through the semiconductor because of the movement of the free electrons produced by the donor atoms that have been added to the semiconductor material. In the P-type semiconductor, current flow through the crystal is by means of holes which are produced when an accepter-type impurity is added to the crystal.

In both cases current flow in the external circuit is from the negative terminal of the battery to the crystal and from the crystal to the positive terminal of the battery. In the N-type material, electron flow through the crystal is from the end connected to the negative terminal of the battery to the end connected to the positive terminal of the battery. In the P-type semiconductor, the holes flow from the end of the semiconductor connected to the positive terminal of the battery to the end of the semiconductor connected to the negative terminal of the battery.

The speed with which electrons move through N-type material is about twice the speed with which holes move through P-type material. Thus N-type material has better conductivity than P-type material, which means that N-type germanium will have a lower resistance than P-type germanium.

SELF-TEST QUESTIONS

(t) When an accepter-type impurity is added to a silicon or a germanium crystal, what type of carrier is produced in the crystal?

(u) What is diffusion?

(v) What is the name given to the movement of carriers in a semiconductor material when a voltage is applied across the material?

(w) What are the majority carriers in an N-type material and in what direction do they move when a voltage is applied across the material?

(x) What are the majority carriers in a P-type material and in what direction do they move through the material when a potential is applied across the material?

(y) When current is flowing through a crystal, will the crystal be charged?

(z) Is the rate of travel of electrons through N-type material the same as the rate of travel of holes through P-type material?

(aa) If you had two identical pieces of silicon and one was doped so that it was N-type material and the other doped so that it was P-type material, which would have the lower resistance?

Semiconductor Diodes

Just as there are diode tubes, there are also diode semiconductors. Some diode semiconductors are used as detectors; others are used as rectifiers in power supplies to change ac to pulsating dc. Diodes used as detectors are often referred to as signal diodes. Both germanium and silicon signal diodes are widely used. Diodes used for power rectification are almost exclusively silicon diodes. Relatively small silicon diodes can often handle considerably more current than a large rectifier tube.

A semiconductor diode is made by taking a single crystal and adding a donor impurity to one region and an accepter impurity to the other. This will give us a single crystal with a P section and an N section. Where the two sections meet, we have what is called a junction. Contacts are fastened to the two ends of the crystal so that a simple PN junction diode like the one shown in Fig. 12 is formed. For simplicity in the diagram we have represented the crystal as a box-like structure with one half being P-type material and the other half N-type material with a junction between the two sections.

This type of diode is called a junction diode. The action that takes place at the junction of the P-type crystal and the N-type crystal is what we will be most concerned with now. In order to understand how a junction diode works, you must learn something about the movement of electrons and holes near the junction. The movement of holes and

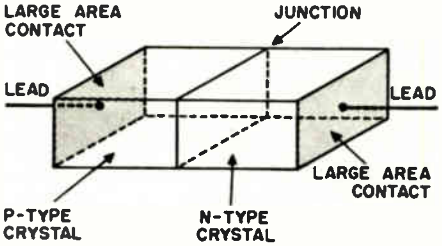

Fig. 12. Simple PN junction.

electrons will form what is called a depletion layer at the junction. Now let us see what the depletion layer is and how it is formed.

DEPLETION LAYER

Remember that in an N-type crystal there are free electrons, and in a P-type crystal there are free holes. Also remember that the electrons and holes are moving about the crystal with a random motion, called diffusion. In the PN junction diode, holes will be moving about in the P section and electrons in the N section. Some of the holes will cross over the junction from the P section into the N section and be filled by a free electron. Similarly, some of the electrons in the N-type material will diffuse across the junction and fill a hole in the P section.

When an atom in the N section loses an electron the atom becomes charged or ionized. It will have a positive charge because it will have one less electron than is needed to completely neutralize the charge on the nucleus. Thus electrons diffusing across the junction to fill a hole on the P side of the junction will leave behind atoms with a positive charge. At the same time, when an electron fills a hole on the P side, the atom will have one more electron than it needs to completely neutralize the charge on its nucleus, and therefore that atom will have a negative charge. Similarly, holes diffusing from the P side of the junction over into the N side will leave behind atoms with a negative charge. When the hole moves over to the N side, it will mean the atom into which it moves will have an electron missing and therefore it will assume a positive charge. When the hole leaves the P side of the junction because it has been filled by an electron, the atom that gains the extra electron will have a negative charge.

As a result of this diffusion across the junction, a region will build up around the junction called the depletion area. On the P side of the junction there will be an area where the holes are missing. On the N side of the junction there will be an area where electrons are missing; thus we get the name depletion layer.

The missing holes on the P side of the junction will result in a negative charge on the P side and the missing electrons on the N side will produce a positive charge on the N side of the junction. The negative charge on the P side of the junction will build up until it has sufficient amplitude to prevent any further electrons from the N side from crossing the junction to the P side. Remember that the negative charge built up on the P side of the junction will repel electrons from the negative side. Similarly, the positive charge built up on the N side of the junction will prevent holes from the P side from crossing the junction into the N-type material. Thus this area, which is called the depletion layer because it is short holes on one side and electrons on the other side, is also sometimes called the barrier layer, because the charges built up form barriers to prevent any further diffusion of holes or electrons across the junction. It is also sometimes called a potential barrier because a negative potential is built up on the P side of the junction and a positive potential is built up on the N side of the junction.

The action taking place at the junction is quite important and is illus-

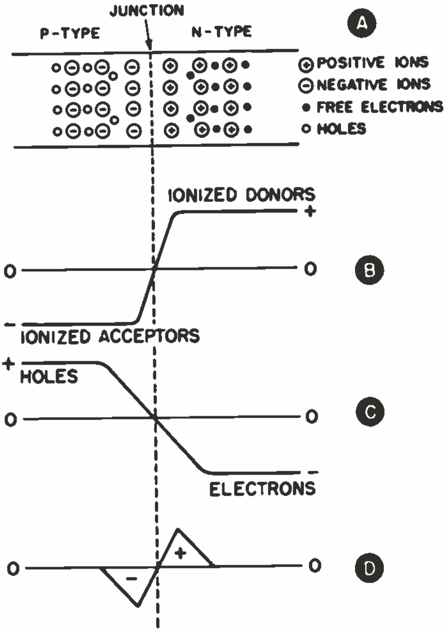

Fig. 13. (A) locations of ions and carriers at a PN junction; (B) charges at junction due to ionized impurity atoms; (C) carrier charges available; (D) resultant charges.

trated in Fig. 13A. On the P side of the junction we have shown ionized atoms that have a negative charge because the holes in these atoms have been filled by electrons. The holes have escaped and travelled or diffused across the junction into the N-type material. On the N side of the junction we have shown atoms that are ionized and have a positive charge. These atoms have a positive charge because they have lost electrons. These electrons have diffused across the junction into the P-type material. Thus we have a charged area at the junction. The negative charge on the P side of the junction prevents any further movement of electrons from the N-type material across the junction into the P-type material, and the positive charge on the N side of the junction prevents any further movement of holes from the P-type material across the junction into the N-type material.

The charge on the ions is shown in Fig. 13B. Notice that on the P side of the junction the atoms that have lost holes by gaining electrons have a negative charge. At the junction the potential drops to zero and then reverses on the N side where the ionized atoms have a positive charge because they have lost electrons.

In Fig. 13C we see the carrier charges which are available to neutralize the ionized atoms. At some distance from the junction there are holes with a positive charge. However, as we approach the junction, the concentration of these holes decreases because they are repelled away from the junction by the positive ions on the N side of the junction. On the N side of the junction at some distance from the junction we have many electrons available, but as we approach the junction, the charge drops to zero because these electrons are repelled away from the junction by the negative ions on the P side of the junction.

The resultant charges on the crystal are shown in Fig. 13D. As before, the crystal will have a tendency to remain neutral, or in other words not to have any charge. Some distance from the junction the atoms will have exactly the correct number of holes and electrons so that the net charge on the atoms is zero. As we approach the junction, the negative ions on the P side will result in an area in the crystal that has a negative charge. As we move closer to the junction, the charge will drop to zero so that at the junction itself the net charge on the atoms is zero. Then the charge builds up in a positive direction on the N side of the junction due to the ionized atoms that have lost electrons. As we move away from the junction we again reach a region where the atoms have exactly the correct number of electrons to neutralize the charges on the nucleus so the net charge in that area will be zero.

So far we have been discussing only the action of the majority carriers at the PN junction. However, there is one other important point we must consider in order to completely understand what happens at the junction. You will remember some time ago that we mentioned that holes and electrons are in a continuous state of motion in the crystal due to the energy of the crystal. For example, even at room temperature, the crystal contains a certain amount of heat energy and this energy is sufficient to cause motion of both electrons and holes. In the N-type material an electron will leave an atom creating a hole. This hole will be filled by an electron from another atom. Thus we have the continual formation of hole-electron pairs. Away from the junction, this formation of hole-electron pairs does not have any effect on the carrier concentration in the crystal. In other words, the holes will remain the majority carriers in the P-type region, and the electrons will remain the majority carriers in the N-type side of the crystal.

However, as we mentioned previously, both holes and electrons are involved in conduction at all times. There are minority carriers in both regions - holes in the N region and electrons in the P region. The holes produced in the N region near the junction will be attracted by the negative ions on the P side of the depletion layer at the junction and pass across the junction. These holes will tend to neutralize the ions on the P side of the junction. Similarly, free electrons produced on the P side of the junction will pass across the junction, and neutralize positive ions on the N side of the junction. This is an example of intrinsic conduction, conduction due to the formation of hole-electron pairs, and as we mentioned, this type of conduction is undesirable.

Now let us consider what happens due to the minority carriers crossing the junction. Holes crossing the junction from the N-type material to the P-type material tend to neutralize the positive ions on the P side of the junction. Similarly, electrons traveling from the P side of the junction to the N side of the junction tend to neutralize the negative ions on the N side of the junction. This flow of minority carriers across the junction weakens the potential barrier in the region around the atoms they neutralize. When this happens, the majority carriers are able to cross the junction at the location of the neutral atom. This means that the holes from the P side will cross over to the N side, and electrons from the N side will cross over to the P side.

The result is that we have both holes and electrons crossing the junction in both directions. The hole that crosses from the N side to the P side due to intrinsic conduction permits a hole to cross from the P side to the N side by diffusion. Similarly, an electron that crosses the junction from the P side to the N side due to intrinsic conduction permits another electron to go from the

N side to the P side by diffusion. The result of the holes and electrons crossing the junction in both directions is that these movements cancel each other, and the charge on the atoms at the junction remains the same. This movement of holes and electrons in both directions contributes nothing towards the net charge or current flow through the junction. However, the flow across the junction will produce a certain amount of heating; it will in effect use up a percentage of the total capacity of the junction to pass current so that the net result is to reduce the amount of useful current the diode can pass.

BIASED JUNCTIONS

If a battery is connected to the ends of a PN junction diode, the battery potential will bias the junction. If we connect the battery so that its polarity aids the flow of current across the junction, we call it a "forward-biased junction", whereas if we connect the battery so that the polarity opposes the flow of current across the junction, we say that it is a "reverse-biased junction". In both cases there will be some current flow through the junction, but as you might expect, with forward bias the current flow will be higher.

In order to understand how transistors work, you must understand both conditions of bias. You will study each condition separately, because the action that occurs at the junction is quite different in the two cases. In the operation of transistors both types of bias are used, and therefore it is important that you understand what happens in each case.

Forward Bias.

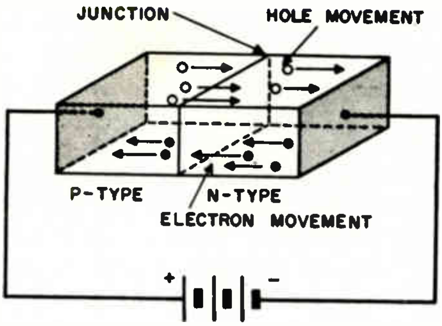

Fig. 14. Forward-biased junction.

When we connect a battery to a junction diode with the polarity such that it aids the movement of majority carriers across the junction, we say that the diode is forward biased. A forward-biased junction is shown in Fig. 14. Here the positive terminal of the battery is connected to the P-type section and the negative terminal of the battery is connected to the N-type section. Now let us consider what happens to the depletion layer at the junction of the P and N-type material when the battery voltage is applied.

The positive voltage connected to the end of the P-type crystal will repel holes towards the junction and attract electrons from the negative ions near it. The combination of holes moving towards the junction to neutralize charged negative ions on the P side of the junction and electrons being taken from the negatively charged ionized accepter atoms tends to neutralize the negative charge on the P side of the junction.

On the N side of the crystal, the negative terminal of the battery repels electrons towards the junction. These electrons tend to neutralize the positive charge on the donor atoms at the N side of the junction. At the same time the negative potential at the N side of the crystal attracts holes away from the charged positive ions on the N side of the junction. Both of these actions tend to neutralize the positive charge on the donor atoms at the junction.

The effect of the battery voltage is to reduce the potential barrier at the junction and allow more majority carriers to cross the junction. This means that we will have more electrons flowing from the N-type material across the junction to the P-type material and to the positive terminal of the battery and more holes traveling from the P-type material across the junction to the N-type material and towards the end of the crystal connected to the negative terminal of the battery. You know that we already had a certain number of intrinsic minority carriers crossing the junction, but now the majority carriers outnumber them, so there will be a steady current flow from the negative battery terminal, through the N-section, across the junction and through the P-section, to the positive battery terminal.

Placing a forward bias on a junction diode drives majority carriers back into the depletion layer and allows conduction across the junction. If the battery voltage is increased, more carriers will arrive at the junction and the current flow will increase. Eventually, if we continue to increase the battery voltage, we will reach a point where all the charges at the junction are neutralized. When this happens, the holes will fill the P-type region right up to the junction; electrons will fill the N-type region up to the junction; and the only limit to current flow through the diode will be the resistance of the material on the two sides of the junction.

It is important for you to remember that in a forward biased junction conduction through the crystal will be by the majority carriers. Any intrinsic conduction across the junction will be by minority carriers and this will subtract from the total current flow across the junction. Increasing the forward bias will increase the current flow across the junction until the point is reached where all the charges at the junction are neutralized, at which time the potential barrier will disappear, and current flow across the junction will be unhindered by any potential across the junction.

Reverse Bias.

If we reverse the battery connections we will have what is known as reverse bias. This condition is shown in Fig. 15.

With a reverse bias applied to a junction diode, the negative terminal of the battery will be connected to the P-type section, and will attract holes away from the junction, and increase the shortage of holes on the P side of the junction. At the same time the positive terminal of the battery is connected to the N-type section of the crystal and this

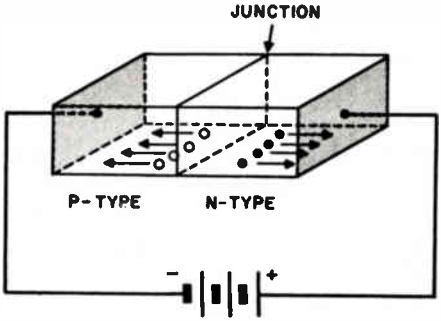

Fig. 15. Reverse-biased junction.

terminal will attract electrons away from the junction and increase the shortage of electrons on the N side of the junction. This movement of holes and electrons away from the junction will in effect result in an increased potential barrier at the junction. The increase in potential barrier occurs because there will be fewer holes on the P side of the junction to neutralize the negative ions and fewer electrons on the N side to neutralize the positive ions formed on this side of the junction. The increase in potential barrier will help prevent any further current flow across the junction due to majority carriers.

The current flow across the barrier, however, is not zero because we will still have minority carriers crossing the junction. Holes forming in the N side of the depletion layer will be attracted by the negative potential applied to the end of the P-type section of the crystal, and electrons breaking loose from their nuclei in the P side of the depletion layer will be attracted by the positive voltage applied to the end of the N-type section of the crystal.

We had this situation when there was no bias applied to the junction. Holes from the N side would cross over to the P section, and electrons from the P side would cross over to the N section. However, when there was no bias applied to the crystal, these minority carriers would neutralize ions near the junction and allow the majority carriers to cross the junction. However, since the minority carriers are now attracted away from the junction by the potential applied to the crystal, all of the minority carriers do not remain near the junction to neutralize charged atoms so they no longer allow the passage of an equal number of majority carriers in the opposite direction. This means that the flow of minority carriers across the junction is not fully offset by a flow of majority carriers in the opposite direction. Therefore, there will be a small current flow across the junction due to the minority carriers crossing the junction. This current flow is very small and nearly constant at all normal operating voltages in signal diodes and power rectifier diodes. However, as you will see later, there are certain types of diodes where this reverse current can increase quite rapidly even at low voltages.

It is important to realize that when a reverse bias is applied to a junction diode, the bias increases the potential difference across the junction and makes it more difficult for majority carriers to cross the junction. However, some minority carriers will still cross the junction with the result that there will be a small current flow across the junction due to the minority carriers.

COMPARISON OF JUNCTION DIODES AND VACUUM TUBES

Although the operation of junction diodes designed for use as rectifiers is quite different from the operation of vacuum tubes, they can perform identical tasks and therefore some comparison of the most important characteristics of both is in order.

When there is no voltage applied to a junction diode, the net current flow across the junction is zero. On the other hand, in a vacuum tube, even though there may be no voltage applied to the plate of the tube, some of the electrons will leave the cathode with sufficient velocity to travel across the space between the cathode and the plate and strike the plate. This will result in a small current flow from the cathode to the plate of the tube even though there may be no voltage applied to the plate of the tube.

We can consider applying a positive voltage to the plate of a vacuum tube and a negative voltage to the cathode as being similar to placing a forward bias on a junction diode. Under both circumstances there will be a current flow through the diode. In this respect the two are similar.

When the voltages applied to the diode vacuum tube are reversed so that there is a negative voltage applied to the plate and a positive voltage to the cathode, there will be no current flow at all through the tube. The negative potential on the plate of the tube will repel electrons from the plate. This reverse voltage situation is similar to a reverse bias across a junction diode. However, when we place a reverse bias across a junction diode, there will be some current flow across the junction due to the conduction by minority carriers. As long as the breakdown voltage of the junction diode is not exceeded, this current will be very small and almost constant. In a good diode, it is so small it can be ignored.

We can summarize the characteristics of diode vacuum tubes and junction diodes as follows: with forward bias both the tube and junction diodes will conduct. With reverse bias, the tube will not pass current; the junction diode will pass a small current. With no bias, the tube will pass a small current; the junction diode will not.

ZENER DIODES

In junction diodes designed for use as rectifiers we must be careful not to exceed the rated reverse voltage of the diode. In other words, if we place too high a reverse bias across the junction, the junction will break down, a very high current will flow across the junction for a short while, and the diode will be destroyed. However, in some diodes we make use of this reverse current due to minority carriers. In diodes of this type both the P section and the N section are doped quite heavily. The junction between the P section and the N section is considerably larger than the junction of the rectifier-type diode, so that when the diode begins to pass current in the reverse direction, it can pass it over a larger area and thus avoid destroying the diode. This type of diode is used as a voltage reference and is referred to as a voltage-reference diode or a Zener diode.

In the Zener diode, the current remains small with low reverse voltages. At a certain voltage, called the breakdown voltage, the current will increase rapidly with any further increase in voltage.

The breakdown voltage can be varied by varying the diode material and construction. Zener diodes can be made with a breakdown voltage as low as 1 volt, up to breakdown voltages of several hundred volts. The current that can pass through any Zener diode before the diode will be damaged will depend upon the junction area and the methods used to keep the diode cool.

In a circuit where a Zener diode is used, it will be used as a voltage reference or a voltage regulator. As the reverse voltage across the diode

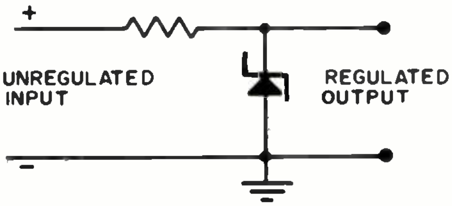

Fig. 16. Circuit using Zener diode as a voltage regulator.

increases, a very small reverse current will flow, and the value of this current will remain essentially constant until the breakdown voltage is reached. At that voltage, any further increase in voltage will result in a large increase in current across the junction. This large increase in current tends to produce a voltage drop in other components in the circuit so that the voltage across the diode will remain essentially constant. Thus a Zener diode can be used as a voltage regulator in a circuit such as shown in Fig. 16. If the input voltage tends to rise, the current through the diode will increase. This increase in current will increase the voltage drop across the resistor so that the output voltage will remain essentially constant. The fact that with even a very small increase in voltage the current through the diode will increase substantially means that the voltage across the diode will remain almost constant.

In some other applications the diode may be used as a reference voltage. This simply means that a Zener diode with a given breakdown voltage is used in a circuit like Fig. 16. The voltage applied to the diode will remain essentially constant. In some circuits, we may compare the voltage across a resistor or another part with the voltage across the Zener diode.

TUNNEL DIODES

A tunnel diode is a highly doped junction diode made either of germanium or gallium arsenite. Both the N region and the P region of the diode are very highly doped. As a result of the high doping, the depletion region around the junction is extremely narrow. Because of the narrow depletion region, holes and electrons can cross the junction by more or less tunneling from one atom to another. The exact action of the charges crossing the junction is somewhat difficult to visualize, but the characteristics of the tunnel diode are comparatively simple. With a reverse bias across the junction, current across the junction increases quite rapidly. If the reverse bias is dropped to zero the current will drop back to zero. If the forward bias, starting at zero and gradually increasing, is placed across the junction, current flow across the junction will increase at essentially the same rate as it increased with a negative bias. The current across the junction will increase quite rapidly as the forward bias is increased until a rather sharp peak is reached. If the forward bias is increased beyond this point, then the current begins to decrease.

As the forward bias is increased still further, the current across the junction decreases, forming a curve such as shown in Fig. 17. This decreasing current, with increasing voltage, results in a negative resistance characteristic. It might be difficult to visualize what a negative resistance is, but you will remember from Ohm's Law that re-

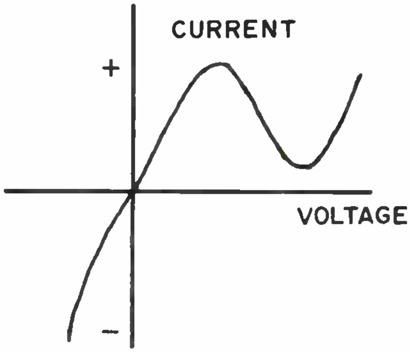

Fig. 17. Voltage-current relation in a tunnel diode.

sistance is equal to voltage divided by current. In a circuit where we have resistance, if the resistance is constant and the voltage increases, then the current must increase; and similarly if the voltage decreases, the current must decrease. Here in the tunnel diode we have a region where the opposite happens. If the voltage increases, the current decreases and if the voltage decreases, the current increases. Thus we have something in the circuit that is giving us the opposite effect of resistance; we call this negative resistance. You will remember that resistance in a circuit introduces losses. It is the resistance in a resonant circuit that prevents a resonant circuit from continuing to oscillate once it has been excited into oscillation. However, if we can put something with negative resistance in the circuit, for example a tunnel diode, since it has the opposite effect of resistance, then the circuit should continue to oscillate. Tunnel diodes can be used for this purpose.

At the present time, tunnel diodes have not appeared in the commercial entertainment-type equipment. However, it is probably just a matter of time until they are used; therefore you should at least have some basic knowledge of what the tunnel diode is.

P-I-N DIODES

The p-i-n diode, which is an abbreviation for positive-intrinsic-negative, is a new diode which is used in a somewhat different manner from the diodes you have studied previously. Rather than being used as a detector or rectifier, this diode is used primarily as a variable resistor. It is a special type of diode, and its resistance can be controlled by applying a dc bias to it. With a reverse bias across the diode, it has a very high resistance. With no bias, its resistance drops to about 7000 ohms, and with forward bias it drops to a comparatively low value.

The diode is particularly useful in circuits where the strength of a signal must be controlled. Its first commercial use has been in fm equipment and it is used in order to prevent extremely strong fm signals from causing overloading in the fm receiver. A dc bias is applied to the diode and the amplitude of the bias depends upon the strength of the signal. When a very strong signal is applied, the reverse bias applied to the diode increases so that the resistance of the diode increases. This reduces the strength of the signal fed to the mixer and i-f stages in the receiver and thus prevents overloading, particularly in the last stage of the receiver.

At this time p-i-n diodes are not widely used in commercial applications, but you should be aware of how the diode is used, because it is quite likely that it will be widely used in the future.

POINT-CONTACT DIODE

Another semiconductor diode is the diode detector used in many TV receivers. This detector is a point-contact diode. A cut-away view of a point-contact diode is shown in Fig. 18 along with the schematic symbol.

The point-contact diode is made of a small piece of either N-type or P-type germanium or silicon. N-type germanium or silicon is used more often than P-type. In manufacturing a diode of N-type material, a large contact is fastened to one side of the crystal. A thin wire, called a catswhisker, is attached to the other side of the crystal. When the catswhisker is attached to the N-type crystal, a small region of P-type material is formed around the contact as shown in Fig. 19. Thus we have a PN junction that performs in much the same way as the junctions we have already discussed.

The characteristics of the point-contact diode under forward and reverse bias are somewhat different from those of the junction diode. With forward bias the resistance of the diode is somewhat higher than that of a junction diode. With reverse bias the current flow through a point-contact diode is not as independent of the voltage applied to the crystal as it was in the junction diode. In spite of these disadvantages, the point-contact diode makes a better detector than the junction diode, particularly at high frequencies because the point-contact diode has a lower capacity than the junction diode.

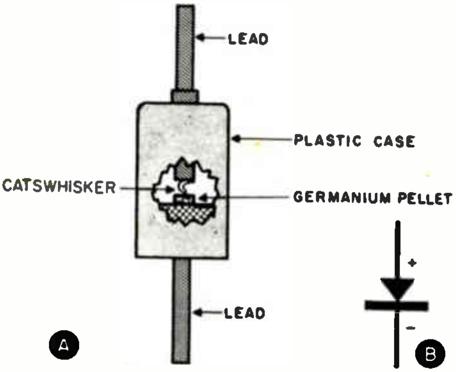

Fig. 18. (A) cut-away view of crystal rectifier. (B) schematic symbol of it.

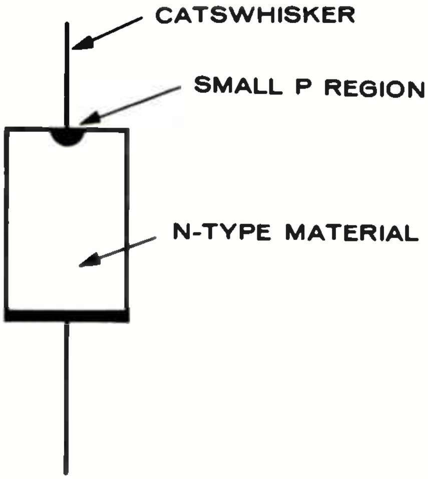

Fig. 19. Sketch of a point-contact diode showing where the P-type germanium is formed around the catswhisker.

SUMMARY

Again this is a very important section, so you should review it before going on to the next section. Make sure you understand what the depletion layer is and why it is formed. Also be sure you understand the movement of holes and electrons across a PN junction when no voltage is applied to the junction.

Current flow across the junction with both forward and reverse bias is important. With forward bias current flow across the junction is by majority carrier, and with reverse bias it is by minority carrier.

(am) What is a p-i-n diode?

Semiconductor Triodes

Even though a junction diode will pass current in both directions, it passes current in one direction much better than it does in the other, and therefore it can be used as a detector. The tunnel diode can be used as an oscillator, and in some special circuits as an amplifier; however, its usefulness in these applications is limited. In most cases, the semiconductor diode is like the vacuum-tube diode; it is more or less useless insofar as amplifying a signal is concerned. In order to amplify a signal, a three element semiconductor is needed. Three element semiconductors that are capable of amplification are called transistors.

There are a number of different types of transistors in use today. The characteristics of the different types vary appreciably, but if you understand the operation of one type, you can understand how the others work without too much difficulty. We started our explanation of. semiconductor devices with a junction diode, so we will start our study of triode semiconductors with a study of the junction transistor. You'll find that most of the transistors you will study operate in a manner similar to the basic junction transistor. The most notable exception to this is the field-effect transistor which you will study later in this lesson.

JUNCTION TRANSISTORS

Both germanium and silicon are used in the manufacture of junction transistors. A triode-junction transistor is made up of single semiconductor crystals with three different regions. The center region is made up of one type of germanium or silicon, and the two end regions are made up of the other type of germanium or silicon. In other words, in one type of junction transistor the center has had accepter-type region impurities added and the two end regions have had donor-type impurities added. In the other type of junction transistor, the center region has had donor-type of impurities added and the two end regions have had accepter-type impurities added.

The center region of the transistor is called the base. This is usually a comparatively thin region. One of the end sections is called the emitter and the other end section is called the collector.

If the center section of the crystal has been treated with donor-type impurities, then the center section becomes N-type germanium in the case of a germanium transistor or N-type silicon in the case of the silicon transistor. In this case, the two end sections will be treated with accepter-type impurities and they will both become P-type germanium or P-type silicon. We call this type of transistor a PNP transistor. We can have both germanium PNP and silicon PNP transistors. An example of this type of junction transistor is shown in Fig. 20A along with the schematic symbol used to identify it.

The other type of junction transistor is an NPN type. This type of transistor is produced by treating the center section with an accepter-

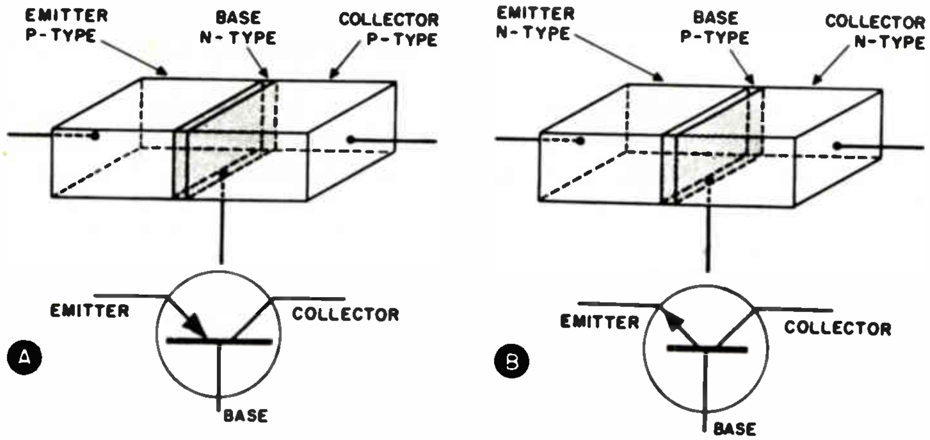

Fig. 20. (A) shows a PNP junction transistor and its schematic symbol. (B) shows an NPN junction transistor and its schematic symbol.

type impurity to produce P-type germanium or silicon, and the two end sections with a donor-type of impurity to produce N-type germanium or silicon. This is the type of junction transistor shown in Fig. 20B along with the schematic symbol for it. As in the case of the PNP transistor, we can have either an NPN germanium transistor or an NPN silicon transistor.

Notice that the schematic symbols for the PNP transistor and the NPN transistor are different. In the PNP transistor the arrow used to represent the emitter points down toward the base, whereas in the NPN transistor the arrow on the emitter points up away from the base. Thus on a schematic diagram of a piece of equipment using junction transistors, you can tell from the direction in which the arrow is pointing whether the transistor is a PNP or an NPN transistor.

There are several different ways of manufacturing junction transistors, and often you hear these transistors referred to by the manufacturing method used. For example a junction transistor might be called a grown junction, a fused junction, an alloy junction or a diffused junction. All these names simply describe the manufacturing process used to make the transistor. They are all junction transistors and all operate on the same basic principle. This does not mean to imply that the characteristics of all junction transistors are the same; they are not. There are wide differences in characteristics just as there are in various triode vacuum tubes.

To understand how junction transistors work, you must understand junction diodes. Because it is so important that you understand the formation of the depletion layers at the junctions we will review the explanation of what happens at the junctions in explaining the junction transistors. The big difference between the junction transistor and the junction diode is that in the transistor there are two junctions close together in the same crystal. One of these junctions is biased in the forward direction and the other in the reverse direction and the presence of one junction affects the operation of the other.

PNP TRANSISTORS

In transistor operation, the emitter-base junction is always biased in the forward direction and the collector-base junction is biased in the reverse direction. Each of the two junctions by itself behaves just like the PN junction already described.

Let us consider what happens in the PNP transistor before any voltages are applied to the transistor.

At the junctions, holes from the P-type emitter section and the P-type collector diffuse across the junctions into the base. At the same time, electrons from the base diffuse across the junctions into both the emitter and the collector. The holes diffusing into the base place a positive charge on the atoms near the junctions. Similarly the electrons diffusing from the base into the emitter on one side of the base and the collector on the other side of the base place a negative charge on the atoms on the emitter and collector sides of the junctions. These charged atoms, which are called ions, will repel electrons and holes from the region of the junctions. The positively charged ions in the base will repel holes in the P sections away from the junctions. Similarly, the negatively charged ions in the emitter and collector will repel electrons away from the junctions in the base. Thus we have two depletion layers formed, one at the emitter-base junction and the other at the base-collector junction.

You will remember that when we discussed the junction diode, we mentioned that hole-electron pairs will be formed in the depletion region. The minority carriers formed in each section can cross over the junction. For example, the electrons released in both the emitter and the collector regions will cross the junctions into the base. These electrons will neutralize a few ions in the base region. When these ions are neutralized they will allow majority carriers from the emitter and collector to cross the junctions. In other words, there will be holes from the emitter and holes from the collector crossing the junctions into the base. Similarly, holes, which are the minority carriers in the base region (and are formed in the depletion layer) will cross the junctions into the emitter and collector. When these holes cross the junctions they will neutralize some of the nega-

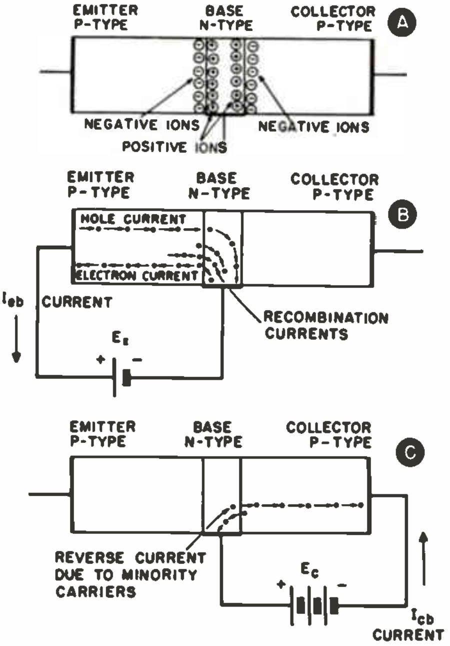

Fig. 21. (A) the formation of ions at the junctions of a PNP transistor. (B) the current flow in the emitter-base circuit and (C) in the collector-base.

tively charged ions in the emitter or collector region and allow some electrons to flow from the base into either the emitter or the collector. Thus, because of the intrinsic conduction due to hole-electron pairs being formed in the depletion region there will be some flow of carriers across the junction. However, the flow of majority carriers across the junction will be exactly equal to the flow of minority carriers across the junction so that the net current flow across each junction will be zero.

The potential barriers formed at the junction regions are shown in Fig. 21A. Notice that the charges formed at the junction are similar to those formed at a junction diode; we simply have two junctions to consider in a transistor.

Now when we place a forward bias between the emitter and the base we have an arrangement like that shown in Fig. 21B. Here the positive voltage applied to the end of the P-type emitter repels holes towards the junction. These holes tend to neutralize the negative charge on the ions on the emitter side of the junction. The holes are formed at the end of the P-type section by electrons being taken out of this section by the positive potential applied to it. At the same time the positive potential applied to the emitter attracts the electrons that have given the ions on the P side of the junction their negative charge. This also weakens the negative charge on the emitter side of the junction.

At the base, which is connected to the negative side of the battery, the holes will be attracted toward the negative terminal of the battery, and electrons will be pushed towards the depletion layer. The pulling of holes away from the depletion area and pushing electrons into the depletion area tends to neutralize the charge on the base side of the junction.

The net effect of biasing in a forward direction is to neutralize the charges on each side of the junction and allow current to flow across the junction. Current flow is by majority carriers: electrons from the N-type base region and holes from the P-type emitter region.

Thus in the emitter-base circuit we have electrons flowing from the negative terminal of the battery to the base, through the base, across the junction, and through the emitter to the positive terminal of the battery. At the same time we have holes being produced because electrons are being pulled out of the P-type emitter by the positive potential applied to it. The holes will move through the emitter, across the junction into the base and to the point where the base is connected to the negative terminal of the battery. At this point they will pick up electrons and disappear.

Not all the electrons going from the base to the emitter will reach the positive terminal of the battery. Some of these electrons will recombine with holes in the emitter. Similarly, some of the holes traveling from the emitter into the base will pick up an electron in the base. This current flow across the junction is called a recombination current, and the transistor is designed to keep this current as low as possible. In other words we want the holes and electrons crossing the junction to reach the terminals connected to the battery.

Now let us consider the other junction, the base-collector junction. This junction is reverse biased as shown in Fig. 21C. Here again we have a depletion layer at the junction. Also we have minority carriers being formed in the depletion layer. However, holes that are formed in the base will cross the junction and then instead of neutralizing a negatively charged atom near the junction in the collector, these holes will be attracted by the negative potential applied to the collector. Similarly, electrons formed in the depletion layer of the P-type collector will cross the junction and be attracted by the positive potential applied to the base. Thus we have a current flow due to the minority carriers. Electrons in the depletion layer of the collector section will cross the junction and flow through the base to the positive terminal of the battery. Meanwhile electrons from the negative terminal of the battery will fill holes that are moving from the base, across the junction, and through the collector to the negative terminal.

Thus you can see that while we have a current by majority carriers due to the forward bias applied between the emitter and the base, we also have a small current flowing through the base-collector circuit by minority carriers due to the reverse bias applied between the base and the collector. Now let us see how the two junctions affect each other.

A transistor with both biased junctions is shown in Fig. 22. Here we have a number of different currents flowing. In the emitter-base circuit we have current flowing due to the forward bias applied between these two. Electrons will flow from the negative terminal of the battery into the base, across the junction, and through the emitter to the positive terminal of the battery. We will also have some holes formed in the P-type emitter section due to electrons being pulled out of this section by the positive terminal of the battery. Some of these holes will cross the junction into the N-type base where they will pick up an electron and disappear. This current is called the recombination current.

Many of these holes will cross the base and flow through the collector, because the negative terminal of the battery connected between the base and collector will attract them. This movement of holes accounts for most of the current flow in the emitter and collector circuits. Remember that holes are being continually formed in the P-type emitter because electrons are

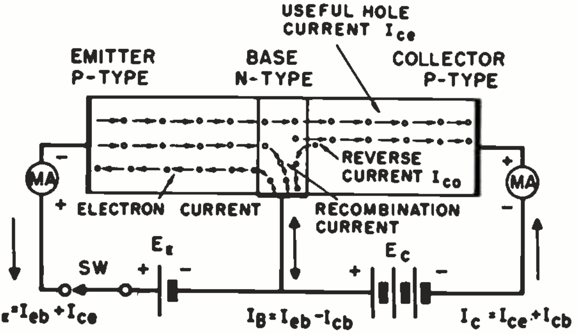

Fig. 22. Current flow and carrier movement in a PNP junction transistor.

being pulled out of the emitter by the positive potential applied to it. These holes will continually move through the emitter, and into the base. Here some of them will combine with electrons and disappear, but the majority of them will flow through the collector to the negative terminal of the collector where they will be filled by electrons and disappear.

Another current that will flow is reverse current I_{CO} that flows in the base-collector circuit. This is due to the formation of minority carriers in the depletion layer.

Thus we have four currents flowing in the PNP junction transistor. The largest of these currents is due to the movement of holes from the emitter through the base into the collector to the negative terminal of the battery connected to the collector. We have in addition to this current three small currents flowing. We have the current due to the electron movement from the negative terminal of the emitter-base battery into the base, across the junction and through the emitter to the positive terminal of this battery. We have the recombination current due to holes combining with electrons in the base, and we have the reverse current due to hole-electron pairs being formed in the depletion layer of the base-collector junction. The directions of the different movements of holes and electrons are marked in Fig. 22.

NPN TRANSISTORS

Although the operation of the NPN transistor is somewhat different from that of the PNP type, if you understand how the PNP transistor works, you should have no difficulty understanding the NPN. Again, we can start our study of this type of transistor by considering what happens at the junctions, remembering that the action at the junction is similar to the action we studied at the simple PN diode junction.

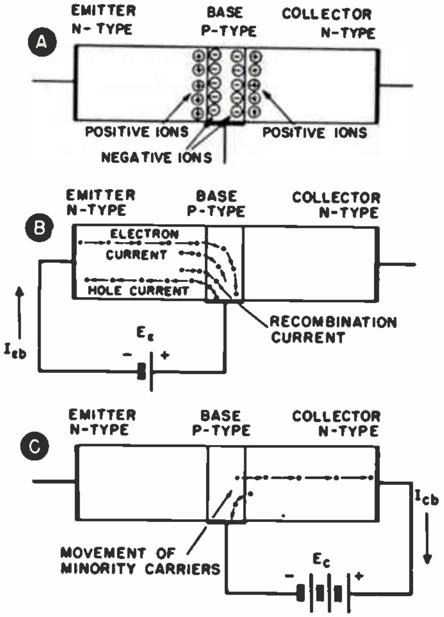

Fig. 23. (A) the formation of ions at the junctions of an NPN transistor. (B) the current flow in the emitter-base circuit and (C) in the collector-base circuit.

Let us first consider the action of the holes and electrons before any voltages are applied to the transistor. The charges that will be built up are shown in Fig. 23A. Remember that holes from the base will diffuse across both junctions into the emitter and the collector. Similarly electrons from the emitter and electrons from the collector will diffuse across the junctions into the base. The holes and electrons diffusing across the junctions will charge atoms near the junction. Holes crossing the junctions into the emitter and the collector will ionize the atoms on the emitter and collector sides of the junctions so that they will have positive charges. Similarly, electrons diffusing across the junctions into the base will ionize atoms in the base near the junctions so that they will have negative charges. Thus we will have potential barriers at the junctions. This is the same kind of potential barrier that we found existed across the PN junction in a diode.

The positively charged ions on the emitter and collector sides of the junctions will force holes in the base away from the junction. Similarly the negatively charged atoms on the base side of the junctions will force electrons in the emitter and collector away from the junction so that at the junctions we have a depletion layer.

Now let us consider what happens when we apply a forward bias between the emitter and the base by connecting a battery between the two as shown in Fig. 23B. Notice that the negative terminal of the battery is connected to the end of the emitter, and the positive terminal is connected to the base.

Now, several things happen. The negative potential applied to the emitter will force electrons toward the junction. At the same time the negative potential will attract holes away from the junction. Both of these actions tend to neutralize the positively charged ions on the emitter side of the junction. At the same time the positive terminal of the battery that is connected to the base will attract electrons away from the negatively charged atoms on the base side of the junction. In addition, the positive potential will repel holes towards the junction so that these two actions tend to neutralize the charge on the base side of the junction.

Once the potential barrier at the junction is weakened, electrons can flow from the negative side of the battery into the emitter, through the emitter, and across the junction into the base and from the base to the positive side of the battery. At the same time the positive terminal of the battery can extract electrons from the base, forming holes. Holes are then repelled toward the junction, across the junction, and through the emitter toward the end of the emitter that is connected to the negative terminal of the battery. Here the holes will pick up electrons and disappear. Thus we have a current flow through the emitter-base circuit as shown in Fig. 23B.

Now let us consider what happens when we apply a reverse bias between the base and the collector. Here the negative potential applied to the base will pull holes away from the junction, and the positive potential applied to the collector will pull electrons away from the junction. Thus the negative charge on the base side of the junction will be increased, and the positive charge on the collector side of the junction will be increased so that the potential barrier at the junction will be increased. This will prevent any current flow through the base-collector circuit due to the majority carriers.

At the same time electrons, which are minority carriers, will break loose from their nuclei in the depletion layer on the base side of the junction and will be attracted by the positive potential applied to the collector. They will cross the junction and flow through the collector to the terminal connected to the positive side of the battery, as shown in Fig. 23C. At the same time holes formed on the collector side of the junction in the layer will be attracted by the negative terminal of the battery, and hence will cross the junction and flow over into the base and toward the negative terminal of the battery. Here they will pick up an electron and disappear.

Thus we will have a current flow in the base-collector circuit due to the minority carriers. This is the same situation that we had in the reverse biased base-collector circuit of the PNP transistor.

Now let us see what happens when bias voltages are applied across both junctions of the complete NPN junction transistor as shown in Fig. 24. Considering first the emitter-base circuit, we have electrons flowing from the negative terminal of the battery to the N-type emitter. Here the electrons flow through the emitter, across the junction, and into the base. Some of these electrons reaching the base will recombine with holes in the base. This is called the recombination current. However, the majority of the electrons reaching the base will be attracted by the positive potential applied to the collector and hence will flow through the base across the base-collector junction and through the N-type collector to the positive terminal of the battery in the base-collector circuit.

At the same time the positive terminal of the battery in the emitter-base circuit is connected to the base, and this potential will pull electrons out of the P-type base, producing holes. These holes will then cross the junction into the emitter, and they will be attracted by the negative potential applied to the emitter and hence will flow through it to the end connected to the negative terminal of the battery. Here they will pick up an electron and disappear.

At the same time, in the base-collector circuit we will have a reverse current flowing due to the minority carriers. Holes appearing in the collector side of the depletion layer will cross the junction into the base and flow to the base terminal connected to the negative terminal of the battery, biasing the base-collector junction. Here each hole will pick up an electron and disappear. Electrons in the depletion layer on the base side of the junction will be attracted by the positive potential applied to the end of the collector. Hence they will cross the junction and flow toward the positive end of

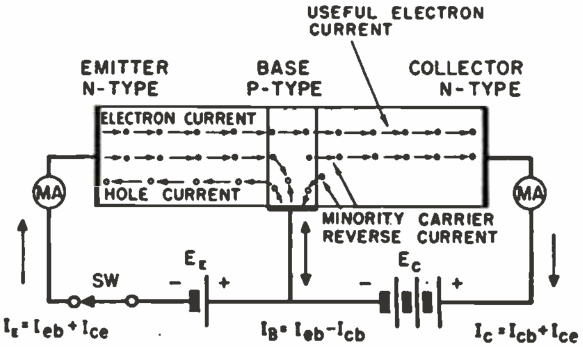

Fig. 24. Current flow and carrier movement in an NPN junction transistor.

the collector and from there to the positive terminal of the battery connected between the base and the collector.

Of these different currents flowing, the important and useful current flow is the flow of electrons from the emitter through the base to the collector. Since this is the useful current, we are interested in making this as large as possible in comparison to the other currents flowing across the emitter-base junction. Thus, the recombination current, which is due to electrons from the emitter crossing into the base and recombining with the holes, serves no useful purpose and should be kept as low as possible. This is accomplished by adding more donor atoms to the emitter than accepter atoms to the base. Thus there will be many more free electrons in the emitter than there will be holes in the base and the recombination current will be kept quite small.

Also, since there are a limited number of holes in the base compared to the number of electrons in the emitter, the number of holes crossing from the base to the emitter is also kept low in comparison to the number of electrons crossing from the emitter into the base. In a good transistor, over 95% of the electrons that cross the emitter-base junction flow to the collector.

Notice the differences and the similarities between the PNP and the NPN transistors. In both cases the emitter-base junction is forward biased and the base-collector junction is reverse biased. However, the battery connections must be reversed to provide the biases. In other words, with the PNP transistor the battery used to bias the emitter-base junction is connected with the positive terminal to the emitter and the negative terminal to the base. With the NPN transistor, the negative terminal of the battery is connected to the emitter and the positive terminal to the base. However, both are forward biased because in each case the positive terminal of the battery is connected to the P-type germanium and the negative terminal to the N-type germanium.

The base-collector junction of both transistors is reverse biased. In the PNP transistor, the positive terminal of this battery is connected to the base and the negative terminal to the collector; whereas in the NPN transistor, the negative terminal is connected to the base, and the positive terminal to the collector. Again, however, in both cases the positive terminal is connected to the N-type germanium and the negative terminal to the P-type germanium.

Also notice that in the PNP transistor the useful current flow is by means of holes, whereas in the NPN transistor the useful current flow is by means of electrons.

SELF-TEST QUESTIONS

(an) What is the base region of a transistor?

(ao) What two materials are widely used in the manufacture of transistors?

(ap) What two types of junction transistors are widely used?

(ar) What type of bias is used across the base-collector junction of a transistor?

(as) Is the base region of a transistor usually a thick region or is it thin?

(at) Draw a diagram of a PNP transistor and show how the batteries are connected to place the correct bias across the two junctions.

(au) Draw a diagram of an NPN transistor and show how the batteries are connected to provide the correct bias across both junctions.

(av) What are the useful current carriers in a PNP transistor?

Semiconductor Types

There are two basic types of transistors that you will run into continuously. You are already familiar with these two types; they are the NPN transistor and the PNP transistor. However, these transistors are made in a number of different ways and the manufacturing processes result in transistors with different characteristics. In this section we are going to briefly discuss some of the important types and characteristics. We don't expect you to remember all these details; the important thing for you to remember is that they are basically either NPN or PNP transistors and operate in the same way as those we have discussed previously.

Also in this section of the lesson we'll discuss two other important semiconductor devices, the field-effect and unijunction transistors.

GROWN-JUNCTION TRANSISTORS

The first commercially available junction transistors were of the grown-junction type. This type of transistor is made from a rectangular bar cut from a germanium crystal that has been grown. Suitable impurities are added so that NPN regions such as those shown in Fig. 25 are formed. The base of the transistor is usually located midway between the two ends. Suitable contacts are then welded to the emitter, base and collector regions.

Of course, the actual bar of semiconductor material used is quite small. The emitter and the collector are considerably larger than the base; the base is kept as thin as possible and may have a thickness of less than .001".

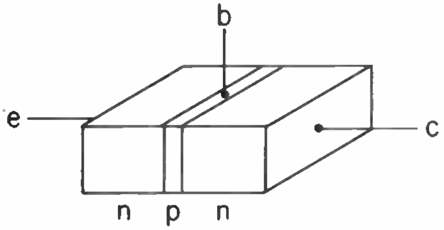

Fig. 25. A grown-junction transistor.

As mentioned the early germanium transistors were of the grown-junction type. The disadvantage of this type of transistor is that it is not particularly suitable for operations at high frequencies. In addition, it is quite temperature sensitive and can become quite unstable at higher temperatures.

ALLOY-JUNCTION TRANSISTORS

The alloy-junction transistor is made from a rectangular piece of

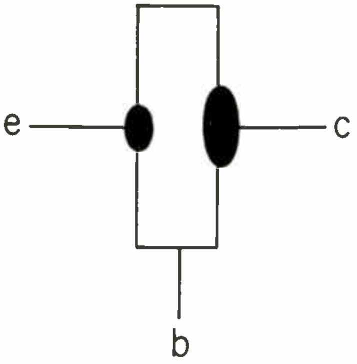

Fig. 26. An alloy-junction transistor.

semiconductor material to which suitable donor materials have been added. This results in an N-type piece of germanium or silicon. Small dots of indium are fused into the opposite sides of the wafer as shown in Fig. 26. The result is that P-type semiconductor material will be formed with the dots fused into the wafer so that we will have a PNP transistor.

An NPN-type alloy-junction transistor may be made by fusing a lead antimony alloy into each of the two opposite sides of a P-type semiconductor wafer. In this type of transistor it is possible to get a more uniform penetration of the lead antimony alloy into the semiconductor material, and this in turn leads to better junction spacing. This will cut down on the width of the space between the emitter and collector and give improved high-frequency performance. In addition, since the mobility of the electrons is more than twice that of holes, the NPN transistor will be better at high frequencies.

The general advantage of the alloy-type junction over the grown-type junction transistors is that they are usable at a somewhat higher frequency. In addition, they have a higher current gain, and the current gain remains stable as the temperature increases.

Surface-Barrier Transistor.

The surface-barrier transistor is similar to the alloy-type transistor except that depressions are etched into the N-type wafer. This permits smaller emitter and collector contacts and results in lower capacities between sections of the transistor which in turn results in better high-frequency performance.

In Fig. 27 we have shown a simplified sketch of a surface-barrier transistor. The sketch in Fig. 27B shows the carrier movement from the emitter across the base to the collector. Notice that in the sketch the emitter is shown smaller than the collector, we have shown it this way because this is the way the semiconductor is actually manufactured.

Various manufacturing techniques are used in the manufacture of the surface-barrier transistor. Both silicon and germanium types are made. In the manufacturing process different materials are evaporated or plated on to the etched depressions depending on the type of tran-

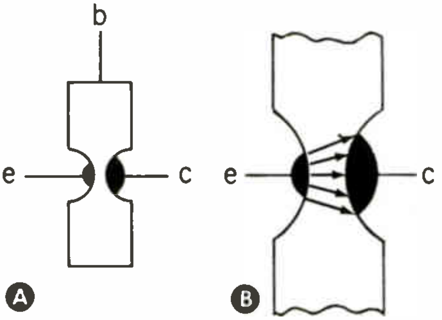

Fig. 27. Sketch of a surface barrier transistor is shown at A. Hole movement across the base is shown at B.

sistor being manufactured. However, regardless of the manufacturing technique used, which is of no interest to the technician, the surface-barrier transistors all have the characteristic of giving good performance at high frequencies.

DIFFUSION TRANSISTORS

To understand diffusion you have to understand a little about the molecular structure of materials. If you look at the wall of a glass jar, to the eye it appears solid with no space between the various molecules making up the jar. However, if you were to fill the jar with hydrogen and store it for any length of time, you would find that in a short while, the jar was no longer filled with hydrogen only, but contained a mixture of hydrogen and air. The reason is that the small hydrogen atoms are able to diffuse or pass right through the spaces between the molecules in the glass. At the same time, molecules of air will diffuse through the glass and pass on into the inside of the bottle. The hydrogen molecule is smaller than the air molecule; therefore the hydrogen will diffuse out of the jar faster than the air will diffuse in.

Diffusion can be used to add impurities to either silicon or germanium, and produce either N-type or P-type semiconductor material. The process can be controlled to provide either very uniform base, emitter, and collector regions, or it can be controlled to provide non-uniform base, emitter, and collector regions.

The Drift Type.

One of the most important uses of the diffusion technique is in the manufacture of transistors with a non-uniform base region. If the emitter and collector junctions are made by the alloy technique, but the base region is made by the diffusion technique and the impurities in the base region varied, we have what is known as a drift transistor. In a typical PNP-drift transistor, accepter impurities are added in the emitter and collector region. These impurities are controlled so that their concentration is uniform throughout the emitter and collector region. At the same time donor impurities are added to the base region. Their concentration is controlled so that it is highest in the region of the emitter-base junction and then drops off quickly and finally reaches a constant value which it maintains over to the base-collector junction, as shown in Fig. 28. This type of transistor is called a drift transistor, and its most important characteristic is its excellent performance at high frequencies. However, notice that it is still a PNP transistor and the basic theory of its operation is similar to that of any other PNP transistor. The improved performance is obtained by varying the concentration of donor impurities in the base region.

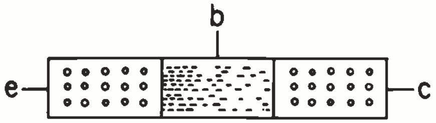

Fig. 28. Diagram showing how a large number of donor impurities increases the electron concentration in the base.

The Mesa Type.

It is also possible to manufacture a transistor using the diffusion technique entirely. An example of this type is the mesa transistor.

In this type of transistor a semiconductor wafer is etched down in steps so that the base and emitter regions appear as plateaus above the collector region as shown in Fig. 29. The advantages of the mesa transistor are good high-frequency performance and very good consistency. By this we mean that it is possible to control the manufacturing techniques quite closely so that the characteristics of mesa transistors of the same type number will be quite similar. This is not necessarily true of other transistors; often their characteristics vary over a wide range.

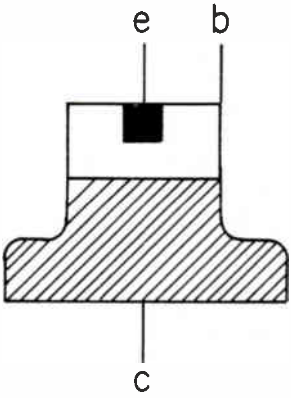

Fig. 29. A mesa transistor.

The Planar Type.

Another type of transistor manufactured by the diffusion technique is the planar type of diffused transistor. This type of transistor is shown in Fig. 30. Notice that each of the junctions is brought back to a common plane, whereas in the mesa type the various junctions are built up in plateaus. The importance of the planar-type transistor is that the junctions can be formed beneath a protective layer. As a result, many of the problems associated with other types of transistors having

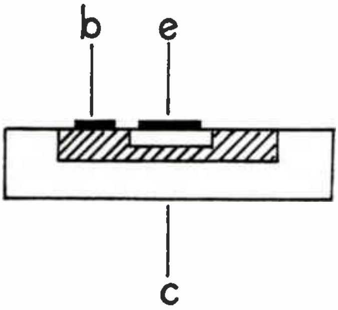

Fig. 30. A diffused planar-type transistor.

junctions exposed at the surface are avoided in this type of construction. Important characteristics of the planar transistor are generally very low reverse current and improved dc gain at low-current levels.

EPITAXIAL TRANSISTORS

One of the disadvantages of the diffusion-type transistor is the relatively high resistance of the collector region. This results in slow switching time; it limits the usefulness of the transistor in high-frequency applications. Reducing the resistance of the collector region reduces the collector breakdown voltage and this in turn again reduces the usefulness of the transistor. These problems can be overcome by the epitaxial technique. In this technique a thin high-resistance layer is produced in the collector region and the remainder of the collector region is controlled to keep its resistance low. This results in a transistor that looks something like the one shown in Fig. 31. The primary advantage of this transistor is that it provides good performance at very high frequencies. This technique can be combined with other techniques to produce transistors having varying characteristics. The epitaxial transistor can be referred to as a double-diffused epitaxial transistor. The thin high-resistance collector region is formed by the epitaxial technique and the base and the emitter are formed by the diffusion process - hence the term double diffusion.

All the transistors that we have discussed so far in this section of the lesson are either NPN or PNP transistors. The manufacturing techniques used to manufacture these transistors result in transistors of different characteristics, but the basic theory of operation of these transistors is the same. Now, we'll look at another semiconductor device which operates on a somewhat different principle.

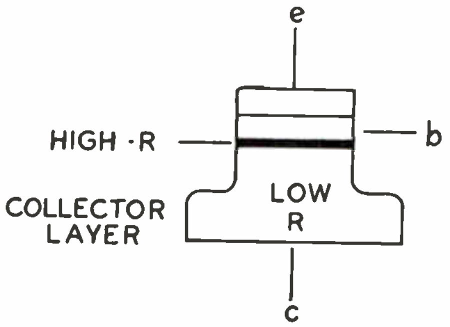

Fig. 31. A double-diffused epitaxial transistor.

THE JUNCTION FIELD-EFFECT TRANSISTOR

An interesting transistor that resembles a vacuum tube very closely in its characteristics and to some extent its operation is a field-effect transistor. One type of field-effect transistor can be made by taking a piece of N-type material as shown in Fig. 32. If the negative terminal of a battery is connected to one end of the material and the positive side of the terminal to the other end, electrons will flow through the material as shown. If we attach a piece of P-type material to one side so that the PN junction is formed and then place a negative voltage on the P-type material as shown in Fig. 32, there will be no current flow across the junction, because the battery biases the junction in such a way that electrons cannot flow from the N-type material to the P-type material nor can holes flow from the P-type material to the N-type.

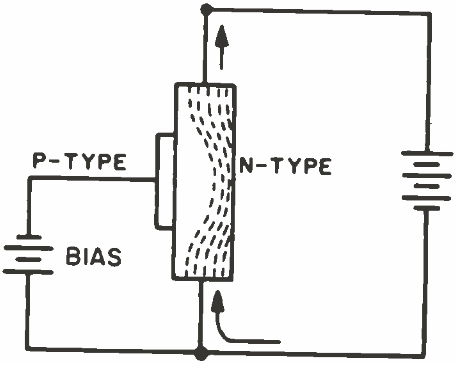

Fig. 32. Drawing showing the basic operation of a field-effect transistor.

However, the negative voltage applied to the P-type material sets up a field in the N-type material. This field opposes the electrons flowing through the N-type material and forces them to move over to one side so that the electron movement follows the path shown in Fig. 32. The negative voltage applied to the P-type material has the effect of increasing the resistance of the N-type material in the area in which the field is affected. It forms a depletion layer around the junction so there will be no free electrons in the N-type material near the junction. If the negative bias voltage is made high enough, it is able to prevent

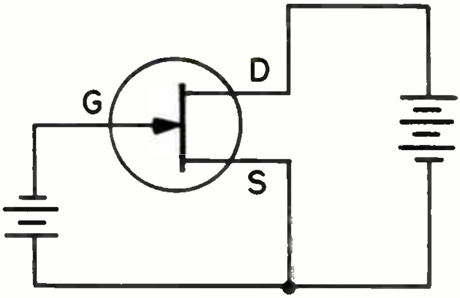

Fig. 33. Schematic representation of the circuit shown in Fig. 32.

the flow of electrons through the N-type material entirely so that the current flow will be cut off. We call this voltage where the bias voltage is high enough to stop the flow of current through the N-type material the "pinch-off" voltage. The N-type material is referred to as a channel, and the P-type material as a gate. This type of transistor is called a "junction field-effect transistor."

The schematic representation of the circuit shown in Fig. 32 is shown in Fig. 33. Notice that the end of the N-type channel at which the electrons from the battery enter is called the "source". The other end, the end from which the electrons leave and flow to the positive terminal of the battery, is called the "drain". The P-type material is called the gate, as we mentioned previously. The transistor is called a field-effect transistor because it is the field produced by the bias voltage applied to the gate that controls the flow of current through the channel. This particular type of transistor is called a junction transistor because a junction is formed between the P and N-type materials. It is called an N-channel transistor because the material in the channel through which current flows has been treated in such a way as to produce an N-type semiconductor material. Thus the complete name for this type of transistor is an N-channel, junction-gate, field-effect transistor. We usually abbreviate field-effect transistor FET, so you will see that this type of transistor is abbreviated JFET to indicate it is a junction-gate type.

An amplifier using a field-effect transistor of this type is shown in Fig. 34. In this circuit we have eliminated the bias battery by means of a resistor connected between the negative terminal of the battery and the source. This resistor might be compared to the cathode-bias re-

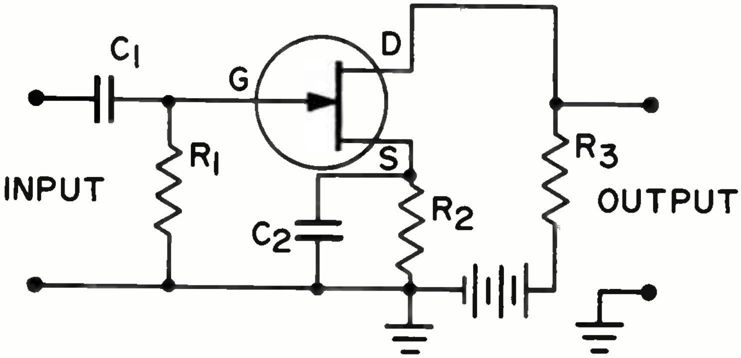

Fig. 34. An amplifier using an N-channel junction gate FET.

sistor in a triode vacuum tube amplifier stage. In the amplifier circuit, electrons flow from the negative terminal of the battery through the resistor R_2 to the source. In so doing they set up a voltage drop across R_2 having a polarity such that the source is positive with respect to ground. Since the gate connects back to ground through R_1, the gate will be at ground potential and this will make the source positive with respect to the gate, or in other words, the gate negative with respect to the source. Therefore none of the electrons in the N channel will flow to the gate, because the gate is negative.

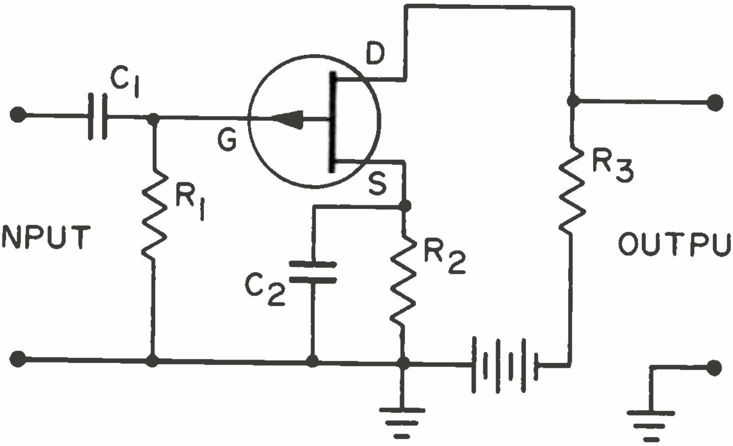

Fig. 35. An amplifier using a P-channel junction gate FET.

Electrons will flow through the N channel to the drain and then through the load resistor R_3 back to the positive terminal of the battery. As the input voltage applied across the input terminals causes the voltage between the gate and the source to vary, the current flow from the source to the drain will vary because the controlling action of the gate on the current through the channel depends upon the voltage between the gate and the source. Thus we have a varying current, which will vary as the input signal varies, flowing from the source to the drain of the transistor and through the load resistor R_3. This varying current flowing through R_3 will produce an amplified signal voltage across R_3.

It is interesting to note the similarity between the circuit shown in Fig. 34 and a triode amplifier. When the input signal swings the gate in a positive direction, current flowing through the transistor will increase; this will cause the voltage drop across R_3 to increase and therefore the voltage between the drain and ground will decrease. Thus a positive-going signal applied to the gate will cause a negative-going signal at the drain. In other words, this transistor inverts the signal phase just as the triode vacuum tube amplifier stage does.

P-Channel JFET.

It is possible to make a P-channel junction-gate field-effect transistor by using a P-type material between the source and drain. The gate is then made of an N-type material. The bias polarity is reversed so that once again the PN junction is biased and no current flows across the junction.

A schematic diagram of an amplifier using a P-channel junction-gate effect is shown in Fig. 35. Notice the schematic symbol for the P-channel unit; we have turned the direction of the arrow around just as we did to distinguish between NPN and PNP transistors. Also notice that in this circuit the battery polarity is reversed. This is because the carriers in the channel in the P-channel unit will be holes. The positive terminal of the battery which connects to the source through R_2 repels the holes and they travel through the channel to the drain where they are attracted by the negative potential connected to the drain. Meanwhile, holes arriving at the drain terminal are filled by electrons which flow from the negative terminal of the battery through R_3 to the drain. At the same time, the positive terminal of the battery attracts electrons from the source creating new holes. These electrons flow from the source through R_2 to the positive terminal of the battery.

The operation of the P-channel, junction-gate effect is the same as with the N-channel unit, except that in one case the majority carriers are electrons, and in the other case they are holes.

In discussing the action of the junction-gate field-effect transistor, we often refer to the reverse bias across the junction creating a depletion layer in the conducting channel. In the case of an N-channel unit, the negative voltage on the P-type gate will repel electrons at the junction so that the electrons have been depleted from that area around the junction. The higher the negative voltage the further the electrons are depleted in the area around the junction, and as we pointed out previously if the voltage is made high enough, all of the electrons will be depleted so that there will be no current flow through the channel. The transistor is referred to as a depletion-type transistor because the bias depletes the number of majority carriers from the channel around the junction region. Remember what we mean by a depletion type of FET; you'll see later there is another type.

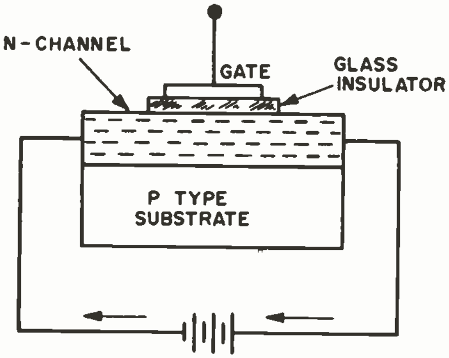

Fig. 36. Current flow through an insulated-gate, N-channel field-effect transistor with no bias applied.

INSULATED-GATE FIELD-EFFECT TRANSISTORS

The transistors we have been discussing so far are called junction-gate field-effect transistors. There is another type of field-effect transistor that is called an insulated-gate field-effect transistor. We usually abbreviate this IGFET.

In the insulated-gate field-effect transistor, the gate is completely insulated from the channel by a thin insulating material. For example, a very thin piece of glass might be placed between the conducting channel and the gate. Thus there is no actual junction formed between the semiconductor materials in the channel and the gate. In an N-channel, insulated-gate field-effect transistor, construction such as shown in Fig. 36 is often used. Here we have an N channel between the source and drain. The substrate on which the channel material is mounted is P-type material and the gate is placed along the channel as shown in the figure. The thin layer of glass prevents any actual contact between the channel and the gate.

In operation, the source and the substrate are connected to the negative terminal of the battery and the drain is connected to the positive terminal. This will permit current to flow from the negative terminal of the battery to the source, through the channel to the drain and then back to the positive terminal of the battery.

When a negative voltage is applied to the gate, it has the effect of repelling electrons away from the gate as before. In addition, the negative potential applied to the gate attracts holes in the P-type material so that the width of the channel is reduced as shown in Fig. 37. Thus the current flow through the channel is restricted by the narrowing of the channel. In effect, the resistance of the channel is increased. We refer to this type of channel as a depletion channel. The transistor is called an insulated-gate-field-effect transistor and it is also referred to as a depletion type because the flow of current through the transistor is controlled by producing a depletion layer in the channel as in the case of the junction transistors discussed previously.

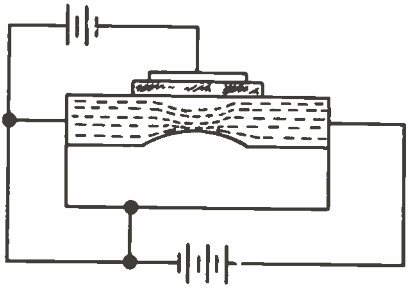

Fig. 37. Current flow through an N-channel IGFET with bias applied.

Both N-channel and P-channel IGFET's are manufactured. The schematic symbols used to represent the two different types are shown in Fig. 38A and B. In A, we have shown the symbol used for an N-channel type, and in B the schematic symbol used for a P-channel type. In operation, the units perform in essentially the same way as the junction-gate units with the exception that there will be no current

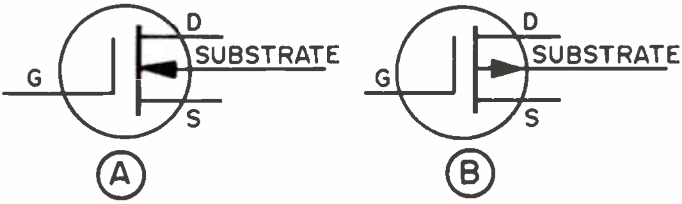

Fig. 38. Insulated-gate field-effect transistors. (A) shows the schematic symbol for an N-channel unit and (B) the symbol for a P-channel unit.

flow at all from the channel to the gate or from the gate to the channel. In the JFET, there may be very small leakage current across the junction. However, a JFET has a high input resistance because this leakage current is low. The IGFET has an even higher input resistance because there is no current flow at all from the gate to the channel or from the channel to the gate. Thus the input resistance of an IGFET is almost infinite.

Enhancement Type.

So far the field-effect transistors we have been discussing are all what are known as depletion types. In the depletion type of FET, the channel is formed and a bias is placed on the gate so as to reduce the size or width of the channel. In the enhancement-type of field-effect transistor, there is no channel present until the bias is applied to the gate. Thus, there is no current flow from the source to the drain through the transistor, unless there is a bias applied to the gate. The polarity of the bias applied to the gate is reversed from what it is in the depletion type, and this bias forms the channel through which current can flow. The operation of the units is the same as with the depletion type with the single exception of the reverse bias. In other words, in the case of an N-channel enhancement-type field-effect transistor, instead of placing a negative bias on the gate to reduce the width of the channel, as we do in the depletion-type transistor, in the enhancement-type we place a positive bias on the gate and produce the N channel.

The enhancement-type field-effect transistor is always an insulated gate type. In the case of a junction FET, if we produced an enhancement type, we would have current flow across the junction because the voltage required to produce the channel would forward bias the junction. However, in the insulated-gate FET, no current can flow across the junction because we have an insulating material between the gate and the channel. Thus we can put any type of bias we want, either forward or reverse bias, on the gate and we still will not get a current flow from the gate to the channel or from the channel to the gate.

The schematic symbol of an N-type IGFET of the enhancement type is shown in Fig. 39A. Notice that we have indicated there is no channel by breaking the channel into three parts. When the correct bias is applied to the gate, an N channel between the source and the drain will be formed. The schematic symbol for the P-channel unit of an enhancement-type IGFET is shown in Fig. 39B.

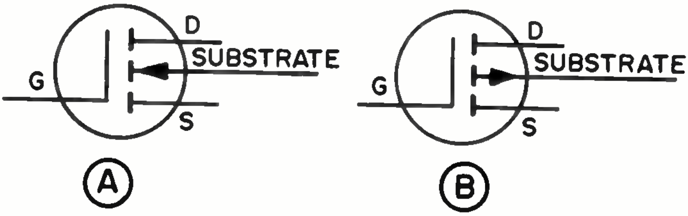

Fig. 39. A shows the schematic symbol for an N-channel enhancement-type IGFET. B shows the P-channel unit.

The operation of the enhancement-type IGFET is basically the same as with the depletion type. It could be used in a circuit similar to the circuits shown in Fig. 34 and Fig. 35.

One of the problems with IGFET's is the very high resistance between the gate and the channel. In shipping these units the manufacturer usually wraps the leads in tin foil to keep them connected together. If he doesn't do this, static charges can build up on the gate because of the very high resistance between the gate and the channel. These static charges may become high enough to actually puncture the insulation between the gate and the channel and thus ruin the unit.

In soldering an IGFET into a circuit, there might be enough leakage from the power line through the tip of your soldering iron to ruin the FET. To prevent this from happening, ground leads should be used on the various connections to the transistor and these leads should be left in place until the transistor is installed in the circuit. Once the transistor is soldered in place, you do not have to be concerned about static charges destroying the unit because the resistance in the circuit will be low enough to prevent static charges from building up to a high enough value to destroy the transistor.

Field-effect transistors are finding their way into commercial equipment, and you should therefore be sure you understand how they operate. You should review the sections on field-effect transistors several times if necessary because you can be sure they are going to be widely used in the future. They offer the advantages of the transistor as well as many of the advantages of the vacuum tube.

THE UNIJUNCTION

Another important semiconductor device is the unijunction. The unijunction is different from a conventional two-junction transistor in that it has only a single junction.

Most unijunctions are made of a bar of N-type silicon. There are two base contacts made to this bar called base 1 and base 2. These contacts are made at the ends of the bar. Between the two bases is a single rectifying contact called the emitter. The schematic symbol of the unijunction is shown in Fig. 40.

In Fig. 41 we have an equivalent circuit showing how the unijunction operates. We have referred to the resistance between base 1 and the emitter as R_{B1} and the resistance between base 2 and the emitter contact as R_{B2}. When a dc voltage is applied to the unijunction between B_1 and B_2, a current will flow through the base as shown. As long as the voltage drop across R_{B1} is greater than the emitter voltage, the emitter will be reverse biased so that there will be no current flow across the junction between the emitter and the base. The voltage across the resistance representing base 1 and the voltage across the resistance representing base 2 will remain constant. The two bases more or less act like two resistors

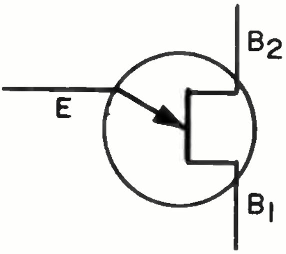

Fig. 40. Schematic symbol of a unijunction.

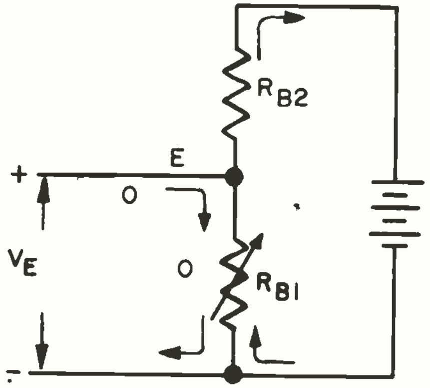

Fig. 41. Equivalent circuit showing the operation of the unijunction.

in series. The positive voltage at the emitter junction prevents any electrons from leaving the base and crossing the junction to the emitter and also prevents holes from traveling from the emitter to the base. There will be a small leakage current across the junction, but this is of no importance insofar as the operation of the unijunction is concerned.

If the voltage, V_E, exceeds the voltage across R_{B1}, then holes will enter the base and flow through R_{B1} as shown by the arrows on the diagram. These holes will cause the number of electrons flowing in R_{B1} to increase. The net result will be that you will have a drop in voltage across R_{B1} but at the same time an increase in current.

You will remember from Ohm's Law that the current flowing in a circuit is equal to the voltage divided by the resistance. If the voltage drops, the current must drop. However, in this device we have a situation where the voltage drops, but the current increases. We refer to this as "negative resistance". Devices that have this characteristic can be used in various types of amplifier circuits.

The unijunctions made for a number of years always made use of an N-type base material and a P-type emitter. However, recently some unijunctions using a P-type base material and an N-type emitter have been developed. The schematic symbol is the same, except that the direction of the arrow is reversed.

Unijunctions have not been widely used in commercial radio and TV equipment; however, they have been used in various pieces of test equipment. It is quite likely that as more transistorized television receivers are manufactured, the unijunction may be used in the sweep circuits since they are quite readily adapted to this type of application.

The important thing for you to remember at this time about the unijunction is that the device has a single junction and that the resistance of the two bases remains essentially constant until the emitter voltage exceeds the voltage across base 1. Then the voltage drop across base 1 decreases while the current flow through it increases, resulting in the negative resistance characteristic of base 1.

SUMMARY

There are too many details in this section to try to summarize them. The important thing for you to do is to realize that the different names assigned to the conventional two-junction transistors indicate the manufacturing process used to make the transistor. Typical two-junction transistors are either NPN or PNP transistors, and the basic theory of operation of the two-junction transistors is the same regardless of the manufacturing technique used. Different manufacturing techniques result in transistors with different characteristics, but the theory of operation is the same.

The field-effect transistor is a transistor that very closely resembles a vacuum tube in many of its characteristics. Remember that there are two basic types: the junction field-effect transistor and the insulated-gate field-effect transistor. In the insulated-gate type, the gate is insulated so that the leakage current to and from the gate is practically zero. This type of transistor has a very high input resistance.

You should also remember that field-effect transistors can be made in both N-channel types and P-channel types. You'll recall that by depletion type we are referring to a transistor where a channel is present. The input voltage to this type of transistor controls its channel width. JFET transistors are all of the depletion type. The IGFET may be either the depletion type or the enhancement type.

The unijunction is a semiconductor device with a single junction. Its use in commercial equipment is somewhat limited at this time, but you should understand the basic fundamentals of the device because it is quite likely that it will be used in the future.

One important point about all types of transistors that we must emphasize is that they are all easily damaged by excessive heat. This is true particularly of germanium transistors, but silicon transistors can also be destroyed by excessive heat. Whenever you have to replace a transistor in a circuit, you should make sure that the point at which you have to solder the transistor in the circuit is clean so that the solder will melt and flow over the connection quickly. Also make sure that the transistor leads are clean. It is a good idea to use a heat sink between the point at which you are soldering and the semiconductor device. A good heat sink is a pair of longnose pliers; simply hold the lead securely in the jaws of the pliers while you are soldering the lead in place. Much of the heat developed at the joint will flow through the pliers and keep the semiconductor device itself from becoming excessively hot. The joint should be soldered as quickly as possible; get the iron off the joint just as soon as the solder has melted and flowed smoothly over the connection.

Semiconductor devices can be damaged by storing them in excessively warm places. Again, this is particularly true of germanium transistors which are more heat sensitive than silicon transistors. Storing semiconductor devices at room temperature will prevent this type of damage. You should avoid storing them in any place where they can become excessively hot.

Now to check yourself on this important section you should answer the following self-test questions.

SELF-TEST QUESTIONS

(aw) Into what two basic types can the grown-junction transistor be divided?

(ax) What type of transistor can the surface-barrier transistor be classified as?

(ay) What is the most important characteristic of the surface-barrier transistor?

(az) What do we mean by a diffussion transistor?

(ba) What is an important use of the diffusion technique in manufacturing transistors?

(bb) What is the difference between a junction-gate field-effect transistor and an insulated-gate field-effect transistor?

(bc) What is a depletion-type field-effect transistor?

(bd) What is an enhancement-type FET?

(be) What is a unijunction?

Answers to Self-Test Questions

(a) Four.

(b) Germanium and silicon.

(c) A covalent bond is the sharing of two electrons by two atoms, one from each of the two atoms.

(d) Four. A single atom of germanium or silicon will share an electron from its outer ring and an electron from the outer ring of a nearby atom to form a covalent bond. It will do this with four electrons to establish four covalent bonds.

(e) Intrinsic conduction is conduction due to the formation of hole-electron pairs throughout a germanium or silicon crystal.

(f) No.

(g) Germanium.

(h) Heat.

(i) Silicon.

(j) An N-type material is a material that has been doped so that electrons are the majority carriers. This is brought about by using an impurity that has five electrons in the valence ring so that when it forms covalent bonds with nearby germanium or silicon atoms there will be an electron left over.

(k) A donor material is an impurity which when added to silicon or germanium will form covalent bonds with four nearby atoms and have an electron left over. When a donor material is added to germanium or silicon, N-type material is formed.

(l) Arsenic and antimony.

(m) P-type semiconductor material is a material that has been doped with an impurity having three electrons in the valence ring. This will leave a covalent bond that is short one electron so there will be a hole in the bond. The hole is in effect a positive charge and hence the majority carriers in the P-type material are the holes or positive charges.

(n) An accepter-type impurity is an impurity with three electrons in the valence ring or shell. It is an accepter-type material because it leaves a hole in the covalent bond which can accept an electron.

(o) Indium, boron and aluminum.

(p) Electrons are the majority carriers in N-type material.

(q) Holes.

(r) When the arsenic loses an electron it will be short one electron to completely neutralize the charge on the nucleus, and therefore the atom will have a positive charge. Meanwhile the atom of silicon or germanium that has received the extra electron will have a negative charge on it.

(s) There is no charge on the crystal, it is neutral. Although some regions may have a positive charge, other regions may have a negative charge; the crystal itself neither gains nor loses electrons and therefore it does not have any charge.

(t) Holes are produced.

(u) Diffusion is a random motion of the carriers in a semiconductor material. It goes on at all times in the crystal and every effort is made to keep diffusion as low as possible since it contributes nothing insofar as the usefulness of the material in semiconductor devices is concerned.

(v) Drift.

(w) Electrons are the majority carriers in an N-type material and they move from the end to which the negative potential is applied towards the end to which the positive potential is applied.

(x) Holes are the majority carriers in a P-type material and they move from the end to which the positive potential is applied to the end to which the negative potential is applied.

(y) No - the crystal will remain electrically neutral. In the case of N-type material, exactly the same number of electrons will leave the positive end of the crystal and enter the negative end of the crystal. In the case of the P-type material, electrons will leave the end to which the positive potential is connected creating holes. Exactly the same number of electrons will enter the end to which the negative potential is connected to fill holes arriving at the negative end.

(z) No. For a given potential and given size of crystal, electrons will move at approximately twice the rate through an N-type crystal as the holes will through a P-type crystal.

(aa) The N-type material will have the lower resistance. This is due to the higher mobility of the electrons in the N-type material than the holes in the P-type material.

(ab) Detectors and rectifiers.

(ac) The depletion layer is an area on both sides of the junction. On the P-side of the junction there is a shortage of holes and on the N-side of the junction there is a shortage of electrons. The shortage is caused by a few of the majority carriers crossing the junction in each way building up a charge at the junction so that the majority carriers are repelled away from the junction.

(ad) The potential barrier is the voltage built up across the junction by the diffusion of majority carriers across the junction. The holes that diffuse across the junction into the N-side of the junction create an area that has a negative charge in the P-side of the junction. Similarly, the electrons diffusing across the junction into the P-side create an area on the N-side of the junction that has a positive charge. This charge across the junction eventually becomes high enough to prevent any further diffusion of holes and electrons across the junction.

(ae) No. The net charge on the crystal will remain zero. There may be areas on the crystal that have a positive charge, and other areas that have a negative charge, but since the crystal itself neither gains nor loses electrons, the net charge on the crystal will remain zero.

(af) Yes. Minority carriers crossing the junction tend to weaken the potential barrier established across the junction by majority carriers diffusing across the junction. When the potential barrier is weakened, additional majority carriers can cross the junction. Thus we end up with carriers crossing the junction in both directions. This adds nothing to the useful current that the diode can handle, but it does contribute to heating and thus limits the useful current that can cross the junction.

(ag) When a junction is forward biased we have a positive potential applied to the P-side and a negative potential applied to the N-side. This permits electrons to freely cross the junction from the N region to the P region. Similarly holes can cross the junction from the P region to the N region.

(ah) When a junction is reverse biased we have a negative potential connected to the P region and a positive potential connected to the N region. The positive potential connected to the N region repels holes in the P region away from the junction so that they cannot cross the junction. Similarly, the negative potential applied to the P region repels electrons in the N region away from the junction so that they cannot cross the junction. When a junction is reverse biased, majority carriers normally cannot cross the junction.

(ai) When there is no voltage applied to a semiconductor diode, the net current flow across the junction is zero. However, in the case of a vacuum tube where there is no voltage applied between plate and cathode, some electrons will leave the cathode with sufficient energy to travel over to the plate. As a result, there will be a small current through the diode even though there is no voltage applied between the plate and cathode.

(aj) When a semiconductor diode is reverse biased, there will be a small current flow across the junction due to minority carriers. As long as the breakdown voltage of the diode is not exceeded, this current will be quite small. In the case of a vacuum tube, when the plate is made negative with respect to the cathode, the plate will repel electrons so that there will be no current flow through the vacuum tube.

(ak) A Zener diode is a diode used in applications where a reverse bias is placed across the junction. The diode is designed to break down at a certain voltage and then maintain a constant voltage. If the voltage tries to increase above this constant value, the current flow through the Zener diode will increase so that the diode can be used in voltage regulating circuits and also can be used as a voltage reference source.

(al) A tunnel diode is a diode where the electrons cross the junction by a process similar to tunneling across the junction. The tunnel diode has a characteristic of introducing negative resistance into the circuit when a certain voltage is applied across the junction. In other words, when the voltage across the diode increases, the current flow through the diode decreases. Similarly, when the voltage decreases the current increases. Because of this negative resistance characteristic, the tunnel diode can be used as an oscillator.

(am) A p-i-n diode is a diode that is primarily used as a variable resistance. The resistance of the diode varies as the voltage across it is varied. The p-i-n diode is used in automatic gain control circuits to vary the strength of the signal reaching amplifier stages.

(an) The base region is the center region of the transistor. On one side of the base region is the emitter, and on the other side is the collector.

(ao) Germanium and silicon.

(ap) PNP transistors and NPN transistors.

(aq) Forward bias.

(ar) Reverse bias.

(as) The base region is usually comparatively thin.

(at) See Fig. 22.

(au) See Fig. 24.

(av) Holes are useful current carriers in a PNP transistor.

(aw) NPN and PNP transistors.

(ax) An alloy-type transistor.

(ay) Good high-frequency performance.

(az) A diffusion transistor is a transistor which has been made by diffusing the impurities into the emitter, base and collector regions.

(ba) One of the most important uses of the diffusion technique is in the manufacture of non-uniform base regions.

(bb) In a junction-gate field-effect transistor there is an actual contact between the channel material and the gate. There will be some current flow across the contact at all times due to minority carriers crossing the junction. In addition, if the junction is forward biased there will be a high current flow across the junction. In an insulated-gate field-effect transistor a glass or similar insulating material is used between the material in the channel and the gate. Since there is an insulator between the gate and the channel, there will be little or no current flow across the insulator either due to minority carriers when there is a reverse bias applied, or due to majority carriers with a forward bias applied.

(bc) A depletion-type FET is a unit in which the channel is present at all times. The transistor works by depleting or reducing the size of the channel.

(bd) An enhancement FET is a unit in which there is no channel present until the operating bias is applied between the gate and the material in which the channel is formed.

(be) A unijunction is a semiconductor device having two base connections but only a single junction. The junction is called the emitter. The single junction makes the unijunction quite different from the conventional two-junction transistor.

LESSON QUESTIONS

Be sure to number your Answer Sheet B112.

Place your Student Number on every Answer Sheet.

Most students want to know their grades as soon as possible, so they mail in their answers immediately. Others, knowing they will finish the next lesson within a few days, send in two sets of answers at a time. Either practice is acceptable. However, don't hold your answers too long; you may lose them. Don't hold answers to more than two sets of lessons at any time, or you may run out of lessons before new ones can reach you.

1. Name the two most important semiconductor materials used for transistors.

2. When a donor type of material is added to a silicon or a germanium crystal, what type of semiconductor material is produced? Does this type have free electrons or free holes?

3. What effect do the two layers of ionized atoms at the junction in a PN diode have on the majority carriers in the vicinity of the junction?

4. To which side of a PN junction diode do you connect the positive battery terminal if you wish to place a forward bias on the junction?

5. If a reverse bias is applied to a junction diode, what effect will a small increase in bias have on the current flowing, provided the reverse voltage does not exceed the breakdown voltage?

6. What is a Zener diode?

7. In a PNP transistor, what happens to a hole that crosses the emitter and the base and moves into the collector?

8. What is a drift transistor?

9. What is an N-channel, junction-type field-effect transistor?

10. What do we mean when we refer to a field-effect transistor as an enhancement type?

CASHING IN ON DISCONTENT

Discontent is a good thing--if it makes you want to do something worthwhile. If you had not been discontented, you would never have enrolled for the NRI course.

Practically everyone is discontented. But some of us are "floored" by discontent. We develop into complainers. We find fault with anything and everything. We end up as sour and dismal failures.

Those of us who are wise use our discontent as fuel for endeavor. We keep striving toward a goal we have set for ourselves. We are happy in our work. We face defeat, and we come out the victors.

At this minute you may be discontented with many things--your progress with your course, your earning ability, yourself.

Make that discontent pay you dividends. Don't let it throw you down. If you do, you may never be able to get up again. Keep striving to remove the cause of your discontent. Remember that it's always darkest before the dawn. And a real NRI man works hardest and accomplishes most when he is face to face with the greatest discouragements.

HOW TRANSISTORS
ARE USED

B113

STUDY SCHEDULE

By dividing your study into the steps given below, you can get the most out of this part of your NRI Course in the shortest possible time. Check off each step when you finish it.

☐ 1. **Introduction** . . . . **Pages 1 - 3**

This gives a brief discussion of the advantages and disadvantages of transistors compared to vacuum tubes, and a look at the basic circuits you will study.

☐ 2. **The Common-Base Circuit** . . . . **Pages 4 - 9**

The common-base circuit for both NPN and PNP transistors is discussed.

☐ 3. **The Common-Emitter Circuit** . . . . **Pages 10 - 15**

The common-emitter circuit is the most frequently used transistor circuit. You learn about both NPN and PNP common-emitter circuits.

☐ 4. **The Common-Collector Circuit** . . . . **Pages 16 - 21**

You study both NPN and PNP common-collector circuits.

☐ 5. **Transistor Characteristics** . . . . **Pages 22 - 28**

You study characteristic curves and various transistor characteristics.

☐ 6. **Typical Transistor Circuits** . . . . **Pages 29 - 37**

You learn how basic transistor circuits are modified to be used as audio and rf amplifiers.

☐ 7. **A Typical Transistor Receiver** . . . . **Pages 38 - 41**

We take a complete schematic diagram of a radio receiver using transistors and see how the stages you have studied are used together.

☐ 8. **Answers to Self-Test Questions** . . . . **Pages 41 - 44**

☐ 9. **Answer the Lesson Questions.**

☐ 10. **Start Studying the Next Lesson.**

HOW TRANSISTORS ARE USED

Just a few years ago a germanium transistor cost considerably more than most vacuum tubes, and the cost of silicon transistors was many times that of germanium transistors. Silicon transistors were priced so high that their use in commercial entertainment devices was prohibitive. Even germanium transistors were priced so high that it was hard to justify their use in entertainment-type equipment. Now, however, both germanium and silicon transistors are relatively inexpensive. There are many transistors of both types priced lower than even the most inexpensive vacuum tubes. For this reason they are widely used in commercial equipment. All portable radio receivers manufactured today use transistors. You will not run into a portable receiver using tubes except in the case of a receiver that is many years old. Automobile radios use transistors, and most stereo and hi-fi equipment is made entirely with solid-state devices. There are many portable television receivers on the market and in use today that use transistors exclusively. In addition, there are hybrid receivers that use both tubes and transistors.

TRANSISTORS AND TUBES

A transistor can do almost anything a vacuum tube can do. Sometimes a transistor can perform a task better than a vacuum tube; sometimes it cannot perform the task as well as a vacuum tube.

Advantages of Tubes.

The big advantage vacuum tubes have over transistors is that it is usually possible to obtain a higher gain with a single vacuum tube than it is with a single transistor. In addition, a number of tubes can be combined in a single envelope so that a single vacuum tube may actually contain three or more separate tubes in the same envelope. This often results in the multi-purpose tube being more economical than the equivalent number of transistors that would be required to perform the same functions.

Another advantage of the tube is that today's engineers are more used to working with them. Thus the cost of designing a piece of electronic equipment, such as a color TV receiver, using tubes is less than the cost of designing a color TV receiver using transistors.

The characteristics of tubes are more uniform than those of transistors. In other words, it is easier to duplicate circuits using tubes than circuits using transistors. Furthermore, when it comes time to replace a transistor, you may find the replacement has quite different characteristics from the original and that the stage will perform quite differently from the manner in which it did with the original transistor. You are not likely to run into this situation with a tube.

Advantages of Transistors.

To offset the advantages of the vacuum tube, the transistor offers many other advantages. Generally speaking, a transistor for a particular job is smaller than a vacuum tube. The transistor is more rugged than the vacuum tube and there is less chance of it breaking. A transistor does not require any power to heat a cathode or filament - this reduces the power requirement of the equipment and also reduces the amount of heat that must be dissipated by the equipment. The lower temperature inside the equipment generally results in longer life from all the other parts in the equipment.

Transistors operate on lower voltages than vacuum tubes. This often results in savings in the power supply and also in the voltage ratings of the other components in the circuit.

BASIC TRANSISTOR CIRCUITS

In the span of the few short years in which transistors have been manufactured for commercial applications, there have been a large number of different transistor types manufactured. Each year manufacturers introduce new types, and we can expect that this will continue year after year. This might make you think that it will be an almost impossible job to keep up with new developments in the field of transistors. However, this is not the case. Like tubes, transistors are used in certain basic circuits. If you learn these basic circuits and how they work, you should be able to understand new circuits as you encounter them. In addition, there are certain basic characteristics of transistors that are important. Once you learn what these characteristics are and what they mean, you will be in a position to evaluate new transistors as they appear on the market in comparison with older transistors with which you may be more familiar.

As you will remember from your study of vacuum tubes, the triode tube has three elements: a cathode, a plate and a grid. You will remember that we found that there are three different types of circuits in which a triode tube can be used: the grounded-cathode circuit, the grounded-plate circuit, and the grounded-grid circuit. Similarly, a triode transistor has three elements: an emitter, a base, and a collector. There are three basic circuits in which a triode transistor can be used. These circuits are called the common-base circuit, the common-emitter circuit, and the common-collector circuit. In transistor circuits we usually use the word "common" when speaking of different circuits, but actually a common-base circuit is a grounded-base circuit--in other words a circuit where the base is at the ac ground potential.

Now let's study the three basic circuits to learn something about the important characteristics of each type. It is important for you to understand these three circuits. If you understand them you should have no difficulty with the other circuits you encounter in this book because they will all be variations of one of these three circuits.

Of the three circuit variations in which a triode transistor may be used, the common-emitter circuit is found more frequently than the other two. This is the circuit that will give the greatest voltage and power gain. However, we will start our study of the three circuits with the common-base because you have already seen the circuit in the preceding lesson and also because it is a little easier to understand than the other two circuits.

In studying these three basic circuits we will compare their characteristics with the three basic vacuum-tube circuits. You will see a great deal of similarity between the three circuits insofar as performance is concerned, but you will also see some very noticeable differences. You should keep in mind that, although the end results may be the same, there is a great deal of difference between the way a circuit using a vacuum tube and one using a transistor works.

The Common-Base Circuit

Typical common-base circuits are shown in Fig. 1. The circuit shown at A is for an NPN transistor; the circuit shown at B is for a PNP transistor.

The solid arrows on the two diagrams indicate the direction of useful electron flow. In the circuit shown at A, electrons flow from the negative terminal of battery B1, through resistor R1, through the NPN transistor, into the emitter, across the emitter-base junction to the base, then across the base-collector junction into the collector, and from the collector through the collector resistor R_C to the positive terminal of battery B2. Notice that the emitter-base junction is forward biased, and the base-collector junction is reverse biased as in all transistor circuits.

In the circuit shown in Fig. 1B, the batteries are reversed. Since this is a PNP transistor, in order to place a forward bias on the emitter-base junction, the positive terminal of the battery must be connected to the emitter and the negative terminal to the base; similarly, battery B2 is reversed because, to place a reverse bias on the base-collector junction, the negative terminal must be connected to the collector and the positive terminal to the base.

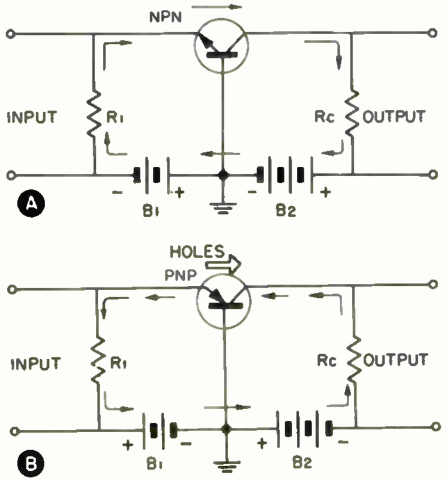

Fig. 1. Basic common-base circuits. The circuit at (A) is for an NPN transistor; the one at (B) for a PNP transistor.

In Fig. 1B the positive terminal of B1 is connected to the emitter through resistor R1. The positive potential applied to the emitter will attract electrons from the emitter. When an electron is attracted from the emitter it will flow in the direction indicated by the solid arrows, through resistor R1 to the positive terminal of B1. Meanwhile, when an electron is pulled from the emitter, a hole is created. The hole travels through the transistor in the direction indicated by the outlined arrow. The hole crosses the emitter-base junction, then travels through the base, across the base-collector junction, and to the terminal of the collector that is connected to the collector resistor R_C. There the hole is filled by an electron and disappears. The electrons needed to fill the holes reaching the collector terminal are supplied by battery B2. Thus there will be an electron flow from the negative terminal of this battery through the resistor R_C to the collector terminal of the transistor as shown by the solid arrows on the diagram.

You will remember from the preceding lesson that the majority carriers diffusing across the junctions in a transistor set up potential barriers which prevent an additional flow of majority carriers across the junction. In the transistor circuits shown in Fig. 1, battery B1 places a forward bias on the emitter-base junction that partially overcomes this potential barrier and allows some majority carriers to cross the junction. The exact number of majority carriers that will cross the junction depends upon the characteristics of the transistor and upon the voltage of battery B1. Thus, in the circuits shown in Fig. 1, we will have a static current flowing. Static current is simply a fixed current or a current flow that depends upon the operating voltages applied and not upon the signal voltage. This current is often called the "zero-signal" current, and it will set up a voltage drop across the collector resistor R_C.

A COMMON-BASE NPN AMPLIFIER

Now let us see what happens when a signal voltage is applied to the input of these transistor circuits. In Fig. 2 we have shown a common-base amplifier circuit using an NPN transistor. Let's see how this circuit can be used to amplify a signal.

Let us consider first the voltage across R_C. The end of R_C that is connected to battery B2 is essentially at signal ground potential. This is because B2 is a low impedance at signal frequencies or is made to act like a low impedance by shunting it with a capacitor. So let's consider this end of R_C as being at ground or zero potential and see what the voltage is at the other end.

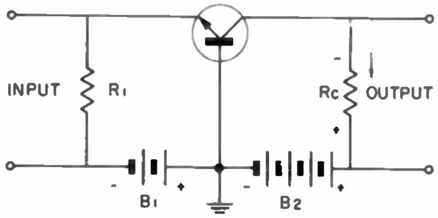

Fig. 2. A common-base amplifier circuit using an NPN transistor.

Since current flows through R_C in the direction shown, the end of R_C connected to the collector is negative. We can show this on a graph as in Fig. 3A. The voltage is negative so we represent it by a line drawn below the zero-voltage axis.

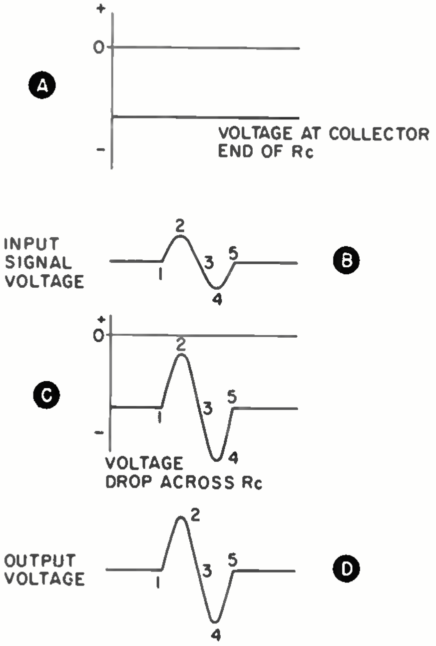

Fig. 3. Voltage waveforms for the circuit of Fig. 2.

Now, what happens when we apply a signal like Fig. 3B to the input? Consider first the input signal at point 1 in Fig. 3B. At point 1 the signal is zero and hence it has no effect on the static or zero-signal current flowing through the transistor. The only current flowing will be the zero-signal current due to the battery voltages. Therefore the voltage across R_C can be represented by the straight line extending to point 1 in Fig. 3C. Now as the ac signal moves to point 2 on the input curve, we have a voltage drop across resistor R1. The polarity of this voltage drop makes the end of R1 connected to the emitter positive and the end connected to the battery negative. This means that the polarity is opposite to the polarity of B1. Therefore the voltage across R1 will subtract from the voltage of battery B1 insofar as the net emitter-base voltage is concerned. This means that the signal will reduce the forward bias applied between the emitter and base and hence reduce the number of majority carriers (electrons) that can cross the emitter-base junction. When the number of carriers crossing this junction decreases, the number of electrons flowing through R_C will decrease.

When the number of electrons flowing through R_C decreases, the voltage drop across the resistor will decrease. This is shown in Fig. 3C. The curve rises, gets closer to zero, between points 1 and 2. This shows that the voltage is decreasing.

When the input voltage drops to point 3, we once again have the situation where the input voltage is zero. The current flowing through the collector resistor R_C will increase to the zero signal current, and the output voltage shown in Fig. 3C will increase to the zero signal voltage, point 3, which is the voltage that appeared across this resistor before any signal was applied. Hence the current will increase.

Now let us see what happens when the input signal swings in the opposite direction. When the signal swings to point 4, the end of resistor R1 that is connected to the emitter will be negative and the end connected to the battery will be positive. Now we have a voltage across R1 that is in series with the voltage of battery B1 and hence adds to it. This means that the forward bias across the emitter-base junction will be increased and the number of majority carriers crossing the junction will increase. The current flow through R_C will increase. When current flow through this resistor increases, the voltage drop across the resistor will increase and the end of the resistor that is connected to the collector will become more negative with respect to the other end. Hence the voltage appearing across the output terminals will swing to point 4 as shown in Fig. 3C. When the input signal drops back to point 5 or zero signal voltage, the voltage across the output similarly will fall back to zero signal voltage at point 5 on the output voltage curve.

Now let's consider what is happening in the output of this amplifier. First we have a dc voltage across R_C; this is the static or zero signal voltage. When a signal is applied to the input, the zero signal voltage varies. If we remove the zero signal voltage, which we can easily do by taking the output off through a capacitor, we have the output voltage shown in Fig. 3D. This is the actual amplified output obtained from the transistor.

Two important things to notice in this circuit are that the output voltage is in phase with the input voltage and that the output voltage is several times the input voltage. In other words when the input voltage swings positive, the output voltage goes positive and when the input voltage goes negative, the output voltage goes negative. We can obtain a voltage gain using this type of circuit.

A COMMON-BASE PNP AMPLIFIER

When a PNP transistor is used as an amplifier in a common-base circuit as shown in Fig. 4, the output voltage is also in phase with the input voltage. However, the way in which this circuit operates is quite different from the way the NPN circuit operates.

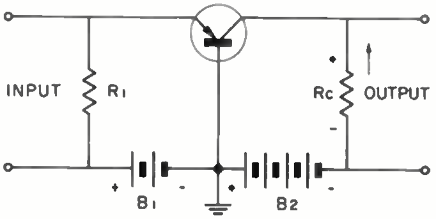

Fig. 4. A common-base amplifier circuit using a PNP transistor.

Notice that the polarity of the voltage across R_C is the opposite to what it was in Fig. 2. In Fig. 4, the end of the resistor connected to the collector is positive and the end connected to battery B2 is negative. Thus the voltage at the collector end of R_C will be positive with respect to the other end of the resistor, and under zero signal conditions can be represented by a straight line above the zero axis as shown in Fig. 5A.

Now, what happens when an input signal like Fig. 5B is applied to this circuit? When the input voltage is zero, the collector current flowing through R_C will be the zero signal current as shown in Fig. 5C extending to point 1 on the curve. But when the voltage applied across R1 swings positive to point 2 in Fig. 5B, the emitter end of this resistor is positive, and the end connected to the battery will be negative. This means that the voltage will be in series with the voltage of battery B1 and hence will increase the forward bias on the emitter-base junction. This will cause an increased movement of holes through the transistor and hence an increase in current flow through R_C. The increase in current flow through R_C results in an increased voltage drop across R_C so that the end of the resistor connected to the collector becomes more positive with respect to the other end. Thus when the input voltage moves from point 1 to point 2 in Fig. 5B, the voltage across R_C will move from point 1 to point 2 as shown in Fig. 5C.

Similarly, when the input voltage swings negative, the voltage across R1 will subtract from the forward bias applied across the emitter-base junction, reducing the bias. This will reduce the hole movement

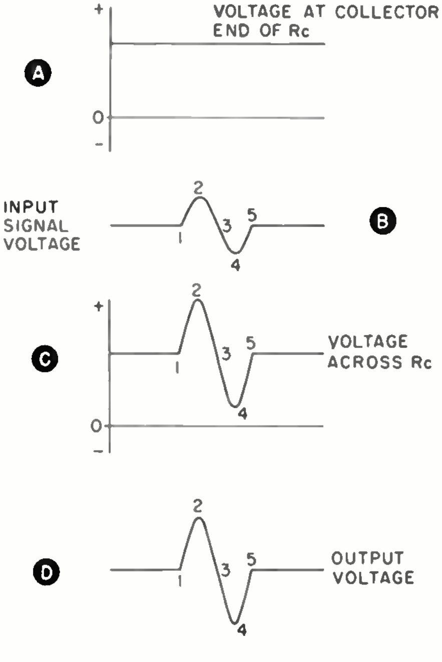

Fig. 5. Voltage waveforms for the circuit of Fig. 4.

through the transistor, which will reduce the number of electrons flowing through R_C. When the number of electrons flowing through this resistor decreases, the voltage drop across the resistor decreases with the result that the end of the resistor connected to the collector will become less positive with respect to the other end. This means that when the input signal swings from point 3 to point 4 on the input curve as shown in Fig. 5B, the signal voltage appearing across R_C will swing from point 3 to point 4 as shown in Fig. 5C.

If we once again remove the zero signal current from our graph, we have the graph shown in Fig. 5D. This represents the actual output signal voltage and, as you can readily see, it is in phase with the input signal.

CHARACTERISTICS OF COMMON-BASE CIRCUITS

Even though the action of the PNP transistor is quite different from the action of the NPN transistor, the net result using the common-base circuit is the same with both types of transistors. In both cases we have the output voltage in phase with the input voltage, and we have voltage amplification. In other words, the output signal voltage is greater than the input signal voltage.

You will remember that when you studied this circuit in the preceding lesson you learned that not all majority carriers leaving the emitter and crossing the emitter-base junction will reach the collector. Some of these carriers will be attracted by the potential of the emitter-base battery and flow out of the base to the battery. Therefore, since all of the emitter current does not reach the collector, the collector current will be less than the emitter current. Technicians say that the current gain is less than 1. For example, if the current in the emitter circuit increases by 1 milliampere, the current in the collector circuit will increase, but the increase will be something less than 1 milliampere.

Two other characteristics of a transistor amplifier that are important are the input impedance and the output impedance. The input impedance is simply the ratio of the signal voltage over the signal current. If we represent the signal voltage by e_{IN} and the signal current by i_{IN} and the impedance by Z_{IN} then the input impedance will be:

$$Z_{IN} = \frac{e_{IN}}{i_{IN}}$$

The output impedance is the ratio of the output signal voltage over the output signal current. If we represent the output signal voltage by e_{OUT} and the output current by i_{OUT} and the output impedance by Z_{OUT}, then the output impedance will be:

$$Z_{OUT} = \frac{e_{OUT}}{i_{OUT}}$$

If we examine the common-base circuit shown in Fig. 2, we see that the input voltage is applied across R1. This will cause some signal current to flow through the resistor R1. In addition, the entire emitter current drawn by the transistor must flow through R1. Therefore, even with the small signal voltage the signal current must be quite high. This means that the ratio of the voltage divided by the current will be low or, in other words, we will have a low input impedance.

On the other hand, since the stage is capable of giving voltage gain, the output voltage which will be developed across R_C will be much higher than the input voltage. At the same time, since the collector current is less than the emitter current the signal current flowing in the output will be lower than the signal current flowing in the input. Therefore the output impedance will be considerably higher than the input impedance. In fact, the output impedance will be quite high. Therefore in the common-base amplifier we have a very low input impedance and a reasonably high output impedance.

COMMON-BASE AND GROUNDED-GRID CIRCUITS COMPARED

The common-base circuit is often compared to the grounded-grid vacuum tube circuit. The two circuits are shown in Fig. 6 for comparison purposes. Notice the similarity between the common-base circuit shown at A and the grounded-grid circuit shown at B. The battery shown between the grid and the cathode of the grounded-grid circuit is seldom found in practice, because resistor R1 can be made to supply the bias required by the tube or, in some instances, a resistor placed in the grid circuit is used to develop bias. In this case the grid resistor will be bypassed by a capacitor.

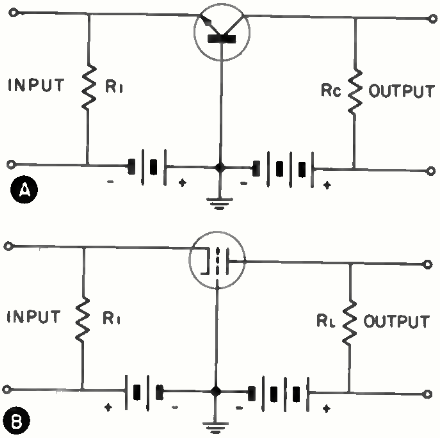

Fig. 6. Comparison of a common-base transistor circuit (A) with a grounded-grid vacuum tube circuit (B).

SUMMARY

The common-base circuit has a very low input impedance and a high output impedance. This output voltage is in phase with the input voltage and is greater than the input voltage. The current gain of the stage is less than one. A common-base circuit is often used in applications where we want to match a low impedance to a high impedance.

SELF-TEST QUESTIONS

(a) In the common-base circuit, is it possible to get a current gain?

(b) What is the phase relationship between the amplified signal voltage and the input signal voltage in a common-base circuit?

(c) What are the majority carriers in a common-base circuit using a PNP transistor?

(d) Why is it possible to get a voltage gain in a common-base amplifier circuit even though we do not have a current gain?

(e) What are the relative input and output impedances of the common-base amplifier circuit?

(f) To what type of vacuum tube circuit can the common-base circuit be compared?

The Common-Emitter Circuit

The most frequently used transistor circuits are the common-emitter circuits shown in Fig. 7. The circuit shown at A is for an NPN transistor, and the circuit shown at B is for a PNP transistor. Battery B1 in both cases provides the forward bias needed for the emitter-base junction, and battery B2 provides the reverse bias needed for the base-collector junction. In Fig. 1A battery B1 was connected so that the emitter was made negative with respect to the base. In Fig. 7A the emitter is also made negative with respect to the base. This provides forward bias for the emitter-base junction of the NPN transistor.

The solid arrows on the two diagrams in Fig. 7 indicate the direction of electron flow in the circuit. In Fig. 7A electrons leave the negative terminal of B1 and flow to the emitter. They cross the emitter-base junction, then flow through the base, across the base-collector junction, and through resistor R_C to the positive terminal of B2.

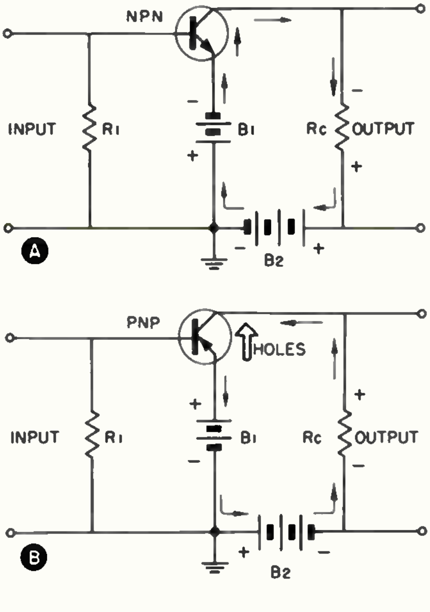

Fig. 7. Common-emitter circuits for (A) an NPN transistor, and (B) a PNP transistor.

In the circuit shown in Fig. 7B the electrons are attracted from the emitter by the positive potential of B1 and flow to the positive terminal of B1. The electrons leaving the emitter leave holes behind. These holes flow through the emitter, across the emitter-base junction, through the base, across the base-collector junction, and to the terminal of the collector. Here the holes are filled by electrons supplied by battery B2. The electrons from B2 leave the negative terminal of the battery, flow through the collector resistor R_C and to the terminal of the collector.

Notice the difference between these circuits and the common-base circuits shown in Fig. 1. In the common-base circuits, the useful transistor current flows through the input resistor R1, whereas in the circuits shown in Fig. 7, the useful transistor current does not flow through R1. The result is that the common-emitter circuit has a much higher input resistance than the common-base circuit. This is an advantage because it means that the generator driving the common-emitter circuit does not have to have such a low output impedance.

Notice that in the two circuits shown in Fig. 7 electrons flow through the collector resistor R_C in opposite directions. In the circuit shown at A, the electrons flow from the collector through the resistor to the battery, making the end of the resistor connected to the collector negative with respect to the other end. In the circuit shown at B, electrons flow from the negative terminal of B2 to the collector, making the end of the resistor connected to the battery negative with respect to the end connected to the collector. In other words, the polarity of the voltage across R_C in the circuit shown in Fig. 7A is opposite to the polarity of the voltage across R_C in the circuit shown in Fig. 7B. Now let us see how this type of circuit works.

A COMMON-EMITTER NPN AMPLIFIER

A common-emitter circuit using an NPN transistor is shown in Fig. 7A. As in the common-base circuit you just studied, battery B2 is a low impedance (or can be bypassed by a capacitor to make it act like a low impedance); therefore, the end of R_C connected to the battery is at signal ground potential. Since current flows through the resistor in the direction shown by the arrows, the end of R_C connected to the collector will be negative with respect to the end connected to the battery. The polarity of the end of the resistor connected to the collector can be represented by the straight line drawn below the zero axis as shown by curve 1 of Fig. 8A.

Now let us consider what happens when an input signal is applied to the input, as shown in curve 2 of Fig. 8A. At point 1, the input voltage is zero, and the only current flowing through the transistor is caused by the battery voltages. The signal voltage across R_C at that instant is zero and identified at point 1 on curve 3 of Fig. 8A. Now when the input signal swings in a positive direction so that the end of R1 connected to the base is positive and the end connected to ground is negative, the voltage across resistor R1 will be in series with the voltage of battery B1. This will increase the forward bias applied across the emitter-base junction of the transistor. This will increase the number of electrons crossing the emitter-base junction and hence increase the number of electrons flowing through the transistor to the collector. Therefore the number of electrons flowing through resistor R_C will increase, and the voltage drop across the resistor will increase, making the end of the resistor connected to the collector more negative with respect to

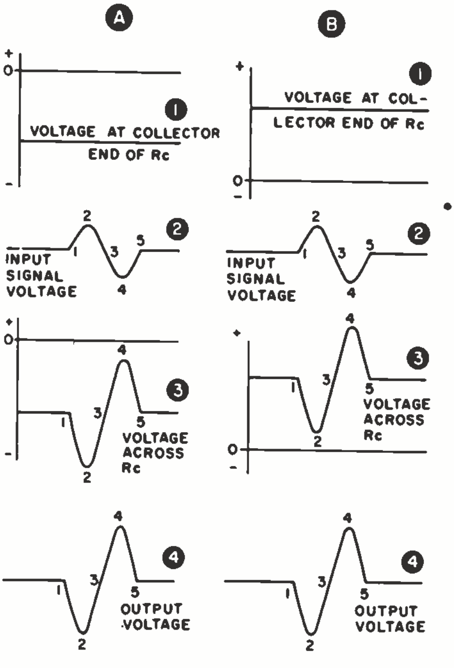

Fig. 8. Voltage waveforms for the circuits of Fig. 7. (A) is for the NPN transistor circuit, and (B) is for the PNP transistor circuit.

the end connected to the battery. Thus the output voltage will swing in a negative direction to point 2 on the output voltage curve, 3 of Fig. 8A.

As the input voltage drops back to zero, the forward bias applied across the emitter-base junction will decrease until, when the signal voltage reaches point 3, the forward bias will be made up of only the battery voltage and zero-signal current will be flowing through R_C. The voltage across R_C will drop to point 3 on the output voltage curve, 3 of Fig. 8A.

When the polarity of the input signal reverses, making the end of R1 that is connected to the base negative and the end connected to ground positive, the input voltage across resistor R1 will oppose the bias voltage applied between the emitter and base by battery B1. Thus the forward bias applied across the emitter-base junction will decrease, and the current flowing across this junction will decrease. When the current flowing across this junction decreases, the collector current, and hence the current flowing through load resistor R_C, will decrease. When the current flowing through this resistor decreases, the voltage drop across it will decrease, and the voltage at the end of the resistor connected to the collector will approach zero. This is represented by point 4 on curve 3 of Fig. 8A.

Finally, when the input signal voltage again drops to zero as shown at point 5 on curve 2 of Fig. 8A, the voltage across R_C will again increase in a negative direction until it reaches point 5 on curve 3 of Fig. 8A.

In curve 4 we have shown the output signal voltage that can be obtained by removing the dc component of the total voltage appearing across the resistor R_C. Again, this dc component can easily be removed by connecting a capacitor in series with one of the output leads.

Compare the output voltage curve shown in 4 of Fig. 8A with the input voltage shown in 2 of Fig. 8A. Notice that when the input voltage swings positive to point 2, the output voltage swings negative to point 2. Similarly, when the input voltage swings in a negative direction to point 4, the output voltage swings in a positive direction to point 4. This means that when the input is going in a positive direction, the output is going in a negative direction. In other words, the output signal voltage appearing across the load resistor R_C is 180° out-of-phase with the input signal voltage appearing across R1. From this we can conclude that when an NPN transistor is used in a common-emitter circuit, the amplified output voltage will be 180° out-of-phase with the input voltage. Also notice when comparing curve 4 with curve 2 that the amplitude of curve 4 is greater than the amplitude of curve 2. In other words, there is a voltage gain in this circuit.

A COMMON-EMITTER PNP AMPLIFIER

Although we have a somewhat different situation in a common-emitter amplifier using a PNP transistor, the net result is the same.

In a common-emitter amplifier using a PNP transistor, as shown in Fig. 7B, the electron current through resistor R_C is in the opposite direction to what it was in the amplifier using the NPN transistor. In the PNP amplifier, the electrons flow from the negative terminal of battery B2, through load resistor R_C into the collector to fill the holes crossing the base-collector junction. The electrons flowing through load resistor R_C set up a voltage drop across it having a polarity such that the end of the resistor connected to the collector is positive with respect to the end connected to the battery, as shown in Fig. 7B. Thus, if we plot the voltage at the collector end of this resistor with respect to the other end we have a curve like the one shown in 1 of Fig. 8B. Here the zero-signal voltage across R_C is represented by a straight line drawn above the zero voltage axis to indicate the fact that this voltage is positive.

Now, when an input signal like the one shown in curve 2 of Fig. 8B is applied across R1, the collector current will vary as before. When the input signal swings positive so that the end of R1 that is connected to the base is positive and the end connected to ground is negative, the voltage across R1 will oppose the voltage of battery B1, thus reducing the forward bias applied across the emitter-base junction. When the forward bias is reduced, the number of holes crossing this junction and traveling through the base, across the base-collector junction to the collector terminal is reduced. If the number of holes reaching the collector is reduced, the number of electrons flowing through R_C to fill the holes reaching the collector will be reduced. Hence the voltage drop across R_C will decrease, in other words drop toward zero. This is shown by curve 3 of Fig. 8B. When the input voltage shown in curve 2 swings in the positive direction, from point 1 to point 2, the output voltage across R_C moves from point 1 to point 2 on curve 3 of Fig. 8B.

When the input signal applied across R1 swings in a negative direction so that the end of R1 that is connected to the base is negative and the end connected to ground is positive, the voltage across resistor R1 will be in series with the voltage of battery B1 and will add to the forward bias applied across the emitter-base junction by the battery. This increased forward bias will result in an increase in the number of holes crossing the emitter-base junction which will, in turn, mean that there will be an increase in the number of holes reaching the collector. If more holes reach the collector, more electrons will have to flow through the output load resistor, R_C, to fill these holes. The result will be that the voltage drop across this resistor will increase above the zero-signal voltage level, and the end of R_C connected to the collector will become more positive with respect to the end connected to B2. This increase in voltage is shown as point 4 on curve 3 in Fig. 8B.

The complete cycle across R_C obtained with an input voltage such as shown in curve 2 is shown in curve 3 of Fig. 8B. When the dc component across resistor R_C is removed, we have the results shown by curve 4 of Fig. 8B. Notice that once again the output signal is 180° out-of-phase with the input signal.

By comparing the NPN amplifier with the PNP amplifier, you can immediately see that, although the action is somewhat different in the two circuits, the net results are the same. In both cases we have voltage amplification, and in both cases we find that in the common-emitter circuit the output signal is 180° out-of-phase with the input. Another way of saying this is that a common-emitter amplifier reverses the phase of the signal.

CHARACTERISTICS OF A COMMON-EMITTER CIRCUIT

The common-emitter circuit is the most important of all transistor circuits; it is by far the most widely used.

It is quite easy to get relatively high gain using the common-emitter circuit. Voltage gains from 80 to 100 are quite easily obtained. You can also obtain a current gain with this circuit.

Although the input impedance of this circuit is not as high as the input impedance of a vacuum tube circuit, it is substantially higher than the input impedance of the common-base circuit. Therefore it can be driven by a much higher impedance device than a common-base circuit. In a typical common-emitter circuit we usually have an input impedance of somewhere between 1000 and 2000 ohms. The output impedance is not quite as high as the output impedance of the common-base circuit, but it is still high, usually having a value of around 20,000 ohms.

COMMON-EMITTER AND GROUNDED-CATHODE CIRCUITS COMPARED

Because of circuit similarities and performance similarities, the common-emitter circuit can be compared to the grounded-cathode vacuum tube circuit. The grounded-cathode is the most common of all vacuum tube circuits. With it, as with the common-emitter transistor circuit, it is possible to obtain voltage gains of 80 to 100, and the phase is shifted 180°.

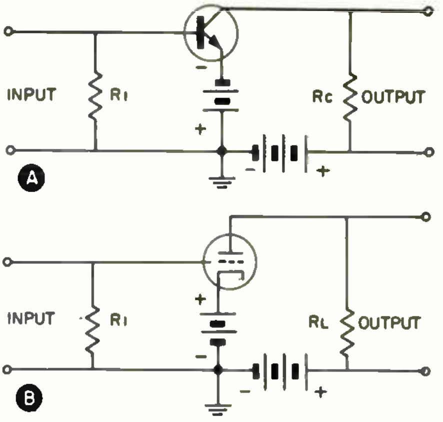

Fig. 9. Comparison of common-emitter transistor circuit (A) and grounded-cathode vacuum-tube circuit (B).

In order to help you see the similarity between these two circuits, the common-emitter circuit and the grounded-cathode vacuum tube circuit are shown in Fig. 9. The battery shown in the cathode circuit of the grounded-cathode amplifier is not found in actual practice because a resistor can be used in this circuit to avoid the necessity of this extra battery. You will see later that similar arrangements are used in transistor circuits to avoid the necessity of using two batteries to operate a single stage.

SUMMARY

The common-emitter circuit is the most frequently used transistor circuit. The voltage gain is from 80 to 100 and there is also considerable current gain. It has a medium input resistance and an output resistance of about 20,000 ohms. The output signal is 180° out-of-phase with the input signal.

SELF-TEST QUESTIONS

(g) Is it possible to get a current gain using the common-emitter circuit?

(h) What is the relationship between the input signal voltage and the amplified output signal voltage?

(i) How does the input impedance of the common-emitter circuit compare with the input impedance of the common-base circuit?

(j) Draw schematic diagrams of common-emitter circuits using NPN and PNP transistors. You should do this from memory since it is important that you remember these circuit configurations.

(k) To what vacuum tube circuit can the common-emitter circuit be compared?

The Common-Collector Circuit

The third possible circuit configuration using a triode transistor is the common-collector circuit. In this type of circuit the collector is operated at signal ground potential. Although this circuit is not found as often as the common-emitter circuit, it does have some characteristics that are useful in some special applications.

A common-collector circuit using an NPN transistor is shown in Fig. 10A, and one using a PNP transistor is shown in Fig. 10B. The arrows on the diagram in Fig. 10A show the direction of electron flow through the circuit. The solid arrows in 10B show the electron flow, and the outlined arrow indicates the direction of hole movement through the PNP transistor. Compare the circuits shown in Fig. 10 with the common-base circuits shown in Fig. 1 and the common-emitter circuits shown in Fig. 7. Let's see how each of these circuits works.

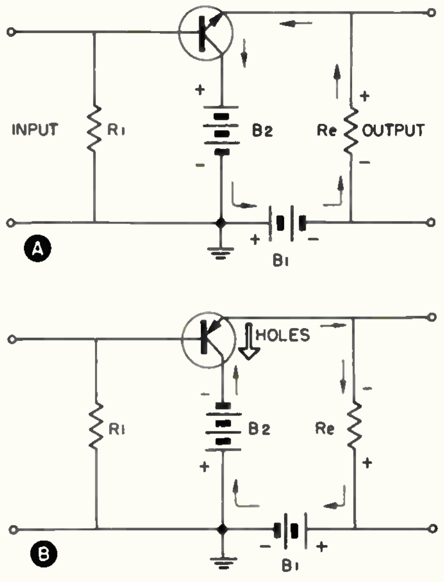

Fig. 10. Common-collector circuits. (A) for an NPN transistor, and (B) for a PNP transistor.

A COMMON-COLLECTOR NPN AMPLIFIER

In the circuit shown in Fig. 10A, electrons flow from the negative terminal of B1 through the emitter resistor Re to the emitter. They flow across the emitter-base junction, through the base, across the base-collector junction, to the positive terminal of B2. Battery B1 biases the emitter-base junction in a forward direction, whereas B2 biases the base-collector junction in a reverse direction.

Electrons flowing through Re set up a voltage drop across Re with the polarity indicated on the diagram. The end of the resistor connected to the emitter is positive with respect to the end connected to the battery. If we plot the voltage at the emitter end of the resistor, it will be like curve 1 of Fig. 11A. The voltage is represented by a straight line drawn above the zero voltage axis to indicate that it is positive with respect to the other end of the resistor.

Now let us consider what happens when an input signal like that shown by curve 2 of Fig. 11A is applied across the input terminals. When this signal swings in a positive direction from point 1 to point 2, the end of R1 connected to the base will be positive and the other end will be negative.

This means that the voltage across R1 will be in series with battery B1 and will add to the forward bias ap-

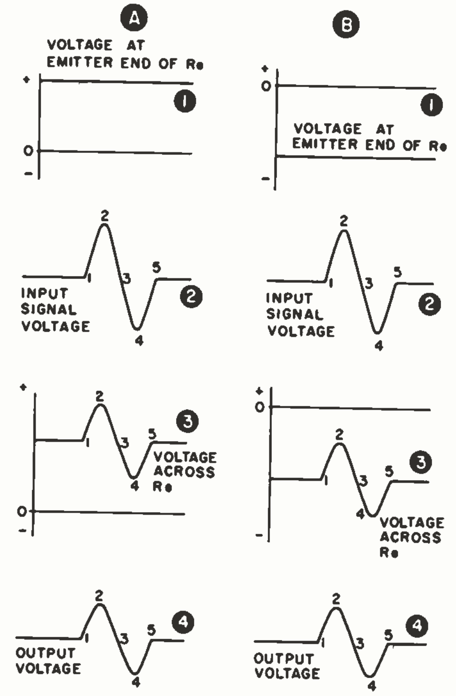

Fig. 11. Voltage waveforms for the circuits of Fig. 10. (A) is for the NPN transistor circuit; (B) is for the PNP transistor circuit.

plied across the emitter-base junction. This will increase the flow of electrons across this junction, and hence increase the current flow through the circuit and through Re. The increase in current through Re will result in an increase in the voltage drop across Re. This means that the end of the resistor connected to the emitter will become more positive with respect to the other end. The change in the voltage is indicated by points 1 and 2 on curve 3 of Fig. 11A.

Let's stop for a minute and consider what happens to the voltage applied across the emitter-base junction at this time. When the volttage across Re increases, it subtracts from the total voltage across the emitter-base junction. You will notice that the voltage across Re opposes the voltage of battery B1. Therefore an increase in the voltage across Re results in an increase in the opposition to the voltage of battery B1. When the input signal swings in a positive direction, the voltage across Re increases, opposing the increase in emitter-base voltage producing it. In other words, we have 100% voltage feedback. All of the amplified voltage appearing across Re opposes the input voltage producing it.

When the voltage across R1 swings in a negative direction as shown between points 3 and 4 on the input voltage curve, 2 of Fig. 11A, the input voltage will oppose the voltage of battery B1. This will reduce the emitter-base bias, resulting in fewer electrons crossing the emitter-base junction. This means that the current flowing in the circuit will decrease, and therefore the voltage across Re will decrease. This is shown between points 3 and 4 on curve 3 of Fig. 11A. This decrease in the voltage across Re will result in a reduction of the opposition of this voltage to the voltage of battery B1. In other words, we again have a situation where the output signal voltage being produced across Re is opposing the input signal voltage producing it.

In curve 4 of Fig. 11A we have shown the output voltage with the dc component removed. Notice that this voltage is in phase with the input voltage. Also notice that this voltage is smaller than the input voltage. Since we have 100% voltage feedback in this circuit, the output voltage will always be less than the input voltage. This situation is similar to the situation in the grounded-plate or cathode-follower vacuum tube amplifier. This transistor circuit is often compared to the grounded-plate amplifier, and we will soon see the similarity between these two circuits.

A COMMON-COLLECTOR PNP AMPLIFIER

In the common-collector circuit using a PNP transistor, the polarity of the voltage across Re is the opposite of what it was with the NPN transistor. Thus the voltage at the emitter end of resistor Re is represented by a straight line drawn below the zero signal axis as shown by curve 1 of Fig. 11B. In curve 2 of Fig. 11B we have shown an input signal similar to the one shown in curve 2 of Fig. 11A. When this input signal swings in a positive direction so that the end of R1 connected to the base is positive and the grounded end is negative, the voltage across R1 will oppose the voltage of battery B1. This will reduce the forward bias applied across the emitter-base junction and reduce the number of holes crossing this junction. You will remember that holes are formed in the emitter by pulling the electrons off the emitter. If fewer holes are formed, fewer electrons will be pulled off the emitter, and hence the current flowing through Re will decrease. When the current flowing through Re decreases, the voltage drop across Re decreases. This can be seen between points 1 and 2 on curve 3 of Fig. 11B.

When the input voltage applied across R1 swings in a negative direction as between points 3 and 4 of curve 2, the end of resistor R1 connected to the base will be negative and the grounded end positive. The voltage across R1 will be in series with battery B1 and will add to the emitter-base forward bias. This will result in an increase in the number of holes crossing the emitter-base junction. More electrons will therefore be pulled out of the emitter to produce additional holes across this junction. The current flowing through Re will increase, resulting in an increase in the voltage drop across Re. This increase is shown between points 3 and 4 on curve 3 of Fig. 11B.

Once again we have shown the output signal voltage in curve 4. Notice this is identical to the output signal voltage obtained with the NPN transistor. Notice that although the basic operation of the two circuits is somewhat different, the net result is the same. In both cases we have 100% voltage feedback, so the output is less than the input. Also notice that in both cases the output signal voltage is in phase with the input signal voltage.

CHARACTERISTICS OF COMMON-COLLECTOR CIRCUITS

The common-collector circuit has several interesting characteristics. It has the highest input impedance of the three circuits. You can see why this is true if you refer to Fig. 10. The input impedance will be the ratio of the input voltage over the input current. The voltage applied across resistor R1 will cause a certain current to flow through it. In addition, this input voltage will cause a signal current to flow from the emitter, through the transistor, to the collector. In the circuit shown in Fig. 10A, part of the electrons travelling from the emitter to the collector will be attracted by the base and hence will flow through R1. However, since the output signal voltage subtracts from the input signal voltage insofar as signal voltage applied between base and emitter is concerned, the actual signal current flowing through the transistor will be quite small. Therefore the total input signal current will be small and this, in turn, will result in the input impedance being high. On the other hand, the output impedance of the transistor will be low. This is due to the fact that the emitter signal current flows through the resistor Re and that very little voltage will be developed across this resistor. As a matter of fact, the voltage cannot be equal to the input signal voltage because if it was it would cancel the signal voltage entirely. Therefore, since the output voltage is small, the ratio of the voltage divided by the current will be small and the output impedance will be low.

In a common-collector circuit the voltage gain is always less than one. This means that the output voltage will always be less than the input voltage. We have already pointed out that this must be true because otherwise the output voltage would completely cancel the input voltage. Of course, this is impossible because it is the input voltage that causes the current change through the transistor which in turn develops the output voltage. All of the output voltage is fed back into the input circuit and therefore we say that we have 100% voltage feedback.

The common-collector circuit has the best stability of the three transistor circuits. This is what you might expect because, with the low output voltage, there is very little voltage to produce feedback into the input circuit which could cause instability or oscillation. Also, there is no phase reversal in the circuit and therefore the output voltage is in phase with the input voltage.

We have redrawn the common-collector circuit in Fig. 12A to make it easier to compare it with a cathode-follower or grounded-plate vacuum tube circuit shown in Fig. 12B. Notice the similarity between the cathode - follower and common collector circuit.

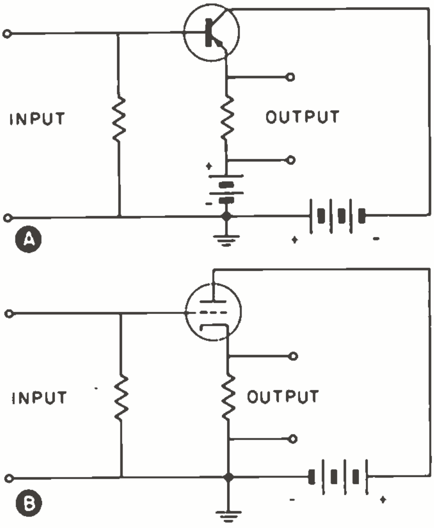

Fig. 12. Comparison of a common-collector transistor circuit (A) and a cathode-follower vacuum-tube circuit (B).

Because the common-collector circuit has a high input impedance and a low output impedance it is often used as an impedance matching device to match a relatively high impedance to a low impedance. An excellent use of this type of circuit is in the video amplifier of color TV receivers. In a color TV receiver a delay line, that slows up or delays the video signal, is used in the video amplifier. This delay line is used so that the brightness signals being fed to the color picture tube will be slowed down a little so that they will arrive at the picture tube at the same time as the color signal. A delay line is a comparatively low impedance device and the common-collector circuit provides an excellent method of matching from the higher impedance video amplifier stages to the low impedance of the delaying line. It is quite likely that when more transistorized color TV receivers are manufactured, this circuit will be very useful in this application.

SUMMARY

It is important for you to understand the three basic transistor circuits. You will find that transistors in commercial equipment will be arranged in one of these three basic circuits.

The most commonly used of the three circuits is the common-emitter circuit. In this circuit, the emitter is common to both the input and the output circuits. It is operated at signal ground potential. In the common-emitter circuit a voltage gain of from 80 to 100 can easily be obtained. In addition, there will be considerable current gain in this circuit. Other important characteristics of this circuit are a medium input resistance, usually somewhere between 1000 and 2000 ohms, and an output resistance in the neighborhood of 20,000 ohms. You should also remember that this is the voltage amplifier circuit that produces a 180° phase shift. In other words, the output signal voltage will be 180° out-of-phase with the input signal voltage.

The common-base circuit is the circuit in which the base is common to both the input and output circuits. It has a very low input resistance but has the highest output resistance of the three basic circuits. The current gain is always less than 1, but this type of circuit is quite stable. In fact, temperature changes have little effect on the operation of the circuit, whereas this is not always true of the common-emitter circuit. There is no phase reversal in a voltage amplifier used in this type of circuit; in other words, the output voltage will be in phase with the input voltage.

The common-collector amplifier is an amplifier in which the collector circuit is common to both the input and output circuits. This circuit has the highest input resistance, but the output resistance is very low; it may be as low as 100 ohms. This is the only one of the three circuits that has a lower output resistance than input resistance. In this circuit the voltage gain is always less than 1 because there is 100% voltage feedback. The stability of this circuit is excellent--the best of the three circuits. Again, there is no phase reversal when this circuit is used; the output voltage is in phase with the input voltage.

SELF-TEST QUESTIONS

(l) What is the phase relationship between the output voltage and the input voltage in a common-collector circuit?

(m) What will the voltage gain of the common-collector circuit be?

(n) What are the relative input and output impedances of the common-collector circuit?

(o) To what vacuum tube circuit can we compare the common-collector circuit?

(p) In which transistor circuits will you find an output voltage that is in phase with the input voltage?

(q) Which transistor circuits give you an output signal voltage that is 180° out-of-phase with the input signal voltage?

(r) Which transistor circuits will give you a voltage gain?

(s) Which transistor circuits will give you a current gain?

(t) Which transistor circuits have a relatively high input impedance?

(u) Which transistor circuit has a low output impedance?

Transistor Characteristics

You will remember from your study of tubes that they have certain important characteristics that tell the technician a great deal about how the tube should perform. The important tube characteristics are the mutual conductance, amplification factor and plate resistance. Likewise, there are certain transistor characteristics that are important to the technician. They enable him to compare one transistor with another and to get an idea of what to expect from a transistor in a certain circuit. All of this information is helpful in determining whether or not a transistor is performing the way it should.

In addition, there are a large number of symbols used in describing transistor performance. Many of these symbols are of interest only to circuit designers and engineers, but the technician should be familiar with the more important ones and be able to evaluate from a transistor manual the important transistor characteristics. In this section of this lesson we are going to cover some of the more important symbols and transistor characteristics.

TRANSISTOR SYMBOLS

As you might expect, the letter I is used to represent current in transistor circuits. When the capital letter I is used, it indicates dc current or rms current. When the small letter i is used, it indicates instantaneous current.

Currents flowing in the various transistor electrodes are identified by means of a letter representing the electrodes. For example, the emitter current is represented by the letter E or e. Base current is represented by B or b and collector current is represented by the letter C or c. Using these symbols, the dc emitter current is designated by the symbol I_E. The rms emitter current is represented by the symbol I_e, and the instantaneous emitter current is represented by the symbol i_e. Similarly, dc base current is represented by I_B, rms base current is represented by I_b, and instantaneous base current is represented by i_b. Collector dc current is represented by I_C, rms collector current is represented by I_c, and instantaneous collector current is represented by i_c.

Two characteristics that are often referred to in transistors are the forward current and the reverse current. The symbol used to represent the dc forward current is I_F, and i_F is used to represent the instantaneous-forward current. The dc reverse current is represented by I_R and the instantaneous-reverse current is represented by i_R.

You will remember that in normal operation a transistor is operated with a forward bias across the emitter-base junction and a reverse bias across the base-collector junction. Thus in an NPN transistor, current can flow from the emitter, across the emitter-base junction, through the base, across the base-collector junction and through the collector to the positive terminal of the battery, placing the reverse bias across the base-collector junction. However, we also point out that there would be at all times some minority carriers crossing the various junctions in a reverse direction. Thus there will be a current flow across the base-collector junction due to holes travelling from the collector across the junction into the base. This reverse current is kept as small as possible because it contributes nothing to the usefulness of the transistor. As a matter of fact, the current crossing the junction tends to heat the junction and cause a number of undesirable effects. Transistor manuals often list the reverse current across the collector-base junction. The current that is listed is the current that will flow across the junction when the junction is reverse biased and the emitter is open circuited. This dc current is represented by the symbol - I_{CBO}. The letters CB indicate that the current is across the collector-base junction in the reverse direction. The letter O indicates that the other electrode, the emitter, is open. This symbol is so widely used, that it is often abbreviated I_{CO}.

Groups of symbols are used in this manner to indicate other transistor current. For example, the symbol I_{CEO} is used to represent the dc collector current with the collector junction reverse biased and the base open circuited.

There are other symbols used in conjunction with transistors, but the ones covered in this section are the most important ones for the technician to remember, along with the few new ones we will cover in the next section. If you read through this section carefully and understand how these symbols are put together, the chances are that you will be able to figure out any that you are likely to encounter that will be of importance to you.

CURRENT GAIN

As we mentioned, a transistor is primarily a current operated device. Its ability to amplify is due to the fact that it can transfer a current from a comparatively low resistant circuit to a higher-resistant circuit. One of the important characteristics of a transistor is its current gain.

Since the current gain that can be obtained with a transistor depends upon the circuit in which the transistor is used, two symbols are used for current gain. These symbols are the Greek letters alpha (α) which represents the current gain in a common-base circuit, and the Greek letter Beta (β), which is used to represent the current gain in a common-emitter circuit. The two are interrelated; let's see how and exactly what each symbol means.

Alpha.

Alpha is equal to the change in collector current divided by the change in emitter current needed to produce this change in collector current. This is often represented by the symbols:

$$\alpha = \frac{\Delta Ic}{\Delta Ie}$$

The small triangles are Greek letter deltas, which are used to indicate a change; in this case, a change in current.

You will remember that in a common-base circuit the current gain is less than 1 because the change in collector current is slightly less than the change in emitter current. This is due to the fact that not all of the carriers crossing the emitter-base junction reach the collector. Some of them are attracted to the battery in the emitter-base circuit, and some of them are lost through recombination in the base. Thus the number of carriers reaching the collector will be slightly less than the number of carriers crossing the emitter-base junction. However, in a good transistor the majority of the carriers do reach the collector so that the current gain in the common-base circuit is close to 1. Typical values run around .95, which indicates that 95% of the carriers crossing the emitter-base junction reach the collector.

Transistor manufacturers often list the alpha of a transistor in the transistor characteristics. This will immediately tell you what current gain can be obtained from the transistor used in a common-base circuit. Also, as you will see later, you can determine from this figure the current gain that will be obtained in the same transistor in a common-emitter circuit. Another characteristic often given is the alpha cut-off frequency. This is the frequency at which the current gain of the transistor in the common-base circuit drops to 70.7% of what it is at lower frequencies.

Beta.

You will remember that in the common-emitter circuit we had a current gain. This means that the value of beta will always be greater than 1.

Beta is defined as the change in collector current divided by the change in base current. It is often represented by the expression:

$$\beta = \frac{\Delta\ Ic}{\Delta\ Ib}$$

Again, the small triangles are used to indicate a change in current. Typical values of beta may run as high as 80 or 100.

Beta is another characteristic frequently found in transistor specifications. If you know the beta of a transistor, you immediately know the current gain that the transistor will give when it is used in a common-emitter circuit. From this, as you will soon see, you can also determine the current gain that will be obtained in the common-base circuit, if the value is not given in the characteristics. The beta cut-off frequency is the frequency at which the current gain of the transistor in a common-emitter circuit drops to 70.7% of what it is at lower frequencies.

Converting Values.

Manufacturers often give either the alpha or the beta of a transistor, but seldom both. Sometimes when the alpha is given you want to know the value of beta and vice versa. Actually it is quite easy to convert from one to the other. If you know the alpha of a transistor you can find beta from the formula:

$$\beta = \frac{\alpha}{1 - \alpha}$$

If you know the beta of a transistor you can find alpha from the formula:

$$\alpha = \frac{\beta}{1 + \beta}$$

Now let's work a couple of examples to see how easy it is to convert from one value to the other. Let's assume that we have a certain transistor and the manufacturer lists the value of alpha as .95. Let's find the value of beta.

Starting with the formula:

$$\beta = \frac{\alpha}{1 - \alpha}$$

We substitute .95 for alpha and get:

$$\beta = \frac{.95}{1 - .95} = \frac{.95}{.05}$$

We can eliminate the decimals in this division by moving both the decimal points two places to the right so we have:

$$\beta = \frac{95}{05} = \frac{95}{5} = 19$$

Thus if alpha is equal to .95, beta will be equal to 19.

Now let's assume we have been given the value of beta as 19 and see what value of alpha we get. We know it should be .95. Starting with the formula:

$$\alpha = \frac{\beta}{1 + \beta}$$

we substitute 19 for beta and get:

$$\alpha = \frac{19}{1 + 19} = \frac{19}{20}$$

to get the value of alpha we need only divide 19 by 20:

```
     .95
20/19.0
   18 0
    1 00
    1 00
```

so we get a value of .95 for alpha if we start with 19 for beta.

Sometimes the gain of a transistor is referred to as a forward current-transfer ratio. In other words, instead of referring to the gain in a common-base circuit we say that the forward current-transfer ratio is alpha; we know this will always be less than one. Similarly, in the common-emitter circuit we refer to beta as the forward current-transfer ratio which, in effect, is the same thing as the current gain of the transistor.

Another characteristic or term that is frequently used in transistor manuals is the gain-bandwidth product. The gain-bandwidth product is the frequency at which beta equals one. In other words, as the frequency at which the transistor is used is increased, the current gain in the common-emitter circuit will drop off. At some frequency beta will be equal to one and this is called the gain-bandwidth product.

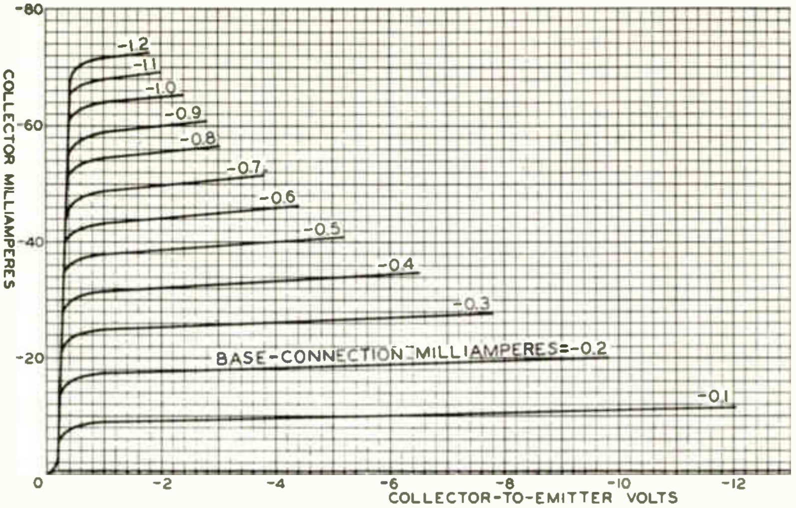
CHARACTERISTIC CURVES

When you studied vacuum tubes, you learned that characteristics are used to supply information about the manner in which a given tube performs. By means of curves a great deal of information about the tube can be condensed and presented in a convenient form. It is possible to see what the tube will do with different operating voltages and under different operating conditions.

Transistor characteristic curves are used for exactly the same reason. The curves give information about the way in which a transistor will perform in a convenient compact form.

A typical set of characteristic transistor curves is shown in Fig. 13. These curves are for a transistor used in a common-emitter circuit. They indicate what the collector current will be with different values of collector-to-emitter voltages and with different base currents. This type of curve is the most widely used transistor characteristic curve.

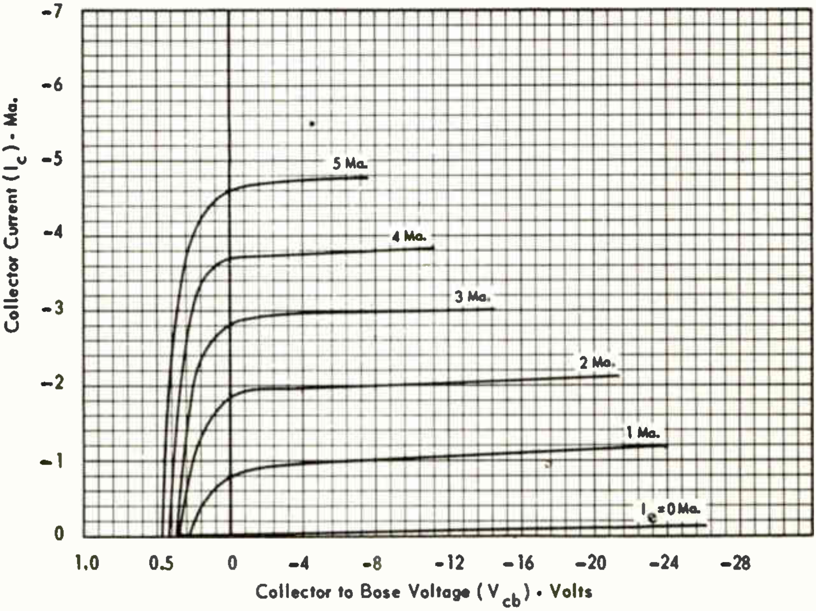
The curves shown in Fig. 13 can be used to determine the beta of a transistor for different collector-to-emitter voltages. For example, at a voltage of -4 volts, notice that when



Courtesy RCA

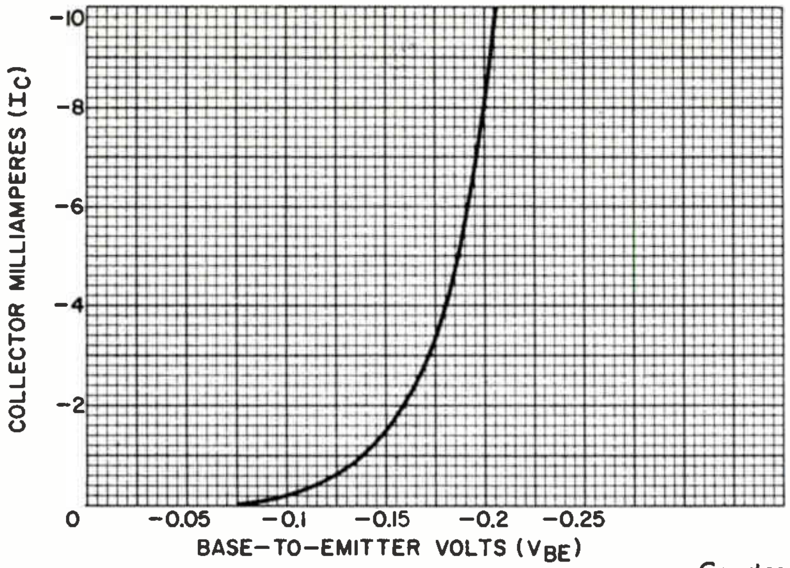
Fig. 13. Typical collector characteristic curves for a transistor used in a common-emitter circuit for different base currents.

the base current changes from -.3 milliamperes to -.4 milliamperes the collector current changes from approximately -26 milliamperes to -33 milliamperes. Thus for the change in base current of -.1 ma we have a change in collector current of -7 ma. Therefore:



Courtesy Raytheon Mfg. Co.

Fig. 14. Typical characteristic curves for a PNP transistor used in a common-base circuit for different emitter currents.



Courtesy RCA

Fig. 15. A typical transfer curve.

$$\beta = \frac{-7}{-.1} = \frac{70}{1} = 70$$

Another set of transistor characteristic curves for a PNP transistor is shown in Fig. 14. This set of curves is for a transistor used in a common-base circuit. Curves of this type are not given as often as those shown in Fig. 13 for the common-emitter circuit, since the common-emitter circuit is more widely used than the common-base circuit.

However, manufacturers often release detailed specification sheets on certain transistor types where curves of this type are given.

Another characteristic curve that is frequently given is the transfer characteristic curve, shown in Fig. 15, which enables you to find the collector current for different base-to-emitter voltages at a fixed collector-to-emitter voltage. An indication of the collector current change that might be expected with a given input voltage can be obtained from a curve of this type. The curve also indicates the range over which the transistor is comparatively linear. For example, with the base-to-emitter voltage of 100 millivolts, you can see that the collector current changes will not be linear with changes in input voltage. However, with a fixed base-to-emitter voltage of about -175 millivolts, small changes in this voltage will result in linear current changes.

SUMMARY

In this section of the lesson we have touched briefly on some of the important transistor characteristics. You learned that alpha is a term used to represent the current gain of a transistor in a common-base circuit. The alpha of a transistor is always less than 1, which means that the current gain of a transistor in a common-base circuit is always less than one.

Beta is the symbol used to represent the current gain of a transistor in a common-emitter circuit. The common-emitter circuit always has a current gain, and therefore the value of beta will always be greater than 1. Remember also that the value of beta is not constant; it depends to some extent upon the collector current.

You studied a number of important symbols that are used in transistor manuals to describe transistor performance and in many technical bulletins on transistor circuitry.

The characteristic curves studied in this lesson are typical of characteristic curves issued by transistor manufacturers. They give you an indication of what the collector current will be for different values of collector voltage and different values of emitter or base currents depending upon whether the transistor is used in a common-base or a common-emitter circuit.

Transistors are newcomers to the electronics field compared to vacuum tubes. As a result, from time to time you may see different types of characteristic curves on transistors issued by manufacturers. However, by studying the curves and the information given by the manufacturer on the transistor you can usually learn a great deal about the transistor and the type of performance you would expect from it, and from this information you can evaluate its performance in the circuit to determine whether or not it is operating properly. Being able to do this is a great help to a technician because he is able to determine whether or not he is getting all he should be able to get out of a particular circuit.

SELF-TEST QUESTIONS

(v) What are the symbols used to represent the dc currents in the various transistor electrodes?

(w) What is meant by the symbol I_{CBO}?

(x) Based on the transistor symbols you studied in this section of this lesson, what would you expect the symbol V_{CE} to mean?

(y) What is the Greek letter α used to represent in transistor circuitry?

(z) What is the maximum value that α can have?

(aa) What is meant by the forward current-transfer ratio in a common-base circuit?

(ab) What symbol is used to represent the current gain of a transistor in the common-emitter circuit?

(ac) What is meant by the alpha cutoff frequency?

(ad) What is the gain bandwidth product of a transistor?

(ae) If the beta of a transistor is 24, what is the value of alpha?

(af) Find the beta value of a transistor if alpha is equal to .99.

Typical Transistor Circuits

So far the circuits we have discussed have been basic transistor circuits. The circuits could be used in essentially these forms, but it is more convenient to modify these circuits slightly in actual usage.

The disadvantage of the circuits we have shown is that they use two separate batteries, one to supply the forward bias required across the emitter-base junction and a second battery to supply the reverse bias required across the base-collector junction. In actual practice, these circuits are modified so that both voltages can be obtained from a single voltage source. In battery-operated equipment this eliminates the need for a second battery. In equipment that operates from a power line, it simplifies the power supply somewhat so that the power supply can be arranged to provide either a positive or a negative voltage with respect to ground instead of having to supply both positive and negative voltages.

In this section of this lesson we will look at a number of typical transistor amplifier stages.

AUDIO AMPLIFIERS

A typical common-emitter audio amplifier circuit using an NPN transistor is shown in Fig. 16. Notice that the circuit is somewhat different from the common-emitter circuits you have seen previously inasmuch as only one battery is used in this circuit. Notice that the negative terminal of the battery is connected to the emitter. The positive terminal of the battery is connected to the base through the resistor R1. This would tend to make the base positive with respect to the emitter, which is what we want in order to place a forward bias across the emitter-base junction. You will remember that some of the electrons travelling from the emitter across the junction into the base leave the transistor through the base connection. These electrons will flow through the resistor R1 and set up a voltage drop across the resistor having the polarity shown. Although the number of electrons flowing through R1 will be very small, by using a large value resistor for R1 we can develop considerable voltage drop across it. Therefore even though the base is connected directly to the positive terminal of the battery through R1, the voltage drop across R1 subtracts from the battery voltage so that the net emitter-base voltage is quite small. Usually the base will be positive with respect to the emitter by only a few tenths of a volt, which is all that is required to forward bias the junction.

The collector is connected to the positive terminal of the battery through R2. The value of R2 is chosen

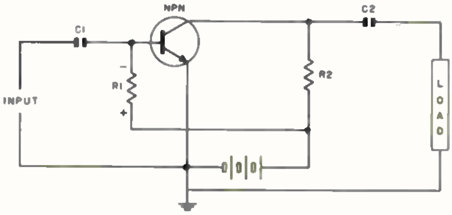


Fig. 16. A common-emitter audio amplifier using an NPN transistor.

so that the current flowing through it will result in a voltage drop across the resistor that is less than the voltage drop across R1. This means that the collector is positive with respect to the base, which is again the condition required to place a reverse bias across the base-collector junction.

In operation, the input signal causes the base-emitter forward bias to vary. This in turn causes the number of electrons crossing the emitter-base junction to vary and hence the collector current varies. The varying collector current flowing through the resistor R2 will result in an amplified signal voltage being developed across R2. This amplified signal voltage is fed to the load through the coupling capacitor C2.

In a typical circuit you will often find that both C1 and C2 are electrolytic capacitors. Electrolytic capacitors are used because the impedances found in transistor circuits are much lower than those found in vacuum tube circuits. You will remember that the capacitor C1 will act as a voltage divider along with R1 and divide the input signal in such a way that part of it will appear across the capacitor and part of it will appear across the transistor input impedance. The amount that will be lost across the capacitor will depend upon its reactance in comparison with the input impedance of the transistor. Therefore, to keep the reactance of the capacitor low, a large value capacitor is usually used.

Fig. 17 is a schematic of a common-emitter amplifier using a PNP transistor. Notice that the circuit is identical except that the battery is reversed. In this circuit, the negative terminal of the battery is connected to the base of the transistor through R1. This places a negative voltage on the base with respect to the emitter, which will forward bias the emitter-base junction. As in the previous case, however, the entire voltage will not be applied across the emitter-base junction because of the voltage drop across R1. Some electrons will flow from the negative terminal of the battery through R1 and into the base of the transistor to fill holes. This will result in a voltage drop across R1 having the polarity shown in the diagram. This voltage drop will subtract from the battery voltage so that once again the forward emitter-base bias is only a few tenths of a volt.

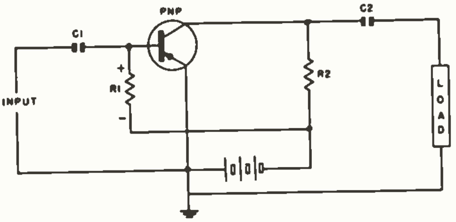

Fig. 17. A common-emitter audio amplifier using a PNP transistor.

In this circuit, as in the previous circuit, the voltage drop across R2 will be less than the voltage drop across R1, and therefore the collector will be negative with respect to the base so that we will have a reverse bias across the base-collector junction.

The operation of this circuit is essentially the same as the operation of the circuit shown in Fig. 16. The only exception is that in the transistor holes will be the majority carriers whereas in the preceding NPN transistor, electrons were the majority carriers.

Bias Stabilization.

In the circuit shown in Fig. 16 we have used an NPN transistor. In the collector region, in addition to free electrons which are the majority carriers, there will be some free holes. These holes, which are the minority carriers, will tend to cross the collector-base junction and flow into the base of the transistor. Some of the electrons travelling from the emitter across the emitter-base junction into the base will fill these holes. This is one of the reasons why the collector current will always be less than the emitter current. Some of the holes, however, will be filled by electrons that would normally leave the transistor at the base and flow through R1.

If the temperature of the transistor increases, the resistance of the base-collector junction will decrease, and this will allow additional holes to cross from the collector into the base. This, in turn, will reduce the number of electrons flowing through R1 which will reduce the voltage drop across it.

If the voltage drop across R1 is reduced, the effective emitter-base forward bias will be increased because this bias is equal to the battery voltage less the voltage drop across R1. The increase in forward bias across the emitter-base junction will result in a higher emitter current. This, in turn, will result in a higher current across the emitter-base junction, through the base, and across the base-collector junction. The increase in current across the base-collector junction will result in a further increase in the temperature of this junction which in turn will reduce the resistance again, causing the number of minority carriers crossing the junction to increase still further. This action will continue until eventually the current through the transistor becomes so high that the transistor is destroyed.

The simplest way to overcome this problem is to add a bias-stabilizing resistor in series with the emitter lead. A typical circuit in which this has been added is shown in Fig. 18. The bias-stabilizing resistor is marked R3 on the diagram. Capacitor C3 bypasses the signal around this resistor to prevent degeneration.

If a transistor heats and the base-collector junction resistance is lowered in this circuit, we will have the same situation as before; the resistance will go down and the minority carriers crossing from the collector into the base will increase. This will cause the current through R1 to go down which in turn will reduce the voltage drop across the resistor and tend to increase the emitter-base forward bias. However, the increase in forward bias will tend to cause the emitter current to increase. This increase in current will result in an increase in the voltage drop across R3. Since this voltage subtracts from the forward bias, it will tend to keep the forward bias across the emitter-base junction reasonably stable. Although there will be some increase in current, it is usually not large enough to damage the transistor.

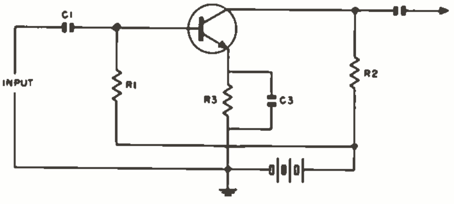

Fig. 18. A common-emitter circuit with a bias stabilizing resistor in the emitter circuit.

Common-Base Amplifier.

The common-base circuit is sometimes found in voltage amplifier circuits. This circuit is particularly useful in TV receivers where some voltage amplification is required without a phase shift. You will remember that with a common-emitter type of amplifier circuit there is a 180° phase shift, whereas in a common-base circuit there is no phase shift.

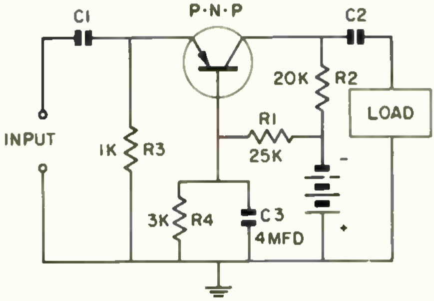

Fig. 19. A single-battery common-base amplifier with bias stabilization.

The circuit shown in Fig. 19 is a common-base circuit modified for use with a single battery. R1 and R4 make up a voltage divider which is connected across the battery. The forward bias, which is required for the emitter-base junction, is developed across R4.

The emitter resistor, R3, serves two purposes in the common-base amplifier. First, it is the impedance across which the input signal is developed. Second, it acts as a bias-stabilizing resistor. As a bias-stabilizing resistor, it works exactly like resistor R3 in Fig. 18, reducing the forward bias of the emitter-base junction if the emitter current tends to increase.

Resistors R1 and R4 are chosen such that the battery current through R1 and R4 is much greater than the base current which flows only through R1. Thus any variations in base current will have little effect on the base voltage which appears across R4. Capacitor C3 bypasses R4 and assures that the base is grounded for ac signals.

RF AMPLIFIERS

Radio frequency amplifiers are almost always tuned amplifiers. They make use of series-resonant and parallel-resonant circuits so that they can be tuned to accept one signal and reject all others. If a low resistance is connected across a parallel-resonant circuit, the resistance will load the circuit so that its selectivity will be destroyed. In other words, it will be unable to select one signal and reject another. This is one of the problems that we face with transistor rf amplifiers. Transistor amplifiers must take into account the fact that transistors are relatively low impedance devices and if they are connected directly across a resonant circuit they will load the circuit and reduce the selectivity.

A typical transistor i-f amplifier is shown in Fig. 20. Although this

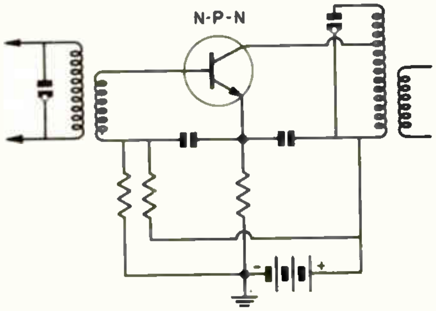

Fig. 20. Transistor input impedance matched by a step-down input i-f transformer and output impedance matched to tuned circuit by tapping down on coil.

is used as the intermediate frequency amplifier in a radio receiver, it is still a radio frequency amplifier since it is designed to amplify radio frequency signals.

Notice that instead of using a double-tuned input transformer, as used in i-f stages using tubes, a single-tuned transformer is used. The secondary of the i-f transformer has far fewer turns than the primary. Therefore the transformer acts like a step-down transformer. The low input impedance of the transistor does not load the primary of the transformer which is a parallel-resonant circuit. Insofar as the primary is concerned, the step-down transformer effectively matches it to the transistor so that excessive loading is avoided.

In the output circuit, the collector is connected to a tap on the primary winding of a second i-f transformer. The lower end of this transformer primary is connected to the positive terminal of the battery and is effectively at signal ground potential. The upper end of the transformer is at some comparatively high impedance with respect to ground. Somewhere along the transformer winding there will be a point at which the impedance of the transformer winding is equal to the output impedance of the transistor. The idea is to connect the collector to this point and by so doing match the collector to the primary winding of the transformer to get maximum signal transfer and at the same time avoid loading the parallel-resonant circuit.

As a technician, you will not have to be concerned about finding the correct impedance point at which to connect a transistor to an i-f transformer; the engineers who designed the set will have taken care of this for you. The important point for you to see is how the transistor is connected into the circuit and to understand why this provision has been made.

One disadvantage of the circuit shown in Fig. 20 is that it is somewhat unstable. This is due to the capacity and resistance across the base-collector junction. Energy can be fed from the collector circuit to the base which is connected directly to the input circuit. If the energy fed back into the input circuit is of the correct phase to reinforce or add to the input signal, the transistor may go into oscillation and generate a signal of its own.

Neutralization.

Two circuits that are used to overcome this undesirable effect are shown in Fig. 21. In both of these circuits neutralization is used to overcome the undesirable effects of feedback.

In the circuit shown in Fig. 21A, tap 2 on the primary of the output i-f transformer is operated at signal ground potential. This tap on the transformer is grounded through the .01-mfd capacitor connected from terminal 2 of the transformer to the emitter. The collector is connected to terminal 1 and signal currents flowing between terminals 1 and 2 will induce a voltage in the portion of the winding between terminals 2 and 3. Thus a voltage is set up at terminal 3 having the opposite polarity to the voltage in terminal 1. This voltage is fed through C1 back to the base of the transistor.

Now, if sufficient energy is fed from the collector of the transistor across the base-collector junction to the base to cause instability, a signal with the opposite polarity is fed through C1 to the base of the tran-

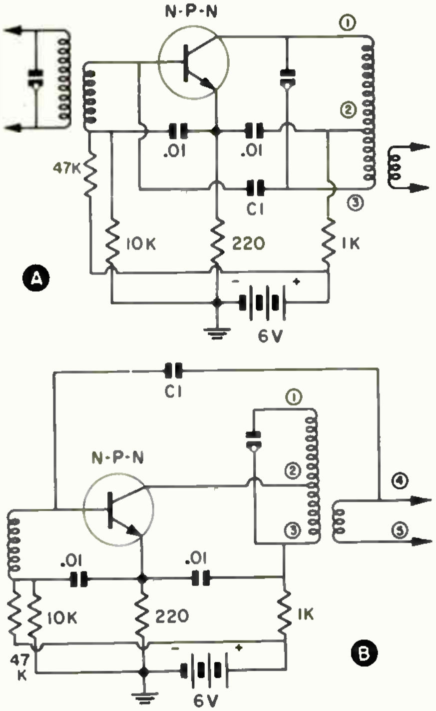

Fig. 21. Two methods of neutralizing a transistor i-f stage.

sistor. These two signal voltages tend to cancel each other so that there is not sufficient net feedback to the base to cause oscillation.

In this circuit the tuned part of the output i-f transformer consists of the entire winding between terminals 1 and 3. You will notice that this winding is tuned by a capacitor so that they form a parallel resonant circuit. Since terminal 2 is operated at ground potential and the collector is connected to terminal 1, the transistor is connected across only a portion of the i-f transformer so that it does not load the transformer excessively and reduce the selectivity of the parallel resonant circuit. At the same time, with this arrangement the instability that was encountered in the circuit shown in Fig. 20 is avoided.

The circuit shown in Fig. 21B is similar to the circuit shown in Fig. 20 except that neutralization is added by means of capacitor C1 connected from the secondary of the output i-f transformer back to the base. The polarity of the signal voltage fed through this capacitor to the base is opposite to the polarity of the signal voltage fed back through the transistor itself across the base-collector junction, so that these two signals will tend to cancel.

When a circuit like the one shown in Fig. 21B is used, the neutralizing capacitor C1 will be somewhat larger than the neutralizing capacitor C1 shown in Fig. 21A because there is quite a step-down in voltage between the primary and secondary windings of the i-f transformer. Since C1 in Fig. 21B is connected to the secondary, the voltage will be considerably lower at this point than it is at the primary. Therefore, a larger capacity is needed in order to feed sufficient voltage back to the base to prevent oscillation. The circuit shown in Fig. 21B is somewhat less critical than the circuit shown in Fig. 21A.

The gain obtained in an i-f stage using a transistor is considerably less than that obtained in an i-f stage using a vacuum tube. As a result, many receivers using transistors in the i-f amplifier have two or more i-f stages. Most modern receivers using vacuum tubes, on the other hand, have only one i-f stage.

OSCILLATOR AND MIXER STAGES

You will remember that modern radio receivers are superheterodyne receivers. In the superheterodyne receiver, the signal being received is mixed in the mixer or converter stage with a signal generated in a local oscillator. Mixing these two signals together results in the formation of two new signals, one with a frequency equal to the sum of the two frequencies and the other with a frequency equal to the difference between the two. Both signals are modulated with the original intelligence being transmitted by the broadcast station.

In modern receivers the difference signal is amplified by the i-f amplifier because the i-f amplifier is tuned to this frequency. This signal is then fed to a detector where the audio signal is separated from the carrier, and then the audio signal is amplified further and fed to a loudspeaker.

Typical mixer and oscillator circuits are shown in Fig. 22. Here an NPN transistor is used in a common-emitter mixer circuit. The primary winding of the loop antenna, L1 on the diagram, is inductively coupled to L2. The signal picked up by the loop is fed to L2 and then applied between the base and ground. This arrangement prevents the input impedance of the transistor from loading the tuned circuit. The signal from the local oscillator is fed through C1 to L2 and hence to the base of the mixer. In the mixer, the two signals beat together to produce the desired i-f signal.

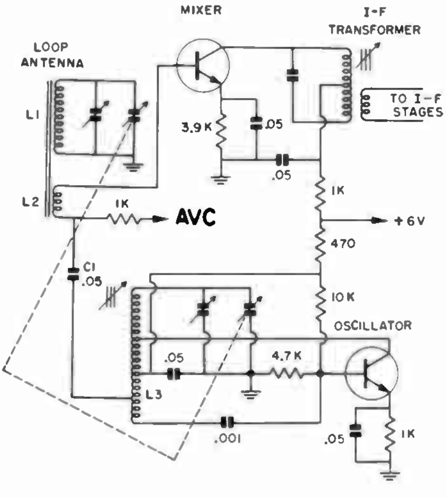

Fig. 22. Oscillator and mixer stages using separate transistors.

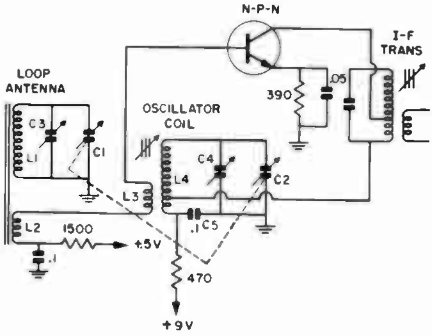

Fig. 23. A converter stage using one transistor as both oscillator and mixer.

The oscillator circuit uses another NPN transistor in a common-emitter circuit. This circuit is one form of the Hartley Oscillator which you have seen used previously with vacuum tubes.

The circuit shown in Fig. 22 works well and seldom gives trouble; it's main disadvantage is that two transistors are required. You are not likely to see this arrangement except in some of the more expensive transistor receivers. The usual practice is to use one transistor as both the mixer and the oscillator.

A converter stage, where a single transistor is used as both the mixer and oscillator, is shown in Fig. 23. Here an NPN transistor is used in a common-emitter circuit. In this circuit the signal is picked up by the loop antenna, which is inductively coupled to L2. The signal voltage is induced in series with L2, and this is applied to the base of the transistor through L3, and to ground through the .1-mfd capacitor.

At the same time, energy is fed from the collector into the primary of the i-f transformer and from the primary of the i-f transformer back to L4. L4, C2, C4, and C5 make up the oscillator tank circuit. L4 is inductively coupled to L3, and energy is fed from L3 to the base of the transistor. Thus we have two signals fed to the base of the transistor, the incoming signal picked up by the loop antenna, and the signal generated in the oscillator tank circuit. These two signals are mixed in the transistor and the resulting difference-frequency signal is selected by the i-f transformer and fed to the first i-f amplifier.

Another transistor mixer-oscillator circuit is shown in Fig. 24. This is quite an interesting circuit inasmuch as the transistor is used in both a common-base and a common-emitter circuit at the same time.

In this circuit the incoming signal induced in L3 is applied to the base of the transistor. As far as the incoming signal is concerned, the emitter is essentially at ground potential and hence the mixer operates as a common-emitter mixer.

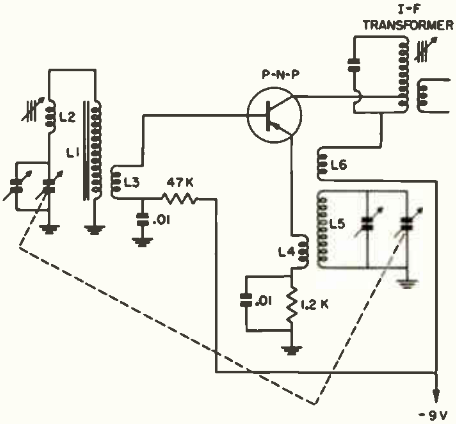

Fig. 24. Converter stage using one transistor connected in a common-base circuit for the oscillator signal, and a common-emitter circuit for the rf signal.

The oscillator signal, on the other hand, is coupled to the feedback winding L4 in the emitter circuit. Therefore, as far as this signal is concerned, the base is the common element and the oscillator operates as a common-base circuit. In spite of the fact that the two signals are fed into different elements of the transistor, mixing still takes place because of the non-linear characteristic of the emitter-base junction.

SUMMARY

The circuits we have studied in these two sections of this lesson are basic transistor circuits. Transistors are found in circuits other than these. Other common circuits in which transistors are found are multivibrators and switching circuits such as used in electronic equipment. However, the circuits that we have studied in this section are what might be considered basic circuits; you should learn these circuit configurations before going on to more complex circuits.

Do not expect to remember what these circuits look like simply by taking a quick look at the diagram in the lesson texts. You should take the time to draw each of these circuits yourself. Draw a circuit two or three times, copying it from the book, then close the book and try to draw it yourself. The chances are that the first time you try to do this you will find that you cannot reproduce the circuit, but after two or three attempts you should be able to do so. Knowing what these basic circuits look like will be a big help to you. You might not understand what all the parts are used for at this time, but we are going to study all of these circuits again in later lessons. If you are familiar with the general circuit configuration, it will be a big help to you because you will know what the circuit looks like and hence will be ready for the next step, that of learning what each and every part in the circuit is used for.

SELF-TEST QUESTIONS

(ag) In the circuit shown in Fig. 16, why is the emitter-base forward bias considerably less than the battery voltage?

(ah) Why is it necessary to provide bias stabilization in transistor amplifiers?

(ai) What advantage does the common-base amplifier circuit offer over the common-emitter circuit?

(aj) In an i-f amplifier such as the one shown in Fig. 20, why is the secondary of the input i-f transformer untuned and shown as having fewer turns than the primary winding?

(ak) What is the purpose of connecting the collector in the transistor circuit shown in Fig. 20 to a tap on the primary winding of the output i-f transformer?

(al) How are the effects of collector-base signal feedback eliminated in transistor amplifiers?

(am) What type of circuits are used in the converter stage shown in Fig. 24?

A Typical Transistor Receiver

One important use for transistors is in portable receivers. Transistors are ideally suited for portable equipment because of their small size and modest current and voltage requirements.

A typical portable receiver is shown in Fig. 25. This receiver uses circuits similar to those you have already studied in this lesson. We will run through this receiver quickly to help you see how the various stages you studied are used together in a complete receiver.

For the purpose of study, we will divide the receiver into two sections, the rf section and the audio section. In the rf section we will include all the stages where the signal present is not an audio signal.

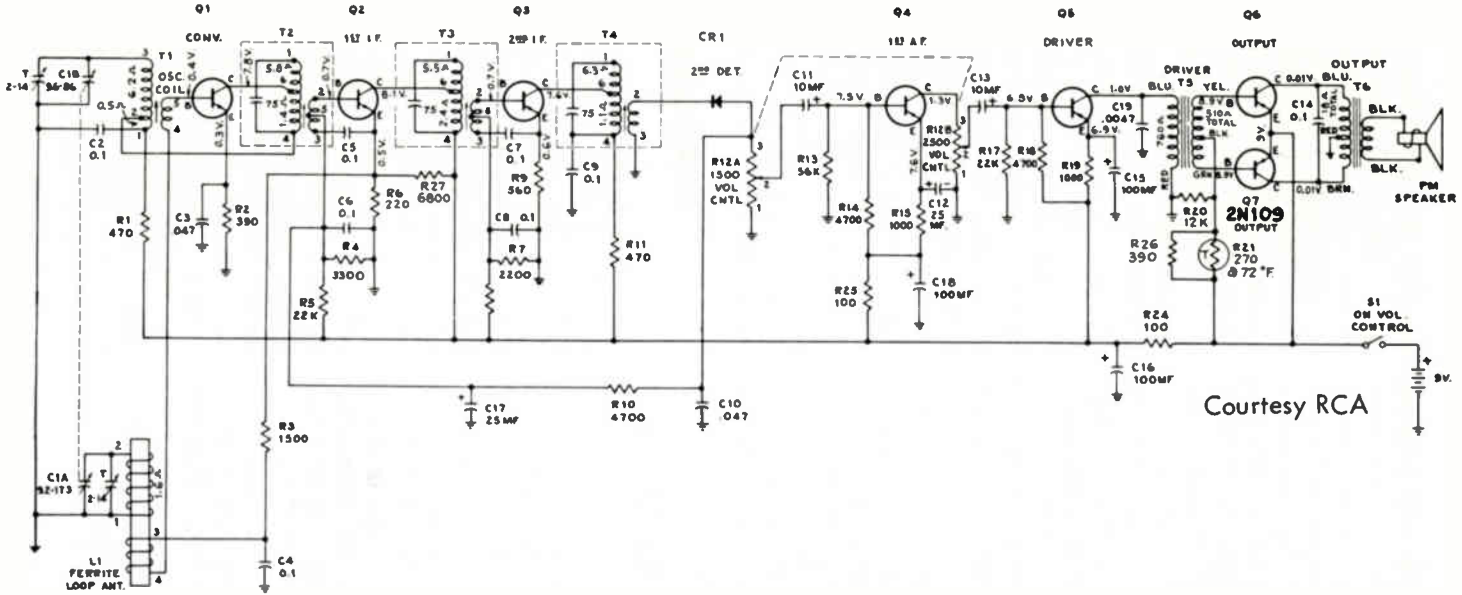
THE RF SECTION

The rf section of this receiver consists of three stages: the converter, which is actually a combination mixer and oscillator, two i-f stages, and the second detector, which is also part of the audio section. The transistors used in these stages are NPN transistors. You will remember that we can identify these transistors as NPN transistors because the arrow used to identify the emitter is pointing up, away from the base.

The converter stage in this receiver is similar to the mixer-oscillator stage shown in Fig. 23. Here we have a transistor used in a common emitter circuit performing the functions of both mixer and oscillator. The primary winding of the i-f transformer T2 is tapped, and the collector is connected to the tap. This is done to avoid loading the high Q i-f transformer and to provide maximum power transfer. Maximum power transfer can be obtained only when impedances are matched. The load impedance of this transistor is quite low, probably about 30,000 ohms, whereas that of the resonant circuit is over 500,000 ohms so the transistor collector is connected to the tap.

The i-f transformer T2 is a step-down transformer. The input impedance of the first i-f stage is very low, approximately 50 ohms. A step-down transformer is required in order to match the high-impedance primary circuit to the low-impedance secondary circuit.

The secondary of transformer T2 is tapped. The center tap, marked 5 on the diagram, is at signal ground potential because it is connected to ground through the .1-mfd capacitor C6. This capacitor is in effect a direct connection at the i-f signal frequency. Signal voltages fed from the emitter through the .1-mfd capacitor C5 will cause a current flow through the part of the secondary between terminals 3 and 5. The current flowing through this half of the secondary will set up a field which will induce a voltage between terminals 2 and 5. This voltage is applied between the base and ground and neutralizes the i-f stage. This voltage applied between the base and ground because of the signal fed back through C5 is out-of-phase with the signal voltage fed from the collector through the transistor back to the base, so the two signals cancel.



Courtesy RCA

Fig. 25. Schematic diagram of a complete portable radio using transistors in all stages.

Both transistors used as i-f amplifiers are connected in common-emitter circuits, and the collector is connected to a tap on the i-f transformer to avoid loading the transformer. The second i-f amplifier is neutralized by the signal fed through the .1-mfd capacitor C7 back to the secondary of the i-f transformer T3.

The forward bias needed across the emitter-base junction is developed by the resistors in the emitter circuit. R2 develops the voltage needed for the converter, and R6 and R9 develop the voltages for the two i-f stages.

The last i-f transformer T4 is a step-down transformer, and the secondary of this transformer is connected to a diode second detector. This diode rectifies the rf signal so that the audio signal appears in the diode output across the 1500-ohm volume control R12A.

THE AUDIO SECTION

The audio section of this receiver is made up of three stages. A PNP transistor is used in a common-emitter circuit as the first audio frequency amplifier. The circuit used in this stage is similar to the audio amplifier you already studied.

The second audio stage is called the driver stage on the schematic diagram. It is called a driver because it is a power amplifier. It is used to supply power to the push-pull output stage. The push-pull output stage in this receiver uses two transistors in a common-emitter circuit. This stage is a class B push-pull amplifier. It is somewhat different from the class A driver used in the preceding stage. In a class A stage, the average collector current does not change when a signal is applied to the input, but in a class B stage the collector current increases appreciably when the signal is applied. A class B transistor stage, like a class B tube stage, is biased to cut-off. In a transistor circuit this means that there is little or no forward bias across the emitter-base junction.

Notice the resistor R21. The symbol used to identify this resistor is that of a conventional resistor with a circle drawn around it and the letter T inside the circle. This is a thermistor. You will remember that a thermistor is a resistor with a negative temperature coefficient. In other words, if the temperature increases, its resistance decreases. Thermistors are used in this circuit to avoid instability in the output stages which temperature changes would otherwise produce.

SUMMARY

We do not expect you to remember all the circuits used in this receiver. The purpose of presenting this schematic diagram is to give you a general idea of how the various circuits you studied in this lesson may be used together in a complete portable receiver. These circuits are typical of those that you will find in portable radio receivers. In the output stages of some receivers there is only a single transistor instead of the two transistors in the push-pull circuit found in this receiver. You will also find some portables with only one i-f stage. Of course a receiver with a single i-f stage will not have the sensitivity of this receiver.

Spend some time studying this schematic diagram; it will help you become familiar with transistor circuits. This will be a big help to you in later lessons when you study these circuits in more detail.

LOOKING AHEAD

In the next group of lessons you are going to study the various types of circuits found in modern electronic equipment. Your next lesson discusses power supplies.

Power supplies are important because they are found in every piece of electronic equipment. In portable equipment the power supply is usually made up of one or more batteries. In equipment designed to operate from the power line, the power supply will often contain a transformer designed either to step-up or to step-down the power-line voltage. In addition it will contain a rectifier designed to change alternating current to direct current and then some means of smoothing out the pulsating direct current at the output of the rectifier into smooth dc. The power supply will often consist of one or more voltage-divider networks designed to provide more than one operating voltage from a single power supply.

In the lesson on power supplies and in the following lessons we will discuss the circuit in general terms first, pointing out what the circuit must do, what is needed to accomplish the desired results, what the basic circuit looks like, and some of the more important variations of the basic circuit. Then we will go into typical circuits; where possible we will give part values and other pertinent information that might help you become more familiar with these circuits. In the following lessons you will find that you will use many of the basic fundamentals studied in the first thirteen lessons. Do not fail to review these early lessons. It is a good idea to review one or two of your earlier lessons with each new lesson you study. By doing this you will pick up many of the fine points you missed the first time you went over the lesson and, in addition, you will be sure that you do not forget what you have already learned.

ANSWERS TO SELF-TEST QUESTIONS

(a) No. In the common-base circuit the collector current is always less than the emitter current because part of the emitter current leaves the transistor through the base. Although this current is quite small, it does subtract from the emitter current. Therefore the collector current will be less than the emitter current and the current gain of the stage will be less than one.

(b) They are in phase.

(c) Holes.

(d) We can obtain a voltage gain in a common-base amplifier because the output load resistor can be made quite large. Thus, even though the signal current flowing through the load resistor is smaller than the input signal current, the fact that the output load resistor can be made many times the input impedance of the transistor results in the output voltage being greater than the input signal voltage. The output voltage will be the product of the output signal current times the load resistor. The input voltage is equal to the product of the input signal current times the input resistance. As long as the output product is greater, we will have a voltage gain.

(e) A very low input impedance; high output impedance.

(f) To the grounded grid vacuum tube circuit.

(g) Yes. In the common-emitter circuit the signal voltage is applied across the input resistor. None of the emitter current that is flowing to the collector flows through this resistor. The actual signal current flowing in the input is comparatively small. At the same time, the collector current is equal to the emitter current minus any current lost in the base and therefore is much larger than the signal input current. As a result, a current gain is possible with the common-emitter circuit.

(h) The amplified signal voltage is many times the input signal voltage and is 180° out-of-phase with it in the common-emitter circuit.

(i) The input impedance of the common-emitter circuit is much higher than the input impedance of the common-base circuit.

(j) See Fig. 7A for the common-emitter circuit using an NPN circuit and Fig. 7B for a circuit using a PNP transistor.

(k) The common-emitter circuit can be compared with the tube circuit in which a tube is used in a typical grounded-cathode circuit.

(l) The output signal voltage will be in phase with the input signal voltage.

(m) The voltage gain of a common-collector circuit is less than one.

(n) The common-collector circuit has a comparatively high input impedance and a low output impedance. Its input impedance is higher than that of the other two circuits, and at the same time, it is the only circuit in which the output impedance is lower than the input impedance.

(o) The grounded plate or cathode follower circuits.

(p) The common-base circuit and the common-collector circuit.

(q) The common-emitter circuit.

(r) The common-base circuit and the common-emitter circuit.

(s) The common-emitter circuit and the common-collector circuit.

(t) The common-emitter circuit and the common-collector circuit.

(u) The common-collector circuit.

(v) Emitter current I_E; collector current I_C; and base current I_B.

(w) I_{CBO} is the symbol used to represent the collector-base reverse current with the collector-base junction reverse biased and the emitter open.

(x) The symbol V is widely used to represent voltage. The capital C and the capital E have been used to represent the collector and emitter under dc conditions. Therefore, the symbol V_{CE} means the dc collector-to-emitter voltage.

(y) The Greek letter α represents the current gain of a transistor in a common-base circuit.

(z) The maximum value that α can have will be some value slightly less than one. The current gain of the transistor in a common-base circuit will always be less than one. This is due to the fact that the emitter current will be greater than the collector current because some of the carriers leaving the emitter are lost in the base and do not reach the collector.

(aa) The forward current-transfer ratio is the gain of the transistor in a common-base circuit and hence it is equal to α.

(ab) The Greek letter β.

(ac) The alpha cut-off frequency is the frequency at which the current gain of a transistor in a common-base circuit drops to .707 of its gain at lower frequencies.

(ad) It is the frequency at which beta drops to one.

(ae) .96.

We find the value of α by using the formula

$$\alpha = \frac{\beta}{1 + \beta}$$

substituting 24 for β, we get:

$$\alpha = \frac{24}{1 + 24} = \frac{24}{25}$$

$$\begin{array}{r} .96 \\ 25\overline{)24.0} \\ \underline{225} \\ 150 \\ \underline{150} \end{array}$$

$$\alpha = .96$$

(af) Beta equals 99.

We find the value of β by using the formula

$$\beta = \frac{\alpha}{1 - \alpha}$$

substituting .99 for α, we get:

$$\beta = \frac{.99}{1 - .99} = \frac{.99}{.01}$$

$$\beta = \frac{99}{1} = 99$$

(ag) The forward bias across the emitter-base junction is equal to the battery voltage less the voltage drop across R1. There will be a substantial voltage drop across R1 because electrons leaving the base of the transistor flowing through this resistor will develop a voltage drop which subtracts from the battery voltage. Even though the current flowing through the resistor is small, the resistance of the resistor is large so that the net forward bias across the emitter-base junction is only a few tenths of a volt.

(ah) Bias stabilization is necessary because reverse collector-base current due to minority carriers crossing from the collector into the base will effectively reduce the base current. This will reduce the voltage drop across the base resistor and increase the forward bias on the transistor. The increased forward bias may cause sufficient current to flow through the transistor to destroy the transistor.

(ai) The common-base amplifier circuit provides voltage amplification without a phase shift. In some applications, particularly in television receivers, this may be an advantage.

(aj) The low input resistance of a transistor would load a resonant circuit and thus reduce the selectivity of the circuit. By using an untuned secondary and a step-down transformer, the effects of loading on the resonant circuit can be eliminated.

(ak) The collector is connected to a tap on the transformer to eliminate the effect of loading on the tuned circuit, which will cause poor selectivity.

(al) By neutralization - that is, feeding a signal equal to but 180° out-of-phase with the collector-base feedback signal back into the base circuit so that the signal deliberately fed back cancels the signal fed back through the transistor itself.

(am) The oscillator circuit uses a common-base circuit; the signal rf circuit uses a common-emitter circuit. The two circuits are used with the single transistor used in the converter stage.

Lesson Questions

Be sure to number your Answer Sheet B113.

Place your Student Number on every Answer Sheet.

Most students want to know their grade as soon as possible, so they mail their set of answers immediately. Others, knowing they will finish the next lesson within a few days, send in two sets of answers at a time. Either practice is acceptable to us. However, don't hold your answers too long; you may lose them. Don't hold answers to send in more than two sets at a time, or you may run out of lessons before new ones can reach you.

1. In a PNP transistor circuit, is the collector made (a) positive or (b) negative with respect to the base?

2. Name the three basic transistor circuits and tell what vacuum-tube circuit each one resembles.

3. Which basic transistor circuit produces a 180° phase shift?

4. Which of the following transistor amplifiers has a current gain? (a) common-base or (b) common-emitter?

5. Which basic transistor circuit has the highest input resistance?

6. (a) What does the term "alpha" applied to a transistor mean? (b) What does the term "beta" mean?

7. If the alpha of a certain transistor is .96, find the beta of the same transistor.

8. If the beta of a certain transistor is 49, find the alpha of the same transistor.

9. In the circuit shown in Fig. 16, the transistor will be very sensitive to temperature changes. How can this be overcome?

10. If a transistor has an alpha cut-off frequency of 100 kc, is it suitable for use as a 455 kc i-f amplifier?

FIRST IMPRESSIONS

First impressions mean a lot in this busy world. An applicant for a job has a pretty tough time making the grade if his appearance and first few words do not make a favorable impression on the employment manager. A salesman likewise gets the "cold shoulder" if there is anything about him which annoys the prospect.

With technical material of any kind, however, first impressions can be very treacherous. Oftentimes a simple technical book will contain a number of apparently complicated diagrams, charts, graphs, sketches or tables. Since we glance mostly at illustrations when inspecting a book, we are apt to get a misleading impression. Also, paragraphs, pages or entire lessons may seem difficult during the first reading, but become almost magically clear during the second or third reading.

If the first impressions of a required task are favorable, fine and dandy; if unfavorable, don't be discouraged, but wade right into the work and give it a chance to prove that first impressions don't always count.

POWER SUPPLIES
FOR
ELECTRONIC EQUIPMENT

B201

STUDY SCHEDULE

☐ **1. Introduction . . . . Pages 1-2**

The basic purpose of a power supply is discussed.

☐ **2. Rectifier Circuits . . . . Pages 3-12**

You learn about half-wave, full-wave, and bridge-type rectifier circuits using both vacuum-tube and selenium rectifiers.

☐ **3. Filter Circuits . . . . Pages 13-25**

In this section we take up capacitor filters, R-C filters, L-C filters, and choke input filters, and learn what factors affect the output voltage of a filter network.

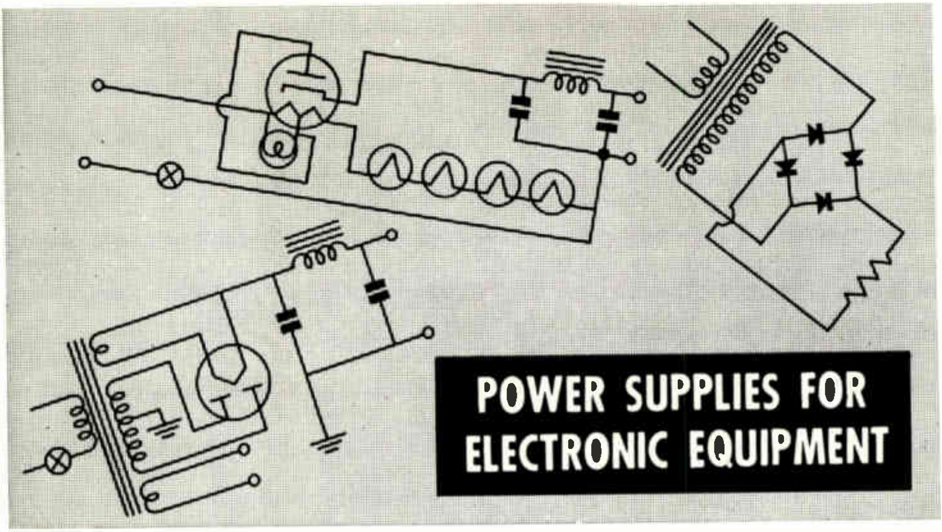
☐ **4. Typical Power Supplies . . . . Pages 26-37**

You study ac-dc supplies, full-wave power supplies, and high-voltage supplies.

☐ **5. Answer Lesson Questions.**

☐ **6. Start Studying the Next Lesson.**

JDL5M373 1973 EDITION Litho in U.S.A.



POWER SUPPLIES FOR ELECTRONIC EQUIPMENT

One of the most important sections in electronic equipment is the power supply. It is the section that furnishes the operating voltages and currents required by the various stages. If the power supply is not operating properly, the equipment can't do the job it's supposed to do.

In your career as an electronics technician, you will encounter many different types of power supplies. In equipment using tubes you will find power supplies that must supply the heater voltage for the various tubes and, in addition, a dc supply voltage that is often considerably higher than the power line voltage.

On the other hand, the power supply in transistorized equipment will be quite different from that used in tube-operated equipment. Most power supplies in transistorized equipment will have to reduce the voltage to some value less than the line voltage.

However, the current requirements of the power supply in a transistorized piece of equipment may be considerably higher than those of a power supply in a similar tube-operated device. All power supplies have basically the same function, regardless of the parts and circuitry used to make them; the power supply must supply the operating voltages and currents required by the various stages in the equipment.

You have already studied the basic components used in power supplies. In this lesson you will learn more about these components and how they are used together in this particular application. You will be introduced to some new circuits and will learn enough about power supplies to enable you to understand the purpose for which each part in a power supply is used. Once you know why the various parts are used and understand what each one is supposed to do, you should be able to service any power supply defect you encounter.

We will first take up the different rectifier circuits used in modern power supplies. The power supplied by power companies for home and industrial use is ac power, whereas the tubes and transistors used in electronic equipment require dc operating voltages. Therefore, in a power supply designed to operate from a power line, we must have some means of changing the ac to dc. The device used to do this is called a rectifier.

Once the ac is changed to dc by a rectifier, we have what is called a pulsating dc at the output of the rectifier. This is actually dc with ac superimposed on it. A power supply must therefore have some means of filtering or smoothing the pulsating dc to get pure dc. This is done by means of a filter network, which separates the ac and dc components of the pulsating dc at the rectifier output so that only the dc appears at the output of the filter network.

Many power supplies also have some type of voltage-divider network. Such a network is designed to provide several different operating voltages from one power supply. All the tubes or transistors in a piece of electronic equipment may not require the same operating voltage. It is more economical to use a single power supply and a voltage divider than to use a separate power supply for each voltage needed.

The power supplies in modern electronic equipment use solid state rectifiers in most low-voltage applications. Vacuum tubes are seldom used today as rectifiers in such devices as radio or television receivers or in other modern equipment. However, there are still millions of radios and television receivers in use today that do use vacuum-tube rectifiers. Therefore, you will probably have to work on this type of power supply as a service technician even though it is obsolete as far as its use in new equipment is concerned and you still should know how this type of rectifier works. For this reason, we will cover not only the new rectifier circuits using solid state rectifiers, but also a number of the older frequently-used rectifier circuits using vacuum tubes.

Rectifier Circuits

Any device that will pass current in one direction but not in the other direction can be used as a rectifier. You have already seen one example of this type of device: the vacuum tube. In a vacuum tube, as long as the voltage applied to the plate is positive with respect to the voltage applied to the cathode, the current will flow from the cathode to the plate of the tube. However, if the voltage applied to the plate is negative with respect to the voltage applied to the cathode, there will be no current flow through the tube because current cannot normally flow through the tube from the plate to the cathode. Thus, a two-element or diode tube was used for many years as the rectifier in the power supply of radio and television receivers.

The diode tube is entirely satisfactory as a rectifier, but it does have one big disadvantage. In order to handle the currents required in large radio receivers or in television receivers a rectifier tube with a rather heavy cathode or filament is required. Considerable power must be applied to the heater to heat the large cathode or filament, thereby bringing it to the temperature required for it to emit an abundant supply of electrons. Not only does this increase the power consumed by the equipment; also, a substantial amount of heat is given off by the diode and this, in turn, heats up other parts in the equipment. This often contributes to a shortened life of the other parts.

As we mentioned, diode vacuum tubes were used for many years as the rectifiers in radio and television receivers. However, a number of years ago the selenium rectifier began to replace the vacuum tube as the rectifier in entertainment-type equipment.

A typical selenium rectifier is shown in Fig. 1. A selenium rectifier is made up of a series of selenium discs with a coating of selenium oxide on the surface of one side of each disc. Electrons can flow from the selenium to the selenium oxide quite readily, but they cannot readily flow in the other direction, from the selenium oxide to the selenium. Thus, a selenium rectifier permits current to flow through it in one direction, but offers a high resistance to current flow through it in the opposite direction.

This type of rectifier is often called a dry-disc rectifier: "dry" to distinguish it from earlier rectifiers that used a wet chemical solution, "disc" because it is made up of discs. The square plates that are visible in Fig. 1 are cooling fins. The discs used are usually round and are

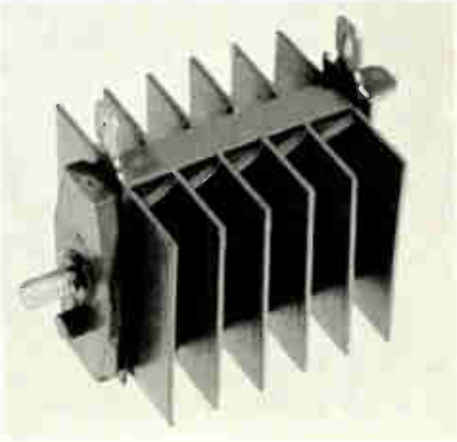


Fig. 1. A typical selenium rectifier designed for use in electronic equipment.

placed between the cooling fins, which are necessary because the rectifier does have some resistance and the current flowing through this resistance produces heat which must be dissipated.

The advantage of the selenium rectifier over the diode tube is that the selenium rectifier does not have a cathode that must be heated, and hence the power required to heat the cathode is saved. In addition, the total heat dissipated into the equipment from the selenium rectifier is somewhat lower than from a tube capable of handling the same current.

Both the vacuum tube rectifier and the selenium rectifier have been replaced in modern radio and television receivers by the silicon rectifier. The silicon rectifier, like the selenium rectifier, does not require any heater power; in addition, a silicon rectifier is much smaller than a selenium rectifier. It has a much lower forward resistance; that is, it offers far less opposition to current flow through it in the forward direction than does a selenium rectifier, and at the same time it has a higher reverse resistance (in other words it will permit a smaller current to flow through it in the reverse direction than a selenium rectifier).

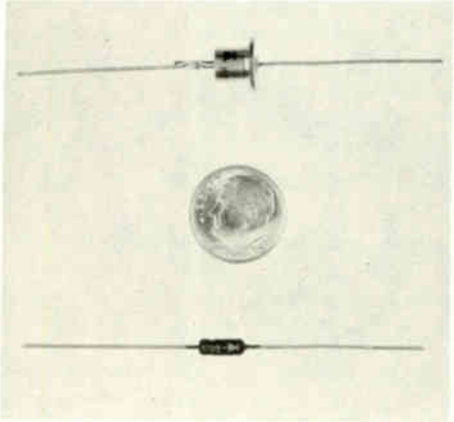

Fig. 2. Two typical silicon rectifiers with a dime between them to show their relative size.

Two typical silicon rectifiers are shown in Fig. 2. The rectifier at the top is called a top-hat rectifier because of its shape. A rectifier of this type and size is capable of handling currents several times those required in a color TV receiver. We have shown a photograph of the two rectifiers with a dime in between them so you can get an idea of the relative size of the two units. The lower rectifier is capable of handling currents of two or three amperes.

In addition to their small size and high current-handling capabilities, silicon rectifiers have another big advantage over selenium and vacuum tube rectifiers due to modern manufacturing techniques: they are relatively inexpensive to manufacture. Furthermore, unless they are overloaded, their life is almost indefinite.

Now, let's see how the various types of rectifiers are used in power supply circuits.

HALF-WAVE RECTIFIERS

You already know that the power supplied by most power companies is ac power and that the voltage supplied has a waveform that is called a sine wave. A typical single cycle is shown in Fig. 3A. A rectifier circuit using a diode tube is shown in Fig. 3B. Let's assume that the waveform shown at A represents the voltage at terminal A of Fig. 3 with respect to the voltage at terminal B. This means that for the first half-cycle (that is, the voltage waveform

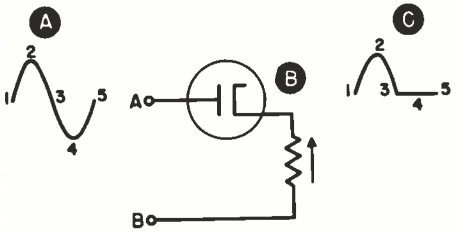

Fig. 3. How current flows in a half-wave rectifier circuit for one ac cycle. We have omitted the rectifier heater to simplify the diagram.

from point 1 to point 3), the plate of the tube will be positive. When the plate of the tube is positive, it will attract electrons from the cathode; therefore, current can flow through the tube.

Thus during the first half-cycle, as the plate voltage starts at point 1 and builds up to point 2, the current through the tube will increase from point 1 to point 2 as shown in Fig. 3C. As the voltage decreases during the first half-cycle from point 2 to point 3, the current through the tube will decrease as shown from point 2 to point 3 in Fig. 3C. When the voltage in Fig. 3A reaches point 3 there will be zero potential between points A and B in the rectifier circuit and current will stop flowing.

During the next half-cycle terminal A will be negative with respect to terminal B. This means that the plate of the tube will be negative; hence no current can flow through the tube. Therefore, the current will be zero (as shown in the waveform in Fig. 3C) as the voltage swings from point 3 to point 5.

The rectifier circuit shown in Fig. 3 conducts when the plate of the tube is positive. Since this occurs during one half the time of each cycle then the rectifier conducts during one half of the cycle but not during the other half. As a result, the rectifier is called a half-wave rectifier. If we operate this type of rectifier from a 60-cycle power line, we will get 60 current pulses through the rectifier during one half-cycle and 60 intervals during which there is no current flow through the rectifier.

Another half-wave rectifier is shown in Fig. 4. Here we have shown a solid-state rectifier in place of the tube. This could be either a selenium rectifier or a silicon rectifier -- the same symbol is used for both types.

Notice the schematic symbol used for the rectifier. Also notice that the arrows indicate that the direction of current flow through the circuit is opposite to the direction in which the arrow points in the schematic symbol. The reason for this is that in the early days of electricity, scientists thought that current flowed from positive to negative. Therefore, this symbol was designed to show the direction in which current flowed. But it was discovered later that current flow was actually electron flow and that it flowed from negative to positive, a direction opposite from that in which the early scientists thought it flowed. Although we know current flow is from negative to positive, we still use the same symbol; it has never been changed so that the arrow is actually pointing in the direction opposite to the direction of electron flow.

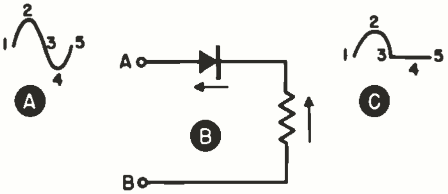

Fig. 4. A half-wave selenium rectifier circuit.

In a power supply of this type using a selenium rectifier, with terminal A positive with respect to terminal B, the selenium rectifier will offer only a low resistance to the flow of current through it; therefore, current flows in the circuit from B through the load and through the rectifier and back to terminal A. During the next half-cycle, when terminal A is negative with respect to terminal B, the selenium rectifier will offer a very high opposition to the flow of current through it so that there will be little or no current flow through the load (as shown in Fig. 4C).

We mentioned that the schematic symbol for the rectifier in Fig. 4 also represents a silicon rectifier. If a silicon rectifier is used, the rectifier will simply consist of a PN junction. The P-type material will be on the side represented by the arrow and the N-type material by the flat line. With a PN junction rectifier in the circuit when terminal A is positive and terminal B is negative, we will have a positive voltage applied to the P side of the junction and a negative voltage applied to the N side of the junction. The negative voltage will repel electrons from the N side of the junction across the junction into the P-type material. Electrons will be attracted through the P-type material by the positive potential applied to it. In other words, there will be a forward bias placed across the junction and current can readily flow through the rectifier because the carriers can cross the junction.

During the next half-cycle when the polarity reverses, terminal A will be negative and terminal B positive. Thus there will be a negative voltage, applied to the P side of the junction, which will repel electrons and prevent them from crossing the junction. At the same time there will be a positive voltage, applied on the N side of the junction, which will prevent any holes from the P side crossing the junction. In other words, there will be a reverse bias placed across the junction; hence the carriers cannot cross the junction and there will be no current flow through the circuit.

Of the three types of half-wave rectifiers, the silicon-type rectifier is the most widely used in modern equipment because of its small size, low cost and very low forward voltage drop.

Sometimes, in order to operate a piece of electronic equipment, a higher voltage is required than can be obtained directly from the power line. Under these circumstances a step-up transformer may be used to step up the voltage as shown in Fig. 5. The secondary-to-primary turns-ratio is simply adjusted to provide the required voltage step-up. A half-wave rectifier is then used as shown to rectify the ac and change it to pulsating dc. The operation of the half-wave rectifier is exactly the same in the circuit as

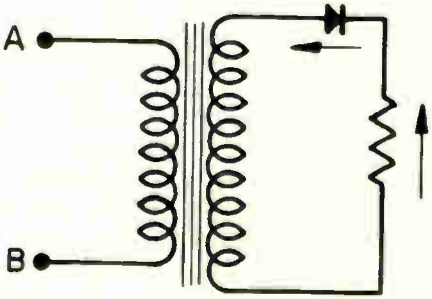

Fig. 5. A half-wave rectifier circuit using a power transformer to produce an output voltage greater than the power line voltage.

it was in the preceding circuits; however, the rectifier will have to have a higher voltage rating to make up for the fact that it is being used in a higher voltage circuit.

The disadvantage of the circuit shown in Fig. 5 is that power transformers are comparatively expensive. By means of the circuit shown in Fig. 6 a voltage approximately twice the voltage obtainable from the half-wave rectifier circuits shown in Figs. 3 and 4 can be obtained. This circuit can be operated directly from the power line and is known as a voltage-doubler circuit.

The operation of this circuit is quite simple. During one half-cycle terminal A will be negative with respect to terminal B. During this half-cycle electrons flow from A into the side of the capacitor C1 marked with the minus sign. The electrons flowing into this side of the capacitor force electrons out of the other side leaving a positive charge on this side of C1. The electrons leaving the positive side of C1 flow through the rectifier D1, back to side B of the power line which is positive and which will attract electrons. Thus, during this half-cycle, when terminal A is negative with respect to terminal B, capacitor C1 is charged with the polarity shown. The peak charge on C1 will be equal to the peak value of the ac input voltage.

During the next half-cycle, when terminal A is positive with respect to terminal B, we have a situation where the voltage between terminals A and B is effectively placed in series with the voltage charging capacitor C1. These series-connected voltages will cause a current to flow through the load and through D2. During this half-cycle terminal A is positive with respect to terminal B. This means that terminal B is negative. Electrons flow from terminal B through the load and through D2. They are attracted by a positive voltage which is equal to the voltage across C1 plus the line voltage. Thus the peak voltage that can be developed across the load will be equal to twice the peak line voltage.

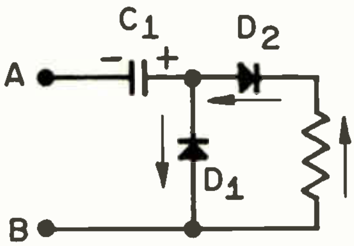

Fig. 6. A half-wave voltage-doubler circuit.

You might wonder why the current flows through only one rectifier during each half-cycle. During the first half-cycle, when terminal A is negative with respect to terminal B, the electrons flowing through D1 and charging C1 cannot flow through D2 because the diode is connected in such a way as to prevent current flow through it in that direction. Similarly, during the next half-cycle, when terminal B is negative and terminal A is positive, current cannot flow through D1 because it would have to flow through it in the reverse direction. Current can flow through the diodes only in the direction shown and it will flow through D1 during one half-cycle and through D2 during the other half-cycle.

This type of power supply is known as a half-wave doubler circuit. It is called a voltage-doubler circuit because the voltage across the load is effectively double the line voltage.

It is called a half-wave circuit because there is a current pulse to the load during only one half of each cycle. The half-wave voltage-doubler circuit is widely used in modern radio and television receivers. It's a very important circuit and you should be sure you understand how it works before leaving it.

When a half-wave rectifier is used in the power supply, the current will flow through the rectifier in a series of pulses. With a 60-cycle power supply line, there will be 60 pulses per second: one pulse during each positive-half cycle and nothing during each negative-half cycle. The net result is that you will have current flowing through the rectifier for no more than half the time. This results in a pulsating dc output from the rectifier that is rather difficult to smooth out to the pure dc required in most equipment to operate the tubes and/or transistors. A somewhat better arrangement is the full-wave rectifier that passes current during both halves of the ac voltage cycles.

FULL-WAVE RECTIFIERS

A typical full-wave rectifier circuit is shown in Fig. 7. Notice that the tube used is a twin diode tube. The tube has two plates and a single filament which is used with both plates. In operation, this tube acts as two separate diode tubes.

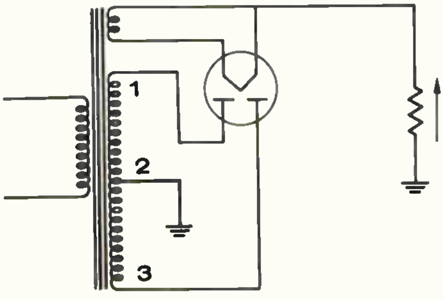

Fig. 7. A full-wave rectifier circuit using a single rectifier tube with two plates.

The power transformer used in the rectifier circuit has three windings. The primary winding is the winding that connects to the power line. A low-voltage winding is used to provide the current required to heat the filament of the rectifier tube. It serves no other purpose as far as the operation of the rectifier circuit is concerned. This winding is often referred to as the filament winding.

The high-voltage winding on the transformer is the winding that will supply the pulsating current to the load resistor. Notice that this winding has a center tap. In operation, one half of the winding first supplies the current and then, during the next half-cycle, the other half of the winding supplies current to the load.

We can see how this rectifier circuit works if we consider one half-cycle during which terminal 1 of the high-voltage secondary is positive. This means that terminal 2 will be negative with respect to terminal 1 and terminal 3 will be even more negative. Electrons will leave the center tap, terminal 2, and flow through ground to the load resistor. They will flow through the load resistor to the filament of the rectifier tube and then be attracted to the plate connected to terminal 1 because this plate has a positive voltage applied to it. No electrons will flow to the other plate because this plate is negative with respect to both terminals 1 and 2.

During the next half-cycle, the polarity of the secondary voltage will reverse. At this time terminal 3 will be positive, terminal 2 negative with respect to it, and terminal 1 even more negative. During this half-cycle electrons will leave terminal 2 and flow through ground to the load, through the load and to the filament of the rectifier tube, and then to the plate connected to terminal 3 because this plate now has the positive voltage applied to it. No electrons will flow to terminal 1 because terminal 1 is negative with respect to both terminals 2 and 3.

Notice that with the full-wave rectifier circuit we get a current pulse through the load resistor during each half-cycle. This means that for a 60-cycle power line we will get 120 pulses of current through the load. Since there is current flowing through the load during each half-cycle, this type of rectifier produces an output that is much easier to filter to a smooth dc than the output from a half-wave rectifier.

Either selenium rectifiers or silicon rectifiers can be substituted in this type of circuit in place of the rectifier tube. This type of circuit was widely used in older television receivers along with vacuum tubes. Modern TV receivers use silicon rectifiers and frequently use bridge-rectifier circuits or voltage-doubler circuits in place of this circuit.

BRIDGE-RECTIFIER CIRCUITS

One of the disadvantages of the full-wave rectifier circuit shown in Fig. 7 is that it requires a transformer with a center-tapped secondary. The total voltage across the entire secondary winding is actually twice the voltage between the center tap and either end of the secondary winding. This type of transformer is more expensive to manufacture than a transformer without a center tap because twice as many turns are required on the secondary to get the required voltage.

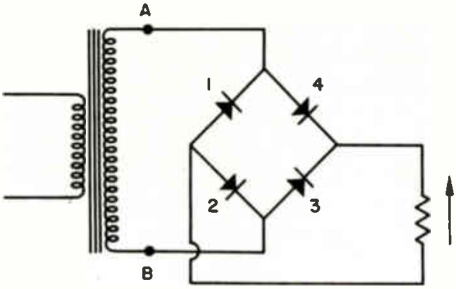

Fig. 8. A bridge-rectifier circuit.

A circuit that gets around the requirement of a center-tapped secondary is shown in Fig. 8. This is called a bridge-rectifier circuit; it is also often called a full-wave bridge-rectifier circuit because current flows to the load during each half-cycle.

A quick look at the circuit immediately shows us that four rectifiers are required in a circuit of this type. At one time this was a disadvantage because of the cost of rectifiers, but silicon rectifiers are comparatively inexpensive today and it is usually more economical to use the extra two silicon rectifiers and avoid the center tap on the secondary winding of the power transformer. The power transformer shown in Fig. 8 would be far more economical to manufacture than the one shown in Fig. 7.

The operation of the bridge rectifier is comparatively simple. When terminal A is positive and terminal B is negative, current will flow from terminal B through the rectifier marked 2 on the diagram and then through the load to the junction of rectifiers 3 and 4. It will then flow through rectifier 4 back to terminal A on the transformer. During the next half-cycle, when terminal A is negative and terminal B is positive, current will flow from terminal A on the transformer through the rectifier marked 1 on the diagram and then through the load back to the junction of rectifiers 3 and 4. This time the current will flow through rectifier 3 back to terminal B of the power transformer.

Notice that during each half-cycle current flows through two of the rectifiers. During one half-cycle it will flow through rectifiers 2 and 4 and during the other half-cycle it will flow through rectifiers 1 and 3. Also notice that current flows during both half-cycles; therefore, this bridge rectifier is a full-wave rectifier.

Bridge rectifiers have been used in television receivers where comparatively high operating voltages and high currents are required. The bridge circuit eliminates the need for the center tap on the power transformer secondary winding and thus reduces the cost of the transformer. The voltage regulation (the ratio of the full-load voltage to the no-load voltage) obtainable with this type of power supply is as good as the regulation that can be obtained from the full-wave rectifier circuit shown in Fig. 7.

FULL-WAVE VOLTAGE DOUBLERS

A full-wave voltage-doubler circuit is shown in Fig. 9. One advantage of this type of circuit is that we get the same load voltage as you have in a circuit like the bridge rectifier shown in Fig. 8, although only half as many turns are required on the secondary of the power transformer. This will result in a savings in the cost of the power transformer. Another advantage of this type of circuit is that only two rectifiers are required instead of the four required in the bridge-rectifier circuit.

The operation of the full-wave voltage-doubler circuit is quite simple. During one half-cycle terminal A of the power transformer secondary will be negative and terminal B will be positive. During this half-cycle current flows from terminal A through diode D2 to the capacitor C2 charging the capacitor as shown. Electrons flow into the negative side of the capacitor and out the positive side back to terminal B of the power transformer. During the next half-cycle, terminal B of the power transformer secondary will be negative and terminal A will be positive. During this half-cycle electrons leave terminal B of the power transformer and flow into capacitor C1. They flow into the side of the capacitor marked with the minus sign and force electrons out of the plus side. Electrons leaving the plus side flow through diode D1 back to terminal A of the power transformer, which is positive.

The capacitors C1 and C2 are connected in series and they supply the voltage to the load. The capacitors are charged by the current flowing

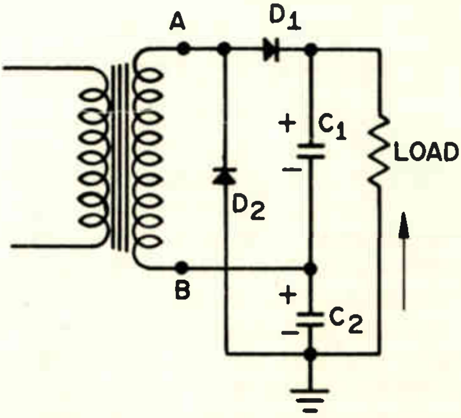

Fig. 9. A full-wave voltage doubler.

through the diodes, and since there is a charging pulse each half-cycle we will get 120 charging pulses from a 60-cycle power line. Since there is a charging pulse during each half-cycle, the circuit is a full-wave rectifier. The actual voltage that will be available across C1 and C2 in series will depend upon the power transformer secondary resistance, the resistance of the diodes when they are conducting, the size of the two capacitors, and the size of the load. As the resistance of the load increases, the current that will flow through the load decreases, and the charge on each capacitor becomes closer to the peak value of the ac voltage between terminals A and B.

Notice that in the diagram we have shown the direction of current flow through the load. The load current is supplied entirely by the charged capacitors C1 and C2. As the capacitors supply current to the load, electrons leave the negative plate of C2 and flow through the load in the direction shown. These electrons flow into the positive side of C1 forcing electrons out of the negative side into the positive side of C2. Thus the current flow through the load tends to reduce the charge across the capacitors. Of course, during each half-cycle one of the diodes conducts to build the charge across one of the capacitors up towards the peak value of the line voltage.

While this type of rectifier circuit offers some advantages over the circuits shown in Figs. 7 and 8, it does not have as good voltage regulation as they have. However, by using capacitors of large capacity for C1 and C2, and with modern silicon rectifiers that have a very low resistance when they are conducting, reasonably good voltage regulation can be obtained from this type of power supply. You will find the power supply widely used both in monochrome and color television receivers. Be sure you understand how it operates because you will run into it frequently.

In comparing this power supply with the half-wave doubler circuit shown in Fig. 6, we immediately see that the full-wave doubler circuit is best suited to equipment where a power transformer is used. The half-wave voltage-doubler circuit is widely used in equipment where no power transformer is used.

SUMMARY

The rectifier circuits that we have discussed in this section of the lesson are extremely important. As you know, the power supplied by the power companies is alternating current and the tubes and transistors in electronic equipment require direct current for their operation. Therefore, equipment designed to operate from the power line must use some type of rectifier to convert the alternating current to direct current. One of the circuits shown in this section of the lesson is likely to be found in any type of electronic equipment you will service.

The half-wave rectifier circuit shown in Fig. 5 is perhaps the most widely used. All table model radio receivers use this type of rectifier circuit without a power transformer so that the receiver can operate directly from the power line. The half-wave voltage-doubler circuit shown in Fig. 6 is widely used in television receivers where operating voltages higher than those that can be obtained directly from the power line are needed. In some of the older radio receivers and many older television receivers a full-wave rectifier circuit such as shown in Fig. 7 will be found. This type of circuit was used almost exclusively in television receivers before the development of low-cost selenium and silicon rectifiers.

The bridge-rectifier circuit shown in Fig. 8 is used in many television receivers, particularly large television receivers where fairly high voltages and high currents are required. This type of circuit is also used in some transistorized equipment where lower than line voltages are required. In this instance, instead of being a step-up transformer, the transformer will be a step-down transformer that steps the line voltage down to a low value. The bridge-rectifier circuit is then used so that good voltage regulation can be obtained and so that at the same time a comparatively large current can be taken from the power supply.

The full-wave voltage-doubler circuit has been used in many television receivers -- in those which use power transformers where voltages higher than the line voltage are required -- yet at the same time, the transformer serves primarily as an isolation transformer. In other words, the secondary voltage is approximately equal to the primary voltage. The higher voltage required is obtained by the voltage-doubling action. The output from the full-wave doubler circuit is somewhat easier to filter or smooth out than the output from the half-wave doubler circuit, because with the former we have 120 pulses per second through the load and with the latter we have only 60 pulses per second.

Before leaving this section regarding rectifier circuits, why not try to draw the circuits yourself? It would be worthwhile, and you don't have to draw them from memory -- copying them first from the book will help you to remember what they look like. Eventually, you'll be able to draw them from memory and recognize various circuits on the schematic diagram of any radio or TV receiver or piece of electronic equipment you may encounter.

After reviewing this section, do the following self-test questions.

SELF-TEST QUESTIONS

(a) In a half-wave rectifier circuit such as the circuit in Fig. 5, how many current pulses per second will there be through the load when the power line frequency is 60 pulses per second?

(b) What is the disadvantage of a half-wave rectifier circuit?

(c) What is the purpose of the diode marked D1 in the half-wave voltage-doubler circuit shown in Fig. 6?

(d) Why is the circuit shown in Fig. 7 called a full-wave rectifier circuit?

(e) What is the disadvantage of the full-wave rectifier circuit shown in Fig. 7?

(f) What are the advantages of the bridge-rectifier circuit shown in Fig. 8?

(g) What advantage does the voltage-doubler circuit shown in Fig. 9 have over the voltage-doubler circuit shown in Fig. 6?

(h) What are the advantages and disadvantages of the full-wave voltage doubler over the bridge-rectifier circuit?

Filter Circuits

The output from the rectifiers we discussed in the preceding section is not pure dc. Instead, it is pulsating dc: "direct" because it flows in only one direction, "pulsating" because it is varying in amplitude rather than flowing steadily. A pulsating dc voltage is a voltage that does not change polarity, but does change in amplitude. The voltage at the output of a half-wave rectifier will be zero during one half of each cycle and swing in a positive direction during the other half of each cycle.

Looking at the half-wave circuits shown in Fig. 3 and 4, you can consider the rectifier more or less as a switch. During one half-cycle the switch is closed so that the load is connected directly across the power line, and during the other half-cycle the switch is open so that no voltage is applied to the load. The voltage across the load in a half-wave rectifier circuit looks like Fig. 10A. The first half-cycle represents the cycle when the switch is closed and the load is connected directly across the power line, and the second half-cycle represents the cycle when the switch is open and there is no voltage applied across the load. We have shown what the voltage across the load will look like for four cycles in Fig. 10A.

In a full-wave rectifier circuit such as shown in Fig. 7, you have two switches. During one half-cycle one switch closes and connects the load across one half of the power transformer secondary; then, during the next half-cycle, the other switch closes and connects the load across the other half of the transformer secondary.

In the bridge rectifier shown in Fig. 8 two rectifiers act as switches and close to connect the load across the transformer secondary during one half-cycle; then during the next half-cycle the other two switches close, giving the effect of turning the load around so that the current flows through it in the same direction and the voltage applied across the load has the same polarity. The output from a full-wave rectifier circuit will produce a voltage across the load that looks like Fig. 10B.

As you can see from the waveforms shown in Fig. 10, the output taken directly from the rectifier is not a pure dc. There is a voltage, but the voltage drops to zero, builds up to the maximum value, and drops to zero again. In the half-wave circuit it remains at zero for a half-cycle and then builds up again in a positive direction. In the full-wave rectifier circuit the voltage builds up across the load during each half-cycle. In either case, this pulsating voltage will cause a pulsating current through the load which is entirely unsuitable for use in electronic equipment. Fortunately, there are convenient methods that can be used to filter or smooth this voltage to a pure dc voltage.

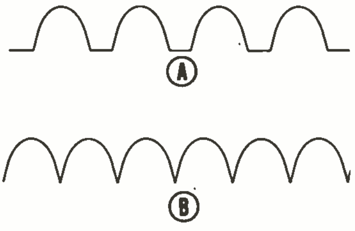

Fig. 10. Output voltage from half-wave and full-wave rectifier.

The pulsating dc voltage at the output of the rectifier is actually a dc voltage with an ac voltage, called a ripple voltage or a hum voltage, superimposed on it. The circuits used to get rid of this ripple or hum voltage are called filter circuits. There are a number of different types of filter circuits found in electronic equipment; in this section we will cover some of the circuits more commonly used.

THE SIMPLE CAPACITOR CIRCUIT

One of the simplest filters is the single capacitor filter shown in Fig. 11. In Fig. 11A we have shown a rectifier circuit using a tube and in Fig. 11B a rectifier circuit using a silicon rectifier. Notice that the circuits are practically identical -- we simply changed the rectifying devices in the two circuits.

The simple capacitor-type filter is sometimes used in circuits where the current drained or taken from the power supply is low. If the rectifier must supply high current to the circuit, this type of filter is generally unsatisfactory because there will be too much ripple or hum present across the load. In other words, the simple filter is simply not capable of eliminating all the ac or ripple voltage present at the output of the rectifier.

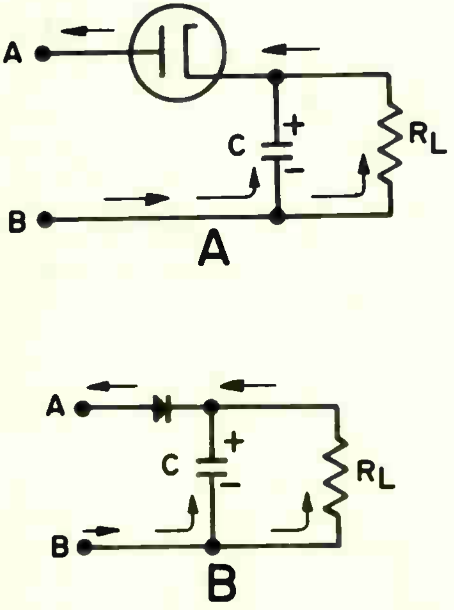

Fig. 11. A simple capacitor-type filter.

Both circuits shown in Fig. 11 work in the same way. Current flows through the rectifier during one half-cycle, as in the half-wave rectifier circuits we studied previously. When terminal A is positive, electrons will flow from terminal B through the load and through the rectifier back to terminal A. At the same time, electrons will flow into the negative side of the capacitor and out the positive side and through the tube or silicon rectifier back to terminal A. The capacitor eventually will be charged to a value almost equal to the peak line voltage. This will happen when the ac line voltage reaches its peak value with terminal A at its peak positive voltage with respect to terminal B.

Now, if the load on the rectifier circuit is light (that is, if the load resistor is a high resistance that draws very little current), as the ac input voltage between terminal A and B drops, capacitor C will begin to supply the current required by the load. Electrons will start to leave the negative side of the capacitor and flow through the load resistor back to the positive side of the capacitor. They will continue doing this as the ac voltage drops to zero and remains at zero during the next half-cycle and starts to build up again in the positive direction. The capacitor will continue to supply current to the load as long as the voltage across the capacitor is greater than the ac input voltage. Eventually, the input voltage will reach a value greater than the capacitor voltage; then we'll get a current flow into the capacitor and through the rectifier to recharge the capacitor.

In Fig. 12 we have shown the ac input voltage. Notice that during the first half-cycle between points 1 and 2 in Fig. 12A the ac voltage is increasing in a positive direction. Let's assume that terminal A in Fig. 11 is becoming positive with respect to terminal B. This explanation applies to both of the two circuits shown. During this first half-cycle the capacitor is charging and follows a curve as shown from point 1 to point 2 in Fig. 12B. Now, as the ac cycle drops from point 2 to point 3 on curve A in Fig. 12, the voltage drops faster than the capacitor discharges. During the interval from point 2 to point 5 and almost to point 6, as shown in Fig. 12A, the capacitor discharges very little. The discharge is shown on the curve from point 2 over to the number 5 on curve B. At this point the ac input voltage exceeds the capacitor voltage, so the capacitor is recharged again.

In circuits where the drain or load current is low, the capacitor will discharge very little between current pulses that recharge it so that the voltage across the capacitor and hence the voltage across the load remain almost constant. Of course, as the requirements of the load increase, the capacitor will discharge more so that there will be more of a voltage drop across the capacitor and across the load than in circuits where current drain is low.

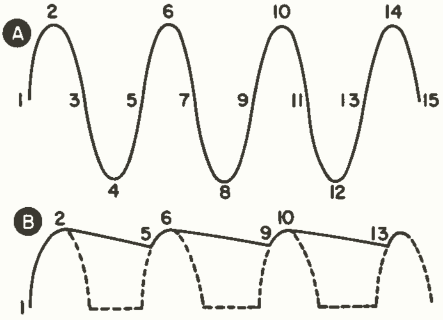

Fig. 12. Voltage waveshapes for a simple capacitor filter. (A) Input voltage; (B) output voltage.

There are several important points you should notice in the circuits shown in Fig. 11. Notice that the current does not flow during an entire half-cycle, but flows only when the line voltage exceeds the voltage across the capacitor. This may be for a very short interval if a load is a high resistance and draws very little current, or it may be for a sizable portion of a half-cycle if the load is a low resistance and draws a high current from the power supply. However, since the current flows through the rectifier in pulses, then the current pulse through the rectifier must be many times the average dc current flowing through the load. This is because the pulse or current that flows through the rectifier during the interval in which the rectifier is conducting must supply enough current to the capacitor to charge the capacitor and make up for the current it is going to supply for the remainder of the cycle.

When the rectifier is not conducting it is because the voltage across it is what we call a reverse voltage. In other words, it has a polarity opposite from that which the rectifier needs to conduct. In the case of the vacuum tube circuit this means that the plate of the tube is negative with respect to the cathode; in the case of the silicon rectifier, that there is a reverse bias across the junction.

One of the important characteristics of a rectifier is the maximum peak reverse voltage that can be placed across the rectifier before it breaks down. In the circuit shown in Fig. 11 the capacitor will be charged as shown and the charge can equal the peak line voltage. During the next half-cycle, when the polarity of the input voltage reverses, terminal A will be negative and terminal B will be positive. When this voltage reaches its peak, the peak reverse voltage across the rectifier will be equal to twice the peak line voltage. The rectifier must be able to withstand this voltage without breaking down. This important characteristic, by which rectifiers are rated, is usually referred to as "PRV" (peak reverse voltage), although it may also be called "PIV" (peak inverse voltage). The two are simply the maximum reverse or inverse voltages that can be applied across the rectifier without its breaking down. In circuits such as those shown in Fig. 11, the PIV should be considerably higher than twice the peak line voltage in order to allow a reasonable safety factor.

As we mentioned previously, the simple capacitor-type filter shown in Fig. 11 is usable only where a small current is required by the load. If the current required is small, the output capacitor can be made large enough so that it discharges very little between pulses. If the current required by the load is high, on the other hand, then the capacitor will discharge appreciably between charging pulses, resulting in a varying voltage applied to the load. This is essentially the same as applying dc mixed with ac to the load. Additional filtering is required in applications of this type in order to eliminate ac so that we will have pure dc across the load.

AN R-C FILTER

An improved filter, which is often called a pi filter because it looks like the Greek letter pi (π), is shown in Fig. 13. You will notice that this filter consists of two capacitors, C1 and C2, and a filter resistor, R1.

The operation of the half-wave rectifier and capacitor C1, which is called the input filter capacitor, is the same as in the simple capacitor filter shown in Fig. 11. The rectifier tube passes current pulses to charge capacitor C1 with the polarity indicated on the diagram. However, if the

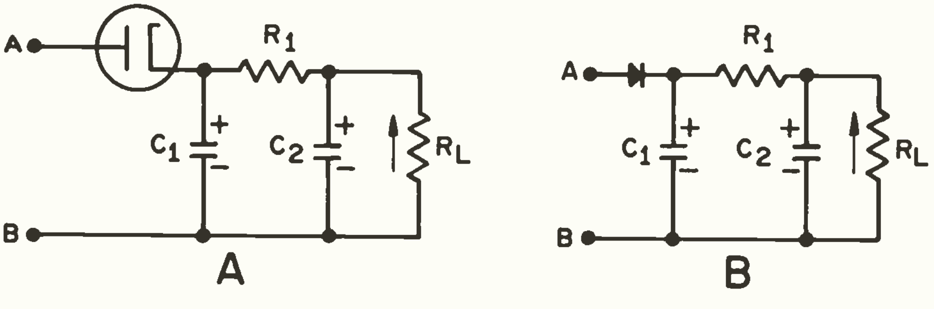

Fig. 13. An R-C pi-type filter.

load resistance R_L is low enough to draw appreciable current from the supply, then the voltage across C1 will discharge appreciably during the portion of the cycle when the rectifier tube is not conducting. Thus, we have dc with an ac superimposed on it across C1.

Now, to see the action of R1 and C2, let us first consider how the capacitor C2 reacts to ac and to dc. Remember that a capacitor is a device that will not pass dc -- it can be charged so that a dc voltage will exist across it, but applying dc to the plates of the capacitor will not cause a current to flow through it. Although electrons cannot cross through the dielectric of a capacitor, however, applying ac to the dielectric of a capacitor yields the effect of a current flowing through it. This is due to the fact that electrons will flow first into one plate and then into the other as the polarity of the ac voltage reverses.

You will remember from your study of capacitors that a capacitor offers what is called capacitive reactance (or opposition) to the flow of ac through it. The exact reactance that any capacitor will offer to the flow of ac through it is given by the formula:

$$Xc = \frac{1}{6.28 \times f \times C}$$

You can see from this formula that the larger the value of the capacitor, the lower the capacitive reactance will be to an ac voltage of a particular frequency. In Fig. 14A we have shown how the filter consisting of R1 and C2 reacts to dc; in Fig. 14B, we have shown how it reacts to ac.

As you know, a "perfect" capacitor will not pass dc -- although no capacitor is really perfect because there will always be a small dc current (called a leakage current). In other words, the capacitor offers a very high resistance to dc, so we have shown it as resistor R_{c2}. Most of the dc voltage applied to the input of this filter network will appear across the capacitor, and there will be very little dc dropped across the resistor R1. The exact drop across this resistor will depend upon the size of the resistor and the current drawn by the load.

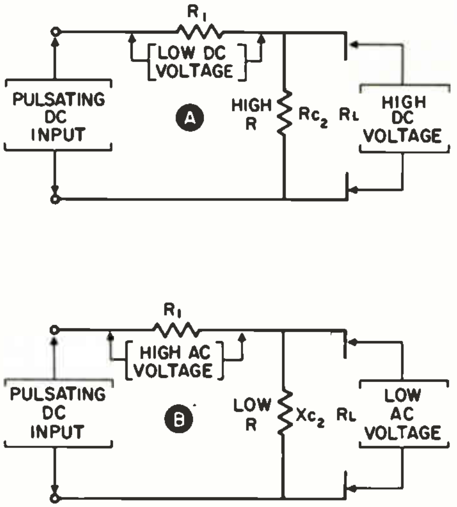

Fig. 14. Equivalent circuits showing the reaction of an R-C filter to dc at A, and to ac at B.

Now look at Fig. 14B which shows the reaction of the circuit to an ac voltage. The capacitor has a very low reactance to ac, so most of the ac voltage will be dropped across R1, because the resistance of R1 is much higher than the reactance (X) of C2. R1 and C2 act as a voltage divider network with most of the ac being dropped across R1 because its resistance is much higher than the reactance of C2.

There is another way of looking at this type of power supply which may help you see exactly what is happening in the circuit. Refer back to Fig. 13; the explanation applies to the circuit using the vacuum tube rectifier shown at A and to the one using the silicon rectifier shown at B.

When terminal A is positive with respect to terminal B, the diode will conduct and current can flow through the diode and through the load. During this part of the cycle electrons will flow into the plates of C1 and C2 marked with a minus sign. At the same time electrons will flow out of the other plate of both capacitors. Electrons leaving the positive side of C1 will flow directly through the diode being attracted by the positive voltage at terminal A. Because the resistance of the rectifier is low, C1 can charge up to a value almost equal to the peak ac voltage. However, the electrons leaving the positive side of C2 must flow through the filter resistor R1. Thus, capacitor C2 cannot charge to as high a voltage as capacitor C1.

When the ac input voltage drops so that the diode no longer conducts, capacitors C2 and C1 begin supplying the power required by the load. However, capacitor C1 is charged to a higher voltage than capacitor C2. Hence, capacitor C1 begins supplying power to the load and also tries to charge capacitor C2. Since electrons flowing from the negative side of C1 to the positive side must flow through filter resistor R1, the attempt of these electrons to charge C2 and flow through the load resistor will be somewhat restricted by R1. The net effect is that the resistor R1 prevents C2 from charging to as high a peak voltage as it would if R1 were not on the circuit. Because C1 charges to a higher voltage than C2, and while discharging tends to charge C2, the voltage across C2 is more nearly constant than the voltage across C1.

AN L-C FILTER

The disadvantage of the resistor-capacitor type of filter shown in Fig. 13 soon becomes apparent if you consider the size of the resistor and capacitor needed to obtain effective filtering and also the effect that the high value of resistance in the circuit has on the dc voltage present.

Consider Fig. 13 again for a minute. Suppose that the ac component of the pulsating dc across C1 is 10 volts and that the maximum ac component that can be applied to the load is only 1 volt. This means that the filter network consisting of R1 and C2 must produce a 9-to-1 voltage division. In other words, of the 10 volts ac appearing across C1 we must drop 9 volts across R1 and 1 volt across C2. This means that the resistance of R1 must be about 9 or 10 times the reactance of C2.

A 25-mfd capacitor (which is fairly large, particularly if it must be built to withstand high voltages), has a reactance of about 100 ohms at a frequency of 60 cycles. If we used such a capacitor for C2, then the resistance of R1 would have to be 10 times its reactance, or about 1000 ohms. If the current drawn by the load is 100 milliamperes, then the voltage drop across R1 due to the load current flowing through it will be 1000 ohms times .1 amp (100 ma), or 100 volts. This means that we will be losing 100 volts of our dc voltage across R1. Furthermore, the power being wasted by this resistor will be

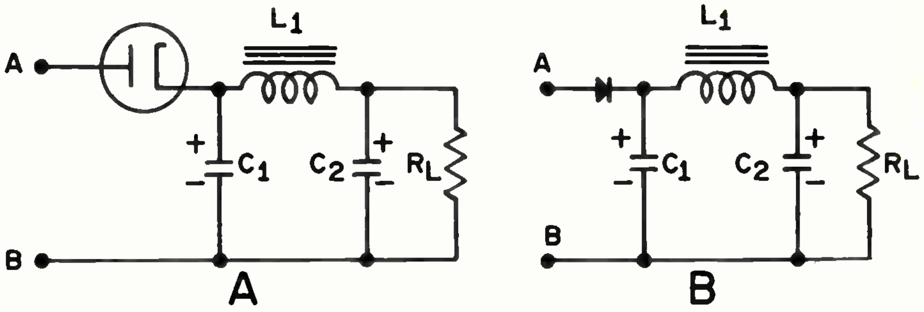

Fig. 15. An L-C filter.

equal to the voltage across it times the current flowing through it, which is 100 × .1, or 10 watts. You can see that we have an appreciable voltage drop and a sizable amount of power wasted by this resistor.

In some cases the current drawn through the filter resistor is not so high that the voltage drop across the resistor cannot be tolerated. Thus you will see this type of filter used in equipment when the current taken from the power supply is moderate. In equipment when the current drawn is high, a different type of filter is used. Such a filter is shown in Fig. 15. Notice that this circuit is identical to Fig. 13, except that we have substituted an iron-core choke for R1. The action of this filter network is quite similar to that of the filter network shown in Fig. 13. Again, capacitor C1 is charged by the rectifier and because there is no resistance in the circuit other than the rectifier resistance, it charges to a fairly high value. Just as before, however, the voltage across it will be pulsating (the equivalent of dc with ac superimposed on it).

Now consider the reaction of the choke to ac and dc. You will remember that a choke has inductance, and an inductance offers reactance to the flow of ac through it. At the same time the only opposition that the choke will offer to the flow of dc through it is due to the resistance of the wire used to wind the coil. By using a large size wire, this resistance can be kept quite low. The choke may have a dc resistance of 100 ohms or less and at the same time have a reactance of several thousand ohms to the 60-cycle ac applied to it.

The reaction of the L-C filter to dc is shown in Fig. 16A, and the reaction to ac is shown in Fig. 16B. In 16A we see that as far as the dc is concerned, the choke acts as a

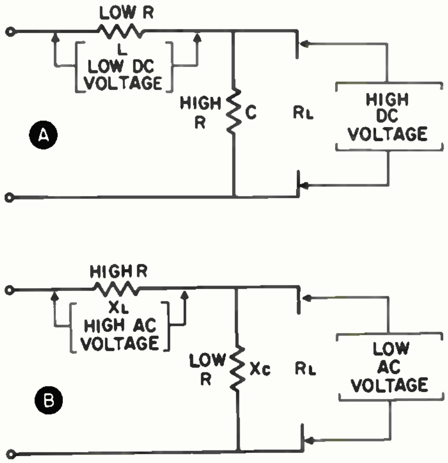

Fig. 16. Equivalent circuit showing the reaction of an L-C filter to dc at A, and to ac at B.

low resistance while the capacitor acts as a very high resistance. Thus, we have practically all of our dc voltage appearing across the capacitor and very little of it being lost across the choke. However, as shown in 16B, the choke acts as a high resistance to the ac while the capacitor acts as a low resistance. Thus, most of the ac voltage will appear across the choke and very little of it will appear across the capacitor.

There is another way of looking at the action of the L-C filter. We can consider the charging of the capacitors and the opposition offered by the choke more or less in the same way as we considered the action of the R-C filter in Fig. 13. During the first half-cycle, when terminal A of either rectifier circuit is positive and terminal B is negative, the rectifier will conduct. Electrons will flow from terminal B into the sides of C1 and C2 marked with a minus sign. These electrons will force electrons out of the positive side of C1 and they will flow through the rectifier with little or no opposition. However, the electrons leaving the positive side of C2 will encounter opposition in the choke. This is because at the instant when the electrons first try to get through the choke there is no magnetic field built up in the choke. You will remember that a choke is a device that opposes any change in current flowing through it. Therefore, the choke tries to keep the electrons leaving the positive side of C2 from flowing through it. Eventually this opposition offered by the choke is overcome, a magnetic field is built up in the choke, and some of the electrons can flow through the choke and capacitor C2 will be charged. However, the voltage to which C2 is charged will not be as high as the voltage to which C1 is charged because of the opposition of the choke.

When the ac input voltage drops below the voltage to which C1 is charged, the rectifier will no longer conduct and no current can flow through it. Now C1 and C2 and choke L1 must supply the current needed by the load. C2 does this by attempting to discharge. C1 also tries to discharge to charge C2 and to supply part of the current required by the load. At the same time there is a magnetic field built up in the choke L1 which does not collapse instantly but instead tries to keep current flowing in the direction it was flowing when the rectifier was conducting. It too helps to maintain the current flow through the load RL. Thus in this type of filter we have energy stored in three places: the capacitors C1 and C2 (as we did in the circuit in Fig. 13), and in the magnetic field of choke L1.

In the circuits shown in Fig. 15, the rectifier tube in Fig. 15A offers a certain amount of resistance to the flow of current through it. In addition, the rectifier tube has a cathode which must be heated by a heater. It takes some time for the cathode to come up to operating temperature; when a tube first starts conducting, the cathode is below normal operating temperature, and the tube offers a higher resistance to the flow of current through it than it does when the tube reaches its full operating temperature. Thus when the power supply is first turned on and the tube reaches a temperature at which the cathode begins to emit electrons, the tube offers considerable resistance to the flow of current through it. This limits the charging current through the tube that charges the input filter capacitor C1. In a matter of a few seconds capacitor C1 is charged and from then on the current that must flow through the tube is within the tube's capabilities.

In the circuit shown in Fig. 15B, however, the silicon rectifier does not have a cathode which must be heated -- as soon as the power is turned on the rectifier begins to conduct to charge the input capacitor C1. If you turn the equipment on at the peak of the ac cycle there will be a very high voltage immediately impressed across C1 and a very high current will flow through the rectifier. As a matter of fact, the current might be so high that it could burn out the rectifier. Even if the power is turned on when the ac voltage is at zero, a high current will flow through the diode to charge C1 as the voltage rises to a peak value with terminal A positive with respect to terminal B. If C1 is large enough, this could burn out the rectifier.

This problem of excessively high charging current can be overcome with the circuit shown in Fig. 17. Here a resistor is connected in series with the silicon rectifier to limit the current flow. In some equipment, this resistor is a fairly low resistance, fixed-value resistor. In other applications, the resistor may be a thermistor. You will remember that a thermistor is a resistor with a negative temperature coefficient. This means that the resistance of the thermistor decreases as its temperature increases.

With a thermistor for the resistor R1 shown in the circuit in Fig. 17, the thermistor will offer a fairly high resistance to current flow when the equipment is first turned on. This will limit the charging current that flows through the diode to charge C1 to a reasonable value. As the current flowing to the thermistor heats the thermistor and its resistance goes down, the charge across capacitor C1 will build up slowly so that the diode current never reaches an excessively high value. By the time the capacitor is fully charged, the thermistor temperature will have increased to a point where the resistance of the thermistor has dropped to a low value so that the thermistor has very little effect on the overall operation of the circuit.

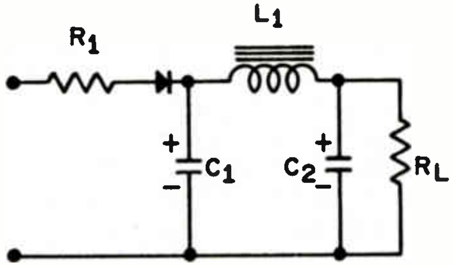

Fig. 17. Power supply with series-limiting resistor.

If you have to service a power supply of this type (where a resistor or a thermistor is used in the circuit in series with a silicon rectifier) and you find that the resistor or thermistor is opened, do not simply short the resistor or thermistor out of the circuit. If you do the chances are that the diode will burn out either the first time that you turn the equipment on or shortly thereafter.

The rectifier tubes used in low power equipment such as radio and television receivers are high vacuum rectifier tubes. However, in transmitters and in industrial applications where high voltages are involved you will often run into mercury-vapor rectifier tubes. Tubes of this type cannot be subjected to high peak currents through them without damaging the tube. A mercury-vapor rectifier tube in the circuit such as shown in Fig. 15A lasts only a short time. We can keep the peak current through the tube down to a safe value by using a somewhat different filter circuit known as a choke-input filter.

CHOKE-INPUT FILTERS

The filter circuits shown in Figs. 15 and 17 are called capacitor-input filters because the rectifier is connected directly to the input filter capacitor. A choke-input filter such as those frequently used with a mercury-vapor rectifier tube is shown in Fig. 18. Here, the rectifier tube is connected to a filter choke rather than a capacitor. Power supplies of this type will be found in radio and television transmitters and in industrial applications where comparatively high voltages are encountered.

It is easy to see how this type of filter works when we remember that the pulsating dc at the output of the rectifier tube is actually dc with ac superimposed on it. The choke offers little or no opposition to the flow of dc through it. On the other hand, the choke offers a high reactance to the flow of ac through it and at the same time the capacitor offers a low reactance to the ac across it. Thus the choke and the capacitor form a voltage divider network for the ac, so that most of the ac is dropped across the filter choke and very little of it appears across the load.

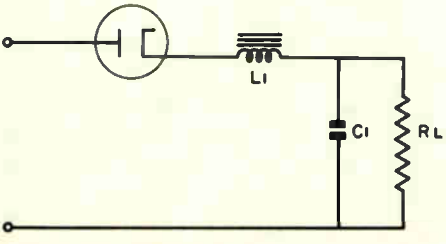

Fig. 18. A choke-input filter.

A more elaborate filter network is the two-section filter shown in Fig. 19. Again, it is a choke-input filter because the first element in the filter network is a choke. This type of filter network is frequently used in power supplies of radio and TV transmitters and of industrial electronic equipment where mercury-vapor rectifier tubes are used.

The choke-input filter has several advantages over the capacitor-input filter, even though the voltage obtained at the output of a choke-input filter is not quite as high as it is at the output of equivalent capacitor-input filters. In other words, if you feed the same pulsating dc into a choke-input filter you will not obtain as high an output voltage for a given load as you can with a capacitor-input filter. However, this type of filter has better voltage regulation than a capacitor-input filter. The voltage regulation of a power supply is the ratio of the full-load voltage to the no-load voltage. With a choke-input filter there is not as great a variation between the no-load and the full-load voltages as there is in the capacitor-input filter.

Another big advantage of the choke-input filter is that the peak current passed by the rectifier tube is held to a reasonable value. In a choke-input filter, the choke offers considerable reactance to any change in current flow through it. Thus, when the rectifier tube tries to conduct current heavily to charge C1 in Fig. 19, the input-filter choke L1 offers considerable reactance or opposition to the change in current flow through it. It tends to smooth

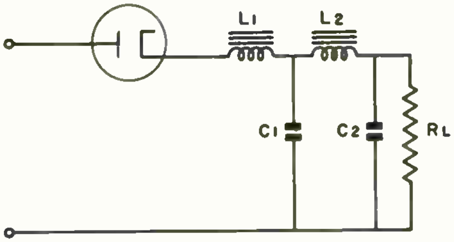

Fig. 19. A two-section choke-input filter.

out the pulses of current through the rectifier tube. The current pulse flowing through the rectifier tube flows for a slightly longer time than it would flow with an equivalent capacitor-input type of filter, and the peak amplitude of the current flowing through the rectifier tube is not as high as it would be with the capacitor input filter. This is a big advantage in a power supply using mercury-vapor rectifier tubes, because they can easily be destroyed by excessively high current pulses through them.

The filter network shown in Fig. 19 is quite effective in eliminating hum. Consider what would happen if the output of the rectifier had an ac voltage of 100 volts superimposed on the dc. If the two sections of the filter network are designed so that each choke has a reactance about 10 times as high as the reactance of the capacitors, each section will have approximately a 10-to-1 ripple voltage division; thus if there are 100 volts ac at the output of the rectifier, L1 and C1 will divide this voltage so that there will be only 10 volts appearing across C1. Now L2 and C2 act as a voltage divider network and divide this 10 volts further, so that the voltage across C2 would be only 1 volt. Thus, the two-section filter has reduced the ac hum or ripple voltage at the rectifier output from 100 volts to 1 volt.

The input filter choke, which is L1 in Fig. 19, is often a swinging choke. A swinging choke is designed so that it saturates rather easily and thus its inductance will vary appreciably as the current through the choke changes. When the current through the choke becomes high, the inductance and hence the inductive reactance of the choke decrease, but when the current through the choke is low, the inductance and hence the inductive reactance increase. Thus we have in effect a variable reactance between the rectifier tube and the input-filter capacitor; this variable reactance helps to improve voltage regulation at the power supply output. This type of choke is particularly useful in circuits where the load current goes through wide variations. If the load current goes down, the reactance of the choke increases. The increased reactance limits the charging action of the rectifier tube and keeps the output voltage from rising appreciably. On the other hand, if the load current increases, the reactance of the choke decreases, allowing the rectifier to charge C1 to a higher value so the capacitor can supply the increased current demand.

FACTORS AFFECTING THE OUTPUT VOLTAGE

In any filter network containing a filter choke or a filter resistor, the dc current flowing through the load must also flow through the filter choke or filter resistor. Thus, there will be a voltage drop across this choke or resistor; the exact value of the voltage drop will depend upon the dc resistance and the current flowing. We already pointed out that if a 1000-ohm filter resistor is used in the circuit and the current that is flowing is 100 milliamperes, the voltage drop across the filter resistor will be 100 volts. On the other hand, if a filter choke having a dc resistance of 100 ohms is used, a current of 100 milliamperes will produce a voltage drop of only 10 volts across it.

If the current drawn by the load changes, the output voltage at the output of the filter network will change. You can see why this is so-- the current must flow through the filter resistor or filter choke. If the current flowing through the choke or resistor changes, the voltage drop across it will change, and hence the voltage at the output of the power supply will have some tendency to change.

The output voltage is also affected by the size of the filter capacitors used. If the filter capacitors used are small, then the rectifier is unable to keep them completely charged; if the filter capacitors are large, once the rectifier gets them charged, they will stay charged to a voltage near the peak ac voltage being applied to the rectifier tube.

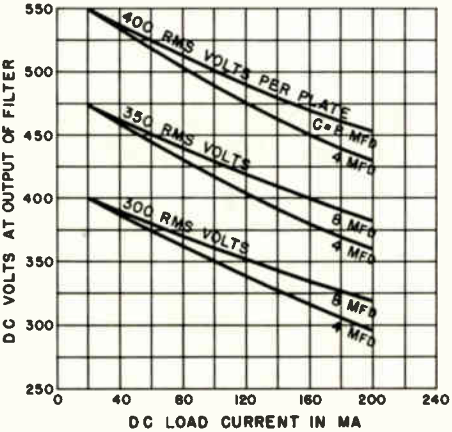

Fig. 20. How the size of the input capacitor of a filter affects the output voltage for different values of load current.

Of course, it is difficult to say whether a filter capacitor is large or small. Whether or not it is large for the particular circuit depends upon how much current is being drawn from the circuit. If the current drain is low, then a capacitor of 10 or 20-mfd will usually be sufficient to keep the power supply output voltage at or near the peak value of the ac voltage applied to the rectifier tube. However, if the current drain from the power supply is large, then the voltage across the power supply output will be considerably less than the peak ac value if the capacitors used are 10-mfd or 20-mfd capacitors.

To give you some idea of how the size of the input filter capacitor affects the output voltage, we have shown a graph in Fig. 20. The graph is for a full-wave rectifier. It shows how the output voltage varies with different load currents for both 4-mfd and 8-mfd capacitors. We have shown this for three separate input voltages. Notice that in each case when the current drain is low, the output voltage is substantially above the rms input voltage applied to the rectifier. Remember, of course, that the peak value of a 300-volt rms voltage is actually 1.4 times 300 volts.

Fig. 21 shows a comparison between a choke-input and capacitor-input type of filter. Notice that with a capacitor input the output voltage at low loads is substantially higher than it is for a choke input. However, as the load is increased, the output voltage from a capacitor-input type of filter drops rapidly. The output voltage from the choke-input type filter also drops as the load is increased, but it does not drop nearly as rapidly as it does with a capacitor-input type of filter.

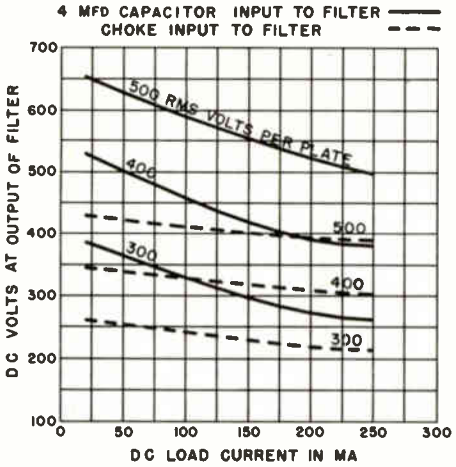

Fig. 21. How the output voltage of a filter network varies for different values of load currents and input voltages. The solid curves are for a capacitor-input filter; the dashed curves for a choke-input filter.

SUMMARY

In this section we have covered some of the more important types of filter networks you are likely to encounter in your career as an electronics technician. You have seen that these networks vary from comparatively simple filters consisting only of a capacitor up to networks containing two chokes and two filter capacitors.

Simpler types of filter networks can be used where the current drain is low and where the filtering does not have to be very good. The more elaborate filters are used in power supplies having a high current drain and in cases where good filtering is required to supply pure dc at the power supply output.

The circuits in this section of the lesson are shown with a half-wave rectifier. The same filter circuits are also used with full-wave rectifiers.

Study the circuits shown in this section. You should be familiar with each of these circuits. You might try drawing these circuits several times to get familiar with the circuit arrangement. Copy them from the book the first few times you try drawing them and then try to reproduce the circuit from memory. This will help you remember what the circuits look like, and if you can remember what they look like, the chances are that you'll be able to remember how they work.

SELF-TEST QUESTIONS

(i) To what value may the input filter capacitor charge in a simple capacitor filter such as shown in Fig. 11?

(j) In what type of application may a simple capacitor-type filter (such as shown in Fig. 11) be used?

(k) What advantage does an R-C pi-type filter (such as shown in Fig. 13) have over the simple capacitor-type filter shown in Fig. 11?

(l) What is the disadvantage of the R-C pi-type filter, and how can this disadvantage be overcome?

(m) What is the purpose of the resistor R1 in the power supply shown in Fig. 17?

(n) Why are choke-input filters used with mercury-vapor rectifier tubes?

(o) What advantage does a choke-input filter have over a capacitor-input filter?

(p) What is a swinging choke?

Typical Power Supplies

The two main sections of the power supply are the rectifier and the filter section. Now that we have discussed both these sections, let's examine some typical power supplies and see what they look like. First we'll look at some power supplies using tube-type rectifiers which might be found in equipment using vacuum tubes. Remember that in these circuits the rectifier operates in the same way as a selenium or silicon rectifier would operate. Insofar as the rectification action is concerned, it makes little difference whether a tube, a selenium rectifier, or a silicon rectifier is used. In the circuits where tubes are used, we will in some cases show how the tube heaters are connected. After looking at a few tube circuits we will look at some typical power supplies using silicon rectifiers and then at a more complex regulated supply.

UNIVERSAL AC-DC POWER SUPPLIES

The universal ac-dc power supply is so called because it can be operated from either an ac or a dc power line. When these power supplies were first used in radio receivers, manufacturers played this feature up, but actually this type of power supply is used to keep costs at a minimum.

The circuit of an ac-dc power supply for a 5-tube radio receiver is shown in Fig. 22. This supply not only supplies the dc voltages required by the plates and screens of the tubes in the receiver but also contains the heater supply for the heaters of the various tubes. First, let us look at the heater supply. Notice that the heaters of the various tubes are connected in series and that they are operated on ac. In this type of power supply you will always find that the heater of the rectifier tube, in this case a 35W4 tube, is connected directly to one side of the power line. The heater of this particular tube is tapped, and a pilot light is connected in parallel with one part of the heater. The pilot light will light when the set is turned on. The tube is designed to be operated with the pilot light connected in parallel with part of the heater, so if in servicing a receiver using a tube with a pilot light tap you should find that the pilot light is burned out, it is a good idea to replace it to keep the heater current in the rectifier tube within its rated value.

Next to the 35W4 rectifier tube in the heater circuit (or heater string, as it is usually called) you will always find the high-voltage power output tube. By a high-voltage tube we mean a tube that requires a high heater voltage. In the diagram we have shown, the tube is a 50B5 tube. As the 50 suggests, a heater voltage of 50 volts is required to operate the tube.

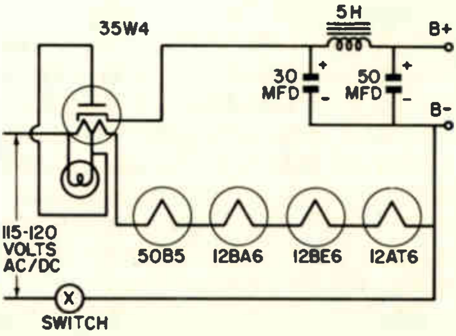

Fig. 22. A typical ac-dc power supply.

Next to the output tube you will usually find the i-f tube. In this diagram, the i-f tube is a 12BA6 tube. It is a tube with a 12.6-volt heater.

Next to the i-f tube you will find the converter tube. The 12BE6 tube is a converter tube designed so that the single tube performs two tasks: one part of the tube is the oscillator and the other part is the mixer.

The last tube in the heater string is always the first audio tube. In this circuit it is a 12AT6 tube. This tube is placed at the end of the heater string nearest B- to keep hum at a minimum, because hum picked up in the first audio tube will be amplified by the entire audio system and could be objectionable. The 12AT6 tube is a dual-diode-triode tube: it has two diodes and a triode inside the same glass envelope. As the 12 preceding the type designation suggests, the tube requires a heater voltage of about 12 volts--to be exact, 12.6 volts.

Now if we examine the rectifier circuit you will see that the plate is connected to a center tap on the rectifier heater. This means that the B supply current flowing through the plate of the tube must flow either through part of the rectifier heater or through the pilot light back to one side of the power line. The purpose of connecting the plate this way is to provide some protection in the event of a short in the receiver. If there is a short in the receiver, the rectifier tube will begin passing excessive current. If this current becomes too high, the pilot light and half the rectifier heater will burn out, opening the circuit and protecting the receiver and the house wiring.

The rest of the power supply is similar to the circuit you studied already. The filter network consists of a capacitor-input filter; the input filter capacitor is the 30-mfd capacitor, and the output filter capacitor is the 50-mfd capacitor. Usually these two capacitors are in a single container that has only three leads brought out from it. Since the negative leads are both connected to B-, a common negative lead and two separate positive leads are usually used. The capacitor is usually a tubular type of capacitor with a paper cover impregnated with wax. The capacitor is mounted on the receiver chassis by means of a mounting strap, or in a receiver with a printed circuit board, the leads are soldered directly to the circuit board. Often this is the only kind of mechanical mounting used.

Capacitors in this type of receiver are usually rated at 150 volts. The normal output voltage of this type of power supply under load is usually somewhere between 90 and 105 volts.

Not all universal ac-dc power supplies use a filter choke. In the circuit shown in Fig. 22, the plates and screens of all of the tubes are operated from the B+ output of this power supply. However, sometimes you will find a filter resistor used in the power supply in place of the filter choke. When this is done, the plate of the output tube is usually connected directly to the cathode of the rectifier tube so that the current drawn by the output tube plate will not flow through the filter resistor. This tube usually draws more current than all the other tubes in the receiver combined.

The output tube is normally a beam tube or a pentode tube, and the plate current depends very little on plate voltage. Therefore if there is some hum voltage applied to the plate of the tube, it usually does not cause any plate current variation and hence is not heard as hum in the output from the loudspeaker. The screen voltage for the output tube and the plate and screen voltages for the remaining tubes are obtained at the output of the power supply where the additional filtering obtained from the filter resistor and the output filter capacitor will reduce the ripple from the rectifier to a low value.

In some of the later table-model radio receivers only four tubes are used; a selenium rectifier or a silicon rectifier is used in place of a rectifier tube because either of these has a considerably longer life. In receivers of this type, tubes with higher heater voltage requirements are often used, so that the sum of the heater voltages required by the four tubes adds up to about 120 volts. If the heater voltage required by the tubes is less than the line voltage, a voltage-dropping resistor can be placed in series with the heaters to use up the leftover voltage. This will cause the total voltage drop across the series-dropping resistor and the tubes to be equal to the line voltage, thus allowing each of the tubes to have its required heater voltage.

Of course, in any heater string where tube heaters are connected in series, all the tubes must have the same heater current rating. Tubes designed for this type of service have what is called a controlled warm-up. This means that the tube heaters are made so that they all reach operating temperature at the same time. This prevents one tube from warming up too quickly and from having too high a voltage across its heater.

The voltage across the tube heater will depend upon its resistance, which changes with temperature. As long as all the tubes warm up at the same rate, their resistances change at the same rate. In this way, a high voltage across any of the tubes is avoided.

Before leaving our study of this type of power supply, it is worthwhile to consider what will happen if a tube such as the 12BA6 tube in Fig. 22 develops a cathode-to-heater shortage. The cathode will usually be connected either to B- directly or to B- through a low-value resistor; this will effectively short out the heaters of the 12BE6 and 12AT6 tubes and, as a result, these tubes will not light.

If you're called upon to service a receiver of this type and you find that one or more of the tubes is not heating, look for a cathode-to-heater short in either the tube which doesn't light that is highest up on the string, or the tube preceding it. If none of the tubes lights this is an indication, since the tubes are connected in series, that the series string is open -- chances are that the heater of one of the tubes has burned out.

A TYPICAL FULL-WAVE POWER SUPPLY

Fig. 23 illustrates a typical power supply using a power transformer and full-wave rectifier. This type is found in many radio and TV receivers and transmitting equipment, as well as in the equipment used in industrial electronics.

Notice that the power transformer has a primary winding to which the 115-volt ac power line is connected; a high-voltage secondary with its center tap grounded, and the two end leads connected to the plates of the rectifier tube; and the two filament

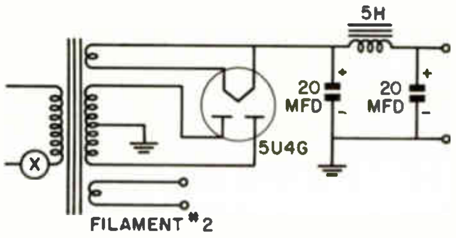

Fig. 23. A typical power supply using a transformer and full-wave rectifier.

windings. One filament winding is used to supply the heater voltage required by the rectifier tube, and one filament winding is used to supply the heater voltage for all the other tubes in the set.

In this power supply we have shown a 5U4G rectifier tube, which requires a heater voltage of 5 volts and a heater current of 3 amps. Thus the rectifier filament winding on the transformer must be capable of supplying 5 volts at a current of 3 amperes.

The winding marked filament number two is used to supply the heater voltage required by all the other tubes in the set. You will notice that this winding is called the filament winding, not the heater winding. This is a carry-over from the old days of radio when most of the tubes were filament-type tubes and few had a separate cathode and heater.

In an electronic device using this type of power supply, the heaters of the tubes (with the exception of the rectifier tube) are connected in parallel. Since the tubes are connected in parallel, you will find that all of the tubes are designed to operate from the same heater voltage. In most cases equipment using this type of power supply has tubes with heater voltage ratings of 6.3 volts. The filament winding must be capable of supplying the heater current required by all of the tubes. The tubes may require different heater currents since they are connected in parallel. You can determine the total current the winding must supply by looking up the heater current required by the individual tubes in a tube manual and adding these figures together.

Again, the filter network used in this power supply is a capacitor-input type. Notice that the capacitors have a lower capacity than those used in the circuit shown in Fig. 22. It is not as necessary to use large capacitors in a full-wave rectifier type of power supply as it is in a half-wave rectifier to obtain the same amount of filtering. Of course, in some power supplies in which it is essential to keep the hum voltage very low, you will find larger filter capacitors. You may also find a two-section filter using an additional choke and a third filter capacitor.

In a power supply such as the one shown in Fig. 23, the two capacitors will probably be mounted in a single container. If a cardboard tubular type is used, one common negative lead and two separate positive leads will be brought out of the container. The same color leads will probably be used for the two positive sections since they both have the same capacity. In some pieces of equipment a metal can-type capacitor might be used -- with this type the can is usually the negative terminal. Mounting the capacitor on the metal chassis automatically makes the connection between the negative terminal and the chassis. The positive leads are brought out of two separate terminals.

DUAL-VOLTAGE POWER SUPPLIES

A diagram of a typical dual-voltage power supply is shown in Fig. 24. This diagram is actually quite similar to the diagram of circuits used in a modern color-TV receiver. Notice that a voltage that is negative with respect to ground is developed by the diode D1 and its associated circuitry. Diodes D2 and D3 are used in a half-wave voltage doubler circuit.

In this circuit when terminal A is negative with respect to terminal B, current flows from A through R1 and D1 to charge capacitor C1. A simple pi-type R-C filter is used in this section of the power supply because the current requirements are low and there will be very little voltage drop across R2. At the same time with the two capacitors, small value capacitors can be used and adequate filtering obtained.

When terminal A is negative, current also flows through the thermistor R3 through R4 and into the negative plate of capacitor C3. Electrons flow out of the positive plate through the diode D2 back to terminal B of the power line. When terminal A of the power line is positive and terminal B is negative the voltage will be placed in series with the voltage built up across C3, so that capacitor C4 is charged to a value approaching twice the peak line voltage through diode D3. This provides an output voltage which is positive with respect to ground and approximately equal to twice the ac line voltage.

The thermistor R3 is put in the circuit to prevent high current surges through the silicon diodes D2 and D3 when the equipment is first turned on. R4 is used in the circuit to provide further protection. If the equipment is turned on and operating for some time, the resistance of the thermistor will drop to a low value. If the equipment is turned off for a

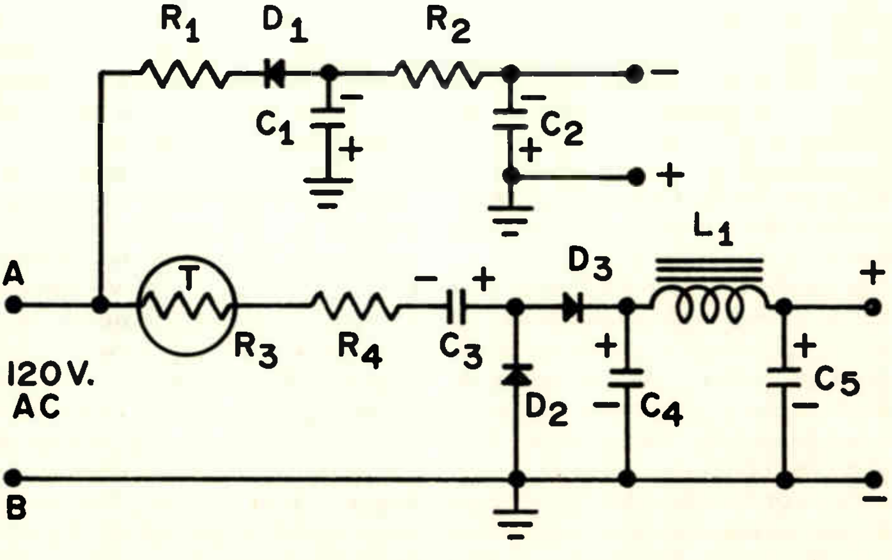

Fig. 24. A typical dual-voltage power supply.

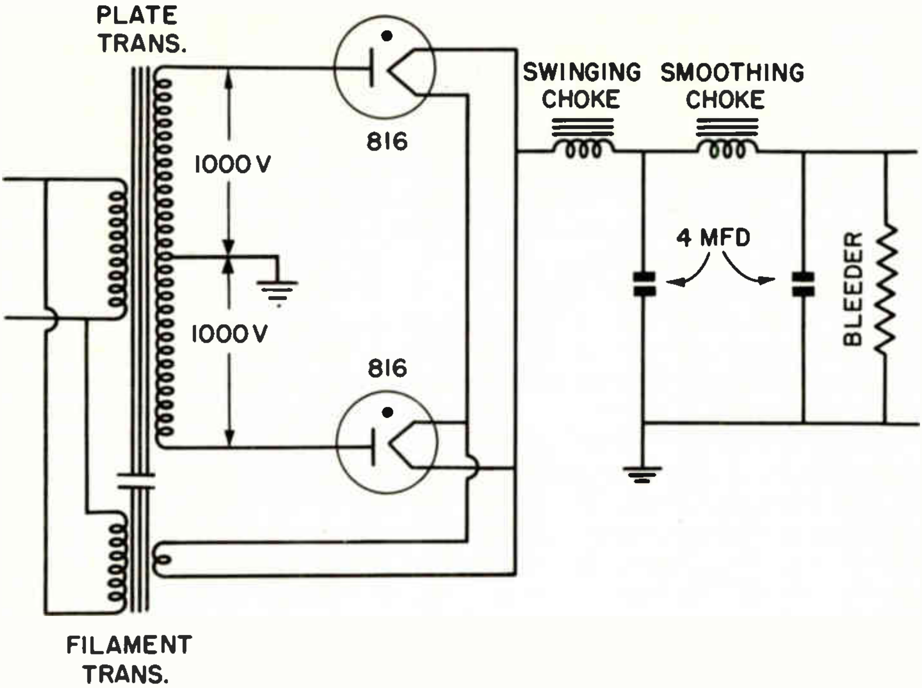

Fig. 25. A typical transmitter power supply.

few seconds and then turned back on, the charging current through the diodes could be quite high and damage them. R4 is put in the circuit; its value does not change and it limits the current through the diodes to prevent their damage under this circumstance.

The power supply shown in Fig. 24 is typical of the power supply you are likely to run into in both monochrome and color television receivers. A voltage-divider network may be used across the output of either supply to provide different value voltages. This power supply is comparatively inexpensive; it eliminates the need of a power transformer and with modern silicon diodes is comparatively trouble-free.

HIGH-VOLTAGE POWER SUPPLIES

Another power supply is shown in Fig. 25. This is the type of power supply you will find in transmitting equipment or in other equipment where high operating voltages are required. Notice that in this power supply, full-wave rectification is used. Also notice that it has two separate rectifier tubes. Separate rectifier tubes rather than a single tube with two plates are used in high-voltage supplies because the voltages are so high that they would simply arc across inside the tube. The type 816 tubes shown in this supply are mercury-vapor tubes designed for use in power supplies where the operating voltages are not too high and where the current requirements are not too great. They are often used in power supplies where the ac input voltage to the rectifier is between 1000 and 2000 volts, and the current drain does not exceed 250 ma. As far as the transmitting-type power supplies are concerned, an output voltage of 1000 volts across each half of the secondary of the high-voltage transformer is not considered high.

The high-voltage transformer found in this type of power supply is frequently called a plate transformer because it is used to supply the high voltage required to operate the plates of the various tubes in the transmitter. The rectifier tubes are operated from a separate filament transformer. In a power supply using type 816 tubes, the filament voltage required by these tubes is 2.5 volts and the current required is 2 amps. Therefore, this filament transformer must be capable of supplying a total of 4 amps at a voltage of 2.5 volts. The filament transformer must have good insulation between the secondary winding, the transformer core, and the primary winding; otherwise the high voltage will arc through the insulation either to the primary winding or to the transformer core.

At the input of the power supply filter network is a swinging choke. This is common practice in transmitter power supplies because it improves the voltage regulation, and also because it affords additional protection for the mercury-vapor rectifier tubes.

The second choke in the power supply is called a smoothing choke. This is the same type of choke shown in the power supplies in Figs. 22 and 23. It is called a smoothing choke in transmitting equipment because its primary purpose is to smooth out the ripple and also to distinguish it from the swinging choke used at the input of the filter network. A smoothing choke is designed to keep its inductance as nearly constant as possible, whereas a swinging choke is designed so that its inductance will vary as the current through it varies.

Notice that the filter capacitors used in this power supply are 4-mfd capacitors. Each of these capacitors is usually mounted in its own separate container. Occasionally you will find two small high-voltage capacitors in the same container, but this is not common practice. Also notice that the capacitors have a much smaller capacity than those in the two power supplies we discussed previously. These capacitors are oil-filled capacitors and it is quite costly to make this type of capacitor with a large capacity. On the other hand, capacitors used in circuits like those in Fig. 22, Fig. 23, and Fig. 24 are electrolytic capacitors and very large capacities can be obtained at a very moderate cost.

Effective filtering is obtained with the smaller-size capacitors in this supply, because two filter chokes are used. The inductance and hence the inductive reactance of these chokes are usually somewhat higher than that of filter chokes used in lower voltage equipment. The choice of using either large chokes or large filter capacitors is simply one of cost. At low voltages it is more economical to use large capacitors and low-inductance chokes, but at high voltages it is more economical to use high-inductance chokes and low capacities. The net result is the same as far as the filtering action is concerned. Another component that you will find in transmitting-type power supplies is a bleeder. A bleeder is a resistor connected across the power supply output. The bleeder serves two purposes: it improves the voltage regulation and is also used for safety.

A bleeder resistor connected across the power supply keeps the minimum current at a reasonable value. If the current drawn by the load connected to this power supply were to drop to zero, the two filter capacitors would be charged up to a value equal to the peak voltage across half of the secondary of the plate transformer. If the transformer had an rms voltage of 1000 volts across each half of the secondary, this would mean that the capacitors would charge up to a voltage of about 1400 volts. This may be high enough to destroy the capacitors. Also, the chokes have a definite maximum voltage that can be applied to them. If the voltage goes too high, the insulation between the choke winding and the core may break down. This will destroy the chokes. If either of the chokes or capacitors shorts, the rectifier tubes will pass such a high current that they may be ruined. There is also the danger of burning out the plate transformer. Furthermore, if the voltage reaches too high a value, the rectifier tubes may arc over internally. A bleeder connected across the power supply output can eliminate this danger. With the bleeder across the output, if the equipment current drops to or almost to zero, the bleeder current will continue to flow. If the output voltage starts to rise, the bleeder current will increase because the current flowing through any resistor increases if the voltage across it increases. The bleeder current will keep the voltage from climbing to an unsafe value.

Another important reason for using the bleeder is that an oil-filled capacitor such as those found in this type of power supply can hold a charge for a long time. If the two 4-mfd capacitors used in the supply were charged up to a voltage of 1000 volts or more and a technician servicing the equipment accidentally touched one of these capacitors, he could receive a very dangerous shock. Under certain conditions it could be fatal. This danger can be greatly reduced by connecting a bleeder across the power supply so that when the equipment is turned off the capacitors are discharged through the bleeder.

You may have occasion to work on high-voltage power supplies at some future date. Remember that a bleeder is connected across the power supply for safety as well as to improve the voltage regulation. Therefore if the bleeder in a power supply burns out, it should be replaced. However, never rely on a bleeder to discharge high-voltage filter capacitors. If you have to work on a high-voltage power supply, your first step should be to remove all voltages from the supply. To do this, turn the power supply off; if there are fuses in it, remove the fuses so that no one can accidentally turn it on; disconnect it completely from the source if you can. Often it is not possible or convenient to completely disconnect the equipment from the voltage source but if it is shut off and any fuse in the circuit is removed, it should be safe. Next, before you start to work on the supply, discharge all filter capacitors in the power supply. The capacitors should be discharged with a heavy metal rod that has a good insulated handle so that you will not come in contact with the metal rod. Use the metal rod to short together the terminals of the capacitor to discharge it. Touch the grounded terminal of the capacitor first and slide the rod over to touch the other terminal. Do this several times to be sure the charge is completely removed. After the capacitors have been discharged, the power supply should be safe to work on.

Keep this point in mind: high voltage capacitors, or for that matter any large capacitors, should be discharged before you start to work on a piece of equipment. Many technicians fail to do this. There are some technicians who can tell about the terrific shock they received when they failed to discharge a filter capacitor. There are others that did not survive the experience to tell about it.

A TRANSISTOR-REGULATED POWER SUPPLY

A regulated power supply employing transistor voltage regulators is shown in Fig. 26. This power supply is used in a TV receiver that is designed for operation from the power line and also from a 12-volt dc source. When the power plug is plugged into a 120-volt line and the switch is turned on, the receiver will operate from the power line. When the power plug is disconnected and switch S1 is closed, the receiver can be operated from a 12-volt battery.

The operation of the power supply from the power line is comparatively simple. Two diodes, D1 and D2, are used in a full-wave rectifier circuit. When the transformer T1, which is a step-down transformer, has a polarity such that the end of the secondary connected to D1 is negative, current will flow through the diode D1 to ground and into the negative plate of C3. Electrons flow out of the positive plate of C3 to the center tap of the power transformer which is positive with respect to the end connected to D1. During the next half-cycle, when the end of the secondary connected to D2 is negative, current will flow through D2 to ground, into the negative plate of C3,

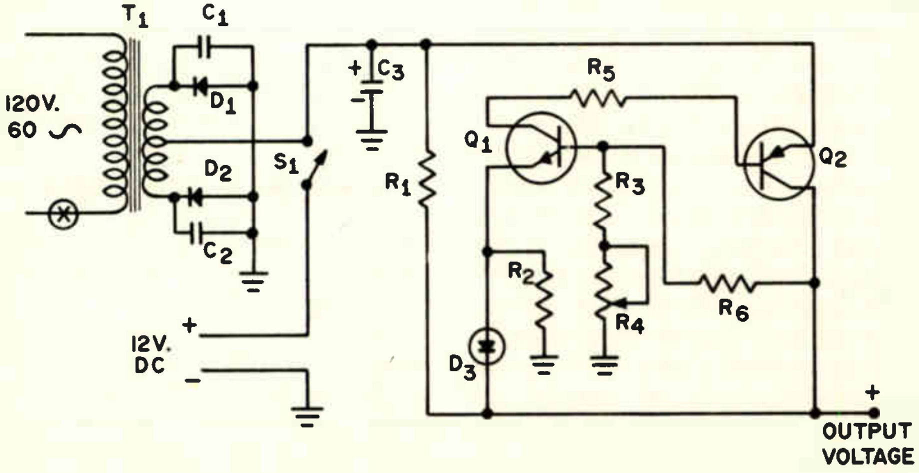

Fig. 26. A transistor-regulated power supply.

out of the positive plate of C3 and back to the center tap of the secondary winding on the power transformer.

The remainder of the components used for the power supply are used for the purpose of regulating the voltage. In other words, the power supply voltage is maintained constant at approximately 12 volts regardless of the load drawn from the supply. The transistor Q2 is a PNP transistor that is used as a series voltage regulator. Notice that the emitter of this transistor connects directly to the positive side of C3. You can consider this transistor as working more or less as a variable resistor: if the output voltage tends to rise, the resistance increases and if the voltage tends to fall, the resistance decreases.

The effective resistance of Q2 is varied by varying the forward bias across the emitter-base junction. Notice the zener diode D3. This diode is connected in series with R2. The zener has a constant voltage of 6.3 volts across it. Therefore, the voltage drop across R2 will be equal to the output voltage minus 6.3 volts. This is the emitter voltage applied to Q1. The base voltage is determined by the voltage division occurring between R4, R3 and R6. R4 is adjustable so that the output voltage can be adjusted to 12 volts. Under these circumstances a certain current will flow through Q1 and through R5 and this will set the forward bias on Q2. If the output voltage tends to rise, the base voltage on Q1 will rise but by an amount less than the emitter voltage. The divider network consisting of R4, R3 and R6 will prevent the base from rising the full amount of the output voltage rise. On the other hand, the voltage across the zener D3 remains constant so that the voltage across R2 will reflect the entire output voltage rise. This will reduce the forward bias on Q1 which, in turn, will reduce the emitter-collector current. The reduction in the emitter-collector current will reduce the voltage drop across R5 which, in turn, will reduce the forward bias on Q2; this has the effect of increasing its resistance. The increased resistance tends to keep the output voltage from increasing.

If the output voltage decreases, the opposite happens. The base voltage on Q1 falls, as does the emitter voltage. However, the emitter voltage falls more than the base voltage, so the forward bias is increased. This increases the emitter-to-collector current through Q1 which increases the forward bias on Q2. This has the effect of reducing the resistance on Q2 and tends to keep the output voltage from falling.

This type of power supply is one of the more complex power supplies that you are likely to encounter in electronic equipment. The voltage regulation is required in order to keep the voltage reasonably constant on the various transistors used on the TV receiver. In most cases, such precise voltage regulation is not required in entertainment-type equipment.

VOLTAGE DIVIDERS

We mentioned previously that more than one operating voltage is sometimes needed in the various stages of a piece of electronic equipment. Rather than use a separate supply for each voltage needed, the usual procedure is to use a single supply designed to give the highest voltage needed, and then obtain the lower voltages required by means of a voltage divider connected across the power supply output. A typical voltage divider is shown in Fig. 27.

In this voltage divider, R1 and R2 are voltage-dropping resistors; they drop the voltage from 300 volts to the required voltages of 200 and 100 volts. R3 is a bleeder used to stabilize the voltages at points B and C. With this type of network, terminal D is the ground or common terminal. Between D and C there is a voltage of 100 volts; terminal C is positive with respect to terminal D. Between D and B there is a voltage of 200 volts and terminal B is positive with respect to terminal D. Finally, between terminals D and A there is the full power supply output voltage of 300 volts, and of course terminal A is positive with respect to terminal D.

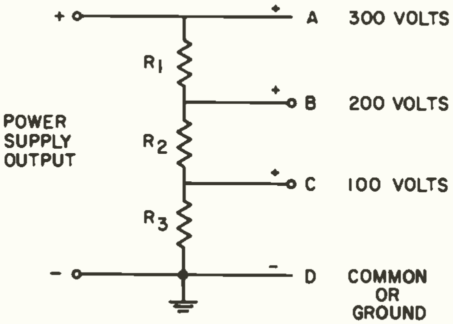

Fig. 27. A voltage-divider network.

The current flowing through R3 is called the bleeder current. It remains fairly constant and is determined primarily by the sizes of R1, R2 and R3. Usually, the size of R3 is chosen so that the bleeder current will be at least as great as the current drawn by the stages connected to terminals C and B. Choosing a value of R3 that will result in a reasonable bleeder current helps maintain good voltage regulation at terminals C and B.

The current flowing through R2 will be made up of the bleeder current plus the current drawn by the stages connected to terminal C. If this current varies, the voltage drop across R2 and hence the voltage at terminal C will vary. However, the bleeder current will remain essentially constant so that if a sizable percentage of the current flowing through R2 is bleeder current, variations in the current drawn by the stages connected to terminal C do not cause too much variation in the voltage drop across R2.

The current flowing through R1 is made up of the bleeder current plus the current drawn by the stages connected to terminals C and B. Again if the bleeder current through R1 represents a sizable part of the total current flow through R1, variations in the current drawn by the stages connected to terminals C and B do not cause too great a variation in the voltage drop across R1 so the voltage at terminal B will remain reasonably constant.

Bleeders are not used in modern midget radio receivers, but you will find them in many of the older sets. They are frequently used in TV receivers, in the low-voltage power supplies in transmitting equipment, and in industrial electronic equipment.

Sometimes one section of a tapped resistor will burn out. Often you can repair the equipment simply by connecting a resistor having the correct resistance and a suitable wattage rating across the defective section. Of course, if separate resistors are used in the voltage divider you can simply replace any defective one. If you do shunt a burned out section of a tapped resistor in a radio receiver and find the equipment is noisy after you have made this repair, the defective section may be making contact intermittently and creating the noise. Of course in this case you must replace the entire unit either with separate resistors connected in series or with a tapped resistor like the original one.

VIBRATOR-TYPE SUPPLIES

The radios installed in automobiles for years used a power supply known as a vibrator type of power supply. A schematic diagram of this type of power supply is shown in Fig. 28. The heart of this type of power supply is the vibrator, which is used to change the dc from the automobile storage battery to a pulsating current in the primary winding of the power transformer.

The vibrator consists of an electromagnet L, and a reed (R-K) placed between two sets of contacts. In the circuit shown in Fig. 28, when the switch is turned to the ON position, current will flow from the negative terminal of the battery through the switch and through the reed towards terminal M. Here it will flow from the reed to contact M, to coil L, through coil L back to the positive side of the battery. The current flowing through the coil creates a magnetic field. This magnetic field attracts the end of the reed K, pulling the reed over toward L and contact N. When the reed makes contact with terminal N, current flows through the upper half of the transformer primary winding. It flows from the top of the winding to the center tap, building up a magnetic field.

At the same instant that the reed is making its contact with terminal N, it will break its contact with terminal M so that the electromagnet will no longer be energized and the field about it will collapse. The reed is made of a spring type material so that it springs back until it makes contact with both terminal M and terminal O. At the instant contact is made with terminal O, current flows through the lower half of the primary winding of the transformer, flowing from the bottom of the winding towards the center tap. The current is flowing through the primary winding in the opposite direction to the direction in which it was flowing through the upper half of the trans-

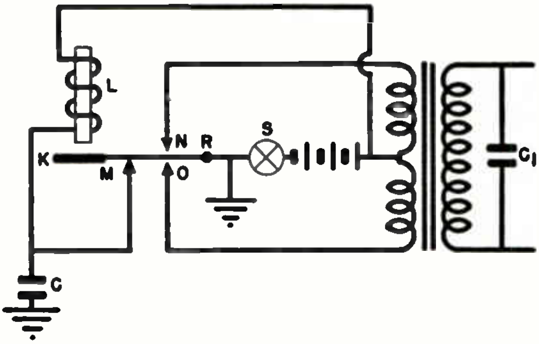

Fig. 28. A vibrator circuit.

former winding. Thus we have a field built up in one direction and then in the opposite direction. At the same time the fact that the reed makes contact with terminal M will once again complete the circuit through the electromagnet so the reed will swing over to the magnet again, making contact with terminal N. As you can see this action causes the reed to vibrate back and forth between terminals N and O. Thus we have a field built up in the primary first in one direction and then in the opposite direction. Building up this field, collapsing it, and then building up a reverse field and collapsing it, means that we have a continually changing magnetic field cutting the secondary of the transformer. By putting a large enough number of turns on the secondary, we can obtain whatever voltage we may require for the operation of the receiver.

A complete vibrator-type power supply is shown in Fig. 29. Notice that the secondary of the vibrator transformer is center tapped and that a full-wave rectifier is used. The capacitor C_2 is called a buffer capacitor. This is a high voltage paper capacitor that is used to keep sharp noise pulses out of the power supply. The size is usually quite critical and if it is necessary to replace the buffer capacitor in a receiver using this type of power supply, you should use a capacitor having the same capacity as the original.

In a vibrator-type power supply there is considerable sparking as the reed vibrates back and forth. This sets up a radio-frequency type of interference which could get through the rectifier and cause considerable interference in the receiver. In the power supply shown in Fig. 29, the choke L and the capacitor C are called hash suppressors. This rf interference or noise is called hash; the choke and the capacitor are put in the power supply in order to keep as much as possible of this hash or noise out of the power supply output. Capacitor C acts like a short circuit to these radio frequency pulses, and choke L acts like a very high impedance to them. Thus L and C form a voltage-divider network, with most of the voltage appearing across the high impedance L and little or no voltage across the low impedance C.

Vibrator-type power supplies were used in almost all automobile receivers in automobiles using 6-volt ignition systems. However, in newer cars, a 12-volt ignition system is used. The first receivers made for these cars also used vibrator type supplies, but tube manufacturers designed special tubes that will operate with plate and screen voltages as low as 12 volts. These 12-volt tubes were used in automobile receivers for a few years, but they too were replaced by transistors. Since transistors operate from low voltages, the vibrator type of power supply is no longer needed. These supplies were not only costly, but in addition they were one of the most troublesome sections of the automobile receiver.

SUMMARY

The power supplies we have shown in this section of this lesson are typical of the various types of power supplies you are likely to encounter as an electronics technician. You will find many variations of these circuits, but these are the basic circuits. Spend some time studying

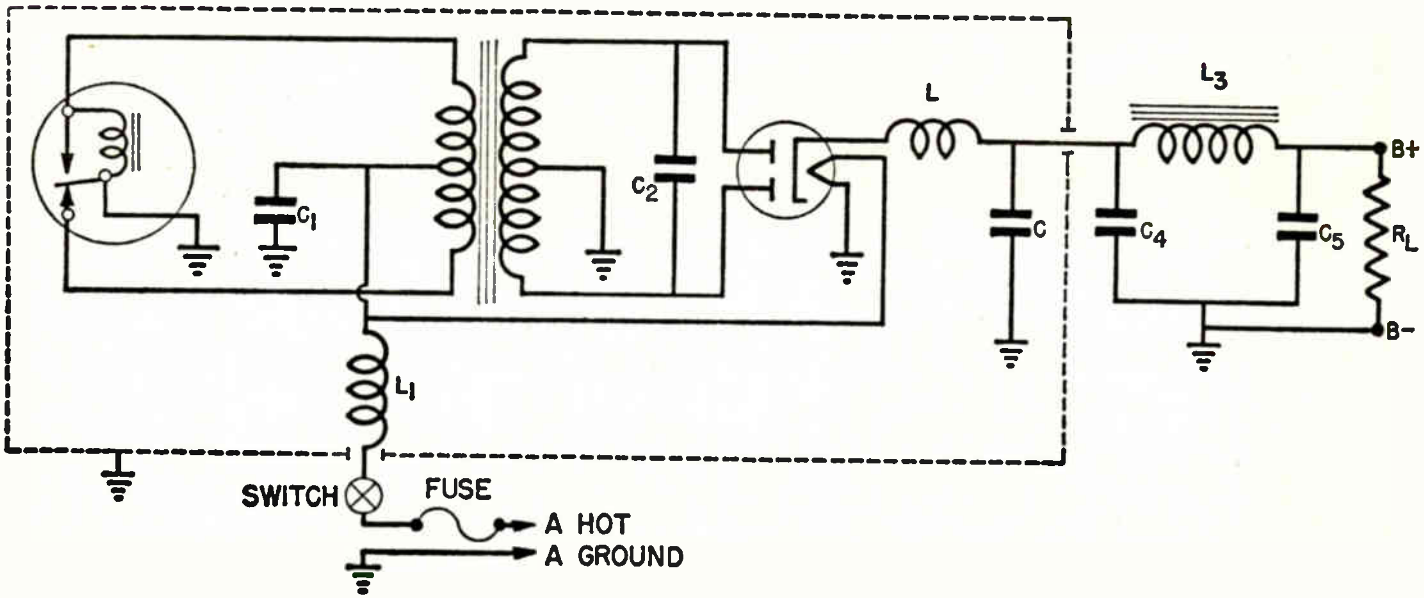

Fig. 29. A complete vibrator power supply.

these circuits so you will know what they look like.

In servicing these power supplies, keep in mind that the values of the various components used are generally not extremely critical. Manufacturers usually use as small a filter capacitor as they can in a circuit. It is more economical to use a small capacitor than to use a large one. Therefore, if you have an ac-dc receiver that uses a 20-40 mfd, 150-volt capacitor and you find it necessary to replace the filter capacitor, there is no reason why you could not use a 30-50 mfd, 150-volt capacitor in its place. Some variation of part values can be made without affecting the performance of the equipment.

It is also possible to use capacitors having a higher voltage rating than those used originally. This will simply provide an additional margin of safety. You may find that you cannot do this in large transmitter power supplies because there isn't room to mount a capacitor with a higher voltage rating, but usually in radio, TV, and most small pieces of industrial electronic equipment there is enough room to put in a capacitor of slightly larger physical size than the original.

SELF-TEST QUESTIONS

(q) Draw a schematic diagram of a typical ac-dc power supply found in a five-tube radio.

(r) In the circuit shown in Fig. 22, why is the 12AT6 tube placed at the B- end of the string?

(s) If in an ac-dc receiver in which the heaters of the tubes are connected in series and none of the tubes lights what would you suspect the cause of the trouble to be?

(t) Why are the filter capacitors used in the power supply shown in Fig. 23 smaller in capacity than the filter capacitors used in the power supply shown in Fig. 22?

(u) What is the purpose of R3 in Fig. 24?

(v) What is the purpose of R4 in Fig. 24?

(w) What type of voltage-doubler circuit is used in the power supply shown in Fig. 24?

(x) What purpose does the transistor Q2 serve in the power supply shown in Fig. 26?

(y) What is the purpose of the diode D3 in Fig. 26?

ANSWERS TO SELF-TEST QUESTIONS

(a) There will be 60 current pulses per second through the load.

(b) The disadvantage of the half-wave rectifier circuit is that current flows through the rectifier during one half-cycle and not during the other half-cycle. As a result, the output is somewhat difficult to filter and smooth out to pure dc.

(c) The diode D1 in the circuit shown in Fig. 6 is used to charge the capacitor C1 during one half of each cycle. Capacitor C1 is charged so that during the next half-cycle the voltage across it will be in series with the line voltage. This will place a voltage equal to twice the line voltage across the load and diode D2. Since diode D2 has a very low resistance when it is conducting, the voltage across the load is twice what it would be without the combination of C1 and D1 in the circuit: hence, the circuit is called a voltage-doubler circuit.

(d) The circuit is called a full-wave rectifier circuit because a current pulse flows through the load during each half-cycle. In other words, if the rectifier circuit is operating from a 60-cycle power line there will be 120 current pulses through the load (one for each half-cycle).

(e) The disadvantage of this circuit is that the high voltage winding on the power transformer must be center-tapped. This means that the high-voltage winding on the transformer must have twice the number of turns required to get the desired output voltage across the load. This circuit requires a rather expensive power transformer.

(f) The advantage of the bridge rectifier circuit is that there is a saving in the power transformer cost over that of a transformer that has a tapped high-voltage secondary winding; also, the circuit is capable of good voltage regulation.

(g) The voltage-doubler circuit shown in Fig. 9 is a full-wave voltage doubler. That is, there will be 120 current pulses per second in the output of the voltage doubling capacitor network consisting of C1 and C2. The circuit shown in Fig. 6 is a half-wave voltage-doubler circuit and there will be only 60 current pulses through the load in this circuit. It will be somewhat easier to filter and smooth the output voltage in the circuit shown in Fig. 9 than it will be in the circuit shown in Fig. 6.

(h) A full-wave doubler circuit requires a less expensive power transformer for a given load voltage than the bridge rectifier circuit requires. Also, the voltage-doubler circuit requires only two rectifiers whereas the bridge-rectifier circuit requires four rectifiers. The disadvantage of the full-wave voltage-doubler circuit is that it does not have as good voltage regulation as the bridge-rectifier circuit.

(i) The capacitor in a simple filter circuit such as shown in Fig. 11 may charge up to a value equal to the peak value of the ac input voltage. In the case of a power supply operating from a 120-volt line this is equal to approximately 1.4 times 120 volts.

(j) A simple capacitor-type filter may be used in applications where the current drain is low. With a low current drain the capacitor discharges very little between cycles so that the voltage across the capacitor, and hence the voltage across the load, remains essentially constant.

(k) The R-C pi-type filter is capable of better hum elimination than a simple capacitor-type filter. This type of filter is particularly desirable where the current drain is high enough to discharge the capacitor appreciably between charging cycles in a simple capacitor-type filter.

(l) The disadvantage of the R-C pi-type filter is that there is considerable voltage drop across the filter resistor. This problem can be overcome by using a filter choke such as in the L-C type filter shown in Fig. 15. A filter choke will offer a high opposition to any ac and thus effectively reduce the ac, while at the same time offering a low resistance to the passage of dc through it.

(m) R1 in the power supply shown in Fig. 17 is used to limit the current through the silicon rectifier when the power supply is first turned on. Without this resistance in the circuit, the charging current through the diode to charge C1 may be so high that the rectifier may be destroyed.

(n) To limit the peak current through the tubes. A mercury vapor rectifier tube is easily damaged by a high peak current. The peak current through the rectifier tube is much lower with a choke-input filter than it is with a capacitor-input filter.

(o) A choke-input filter will provide better regulation than a capacitor-input filter. This means that the voltage across the load will vary less with widely varying currents when the filter is a choke-input filter than it will when the filter is a capacitor-input filter.

(p) A swinging choke is a choke whose inductance changes as the current changes. As the current builds up the choke tends to saturate so that its inductance goes down. This tends to reduce the reactance of the choke and hence helps provide better voltage regulation.

(q) See Fig. 22. If you cannot draw this diagram from memory, copy it from the book. Simply drawing the diagram will help you to become familiar with the circuit and remember it in the future.

(r) The 12AT6 tube is the first audio stage. It is placed at the B- end of the heater string in order to keep hum pick-up in the tube as low as possible. Any hum picked up by this tube will be amplified by the entire audio system.

(s) The chances are that the heater of one of the tubes is open.

(t) The power supply shown in Fig. 23 uses a full-wave rectifier. Therefore there will be 120 pulses per second to charge the filter capacitors. The power supply shown in Fig. 22 is a half-wave power supply and there will be only 60 pulses per second to charge the filter capacitor; therefore, larger capacitors are needed to eliminate hum.

(u) R3 in Fig. 24 is a thermistor. A thermistor has a high cold resistance, but the resistance decreases as the thermistor heats up. The thermistor is used in this power supply to protect the diode rectifiers from high current surges when the power supply is first turned on.

(v) R4 is a fixed resistor that is used to protect the diodes in the event the equipment is turned off and then turned back on almost immediately. Under these conditions the resistance of the thermistor will be too low to provide the required protection for the rectifiers and hence R4, along with the hot resistance of the thermistor, limits the current through the diode rectifiers to a safe value.

(w) A half-wave voltage doubler.

(x) Q2 is in series with the B supply voltage. It operates essentially as a variable resistor and is used to regulate the power supply output voltage and keep it at essentially a constant value.

(y) The diode D3 is the zener diode. It provides a reference voltage so that the voltage variations on the emitter of Q1 will be greater than the voltage variations on the base. Thus, changes in output voltage affect the forward bias of the transistor and hence the conduction through it.

Lesson Questions

Be sure to number your Answer Sheet B201.

Place your Student Number on every Answer Sheet.

Most students want to know their grade as soon as possible, so they mail their set of answers immediately. Others, knowing they will finish the next lesson within a few days, send in two sets of answers at a time. Either practice is acceptable to us. However, don't hold your answers too long; you may lose them. Don't hold answers to send in more than two sets at a time, or you may run out of lessons before new ones can reach you.

1. What advantage does a silicon rectifier have over a vacuum-tube rectifier?

2. Draw the schematic symbol for a silicon rectifier, and indicate by an arrow the direction in which the current will flow through it.

3. How many pulses per second will you get at the output of a full-wave rectifier that is operated from a 60-cycle power line?

4. What is the purpose of C1 and D1 in the circuit shown in Fig. 6?

5. (a) In the circuit shown in Fig. 6, how many current pulses will there be through the load (60-cycle power line)?
   (b) In the circuit shown in Fig. 9, how many current pulses will there be through the load (60-cycle power line)?

6. In the circuits shown in Fig. 11, what part supplies current to the load when the rectifier is not conducting?

7. Explain the following things in connection with the L-C circuit shown in Fig. 15:
   (a) The action of the choke when ac flows through it.
   (b) The action of the choke when dc flows through it.
   (c) The action of the capacitor when ac flows through it.
   (d) The action of the capacitor when dc flows through it.

8. What type of filter network has better voltage regulation -- the capacitor input or the choke input?

9. If you are servicing a five-tube table model radio that uses a universal ac-dc power supply and you see that two of the tubes are not lighting, where would you look for trouble?

10. How does an increase in output voltage affect Q1 and Q2 in the regulated power supply shown in Fig. 26?

HOW TO START STUDYING

For some people, starting to study is just as hard as getting up in the morning. An alarm clock will work in both cases, so try setting the alarm for a definite study-starting time each day. Start studying promptly and definitely, without sharpening pencils, trimming fingernails or wasting time in other ways.

Beginning is for many people the hardest part of any job they tackle. So formidable does each task appear before starting that they waste the day in dilly-dallying, in day-dreaming, and in wishing they didn't have to do it. The next day and the next after that are the same story. Indecision brings its own delays, making it harder and harder to buckle down to work.

Are you in earnest? Then seize this very minute; begin what you can do or dream you can. Boldness in starting a new lesson is a great moral aid to mastery of that lesson; only begin, and your mind grows alert, eager to keep on working. Begin, and surprisingly soon you will be finished.

POWER SUPPLIES
FOR
ELECTRONIC EQUIPMENT

B201

STUDY SCHEDULE NO. 1

☐ **1. Introduction . . . . Pages 1-2**

The basic purpose of a power supply is discussed.

☐ **2. Rectifier Circuits . . . . Pages 3-12**

You learn about half-wave, full-wave, and bridge-type rectifier circuits using both vacuum-tube and selenium rectifiers.

☐ **3. Filter Circuits . . . . Pages 13-25**

In this section we take up capacitor filters, R-C filters, L-C filters, and choke input filters, and learn what factors affect the output voltage of a filter network.

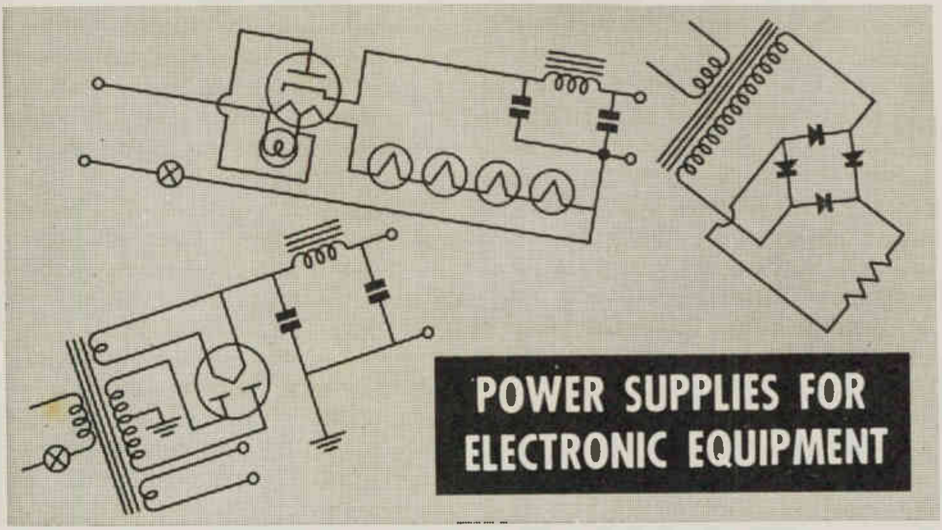
☐ **4. Typical Power Supplies . . . . Pages 26-37**

You study ac-dc supplies, full-wave power supplies, and high-voltage supplies.

☐ **5. Answer Lesson Questions.**

☐ **6. Start Studying the Next Lesson.**

JDL5M369 **1969 EDITION** Litho in U.S.A.



POWER SUPPLIES FOR ELECTRONIC EQUIPMENT

One of the most important sections in electronic equipment is the power supply. It is the section that furnishes the operating voltages and currents required by the various stages. If the power supply is not operating properly, the equipment can't do the job it's supposed to do.

In your career as an electronics technician, you will encounter many different types of power supplies. In equipment using tubes you will find power supplies that must supply the heater voltage for the various tubes and, in addition, a dc supply voltage that is often considerably higher than the power line voltage.

On the other hand, the power supply in transistorized equipment will be quite different from that used in tube-operated equipment. Most power supplies in transistorized equipment will have to reduce the voltage to some value less than the line voltage.

However, the current requirements of the power supply in a transistorized piece of equipment may be considerably higher than those of a power supply in a similar tube-operated device. All power supplies have basically the same function, regardless of the parts and circuitry used to make them; the power supply must supply the operating voltages and currents required by the various stages in the equipment.

You have already studied the basic components used in power supplies. In this lesson you will learn more about these components and how they are used together in this particular application. You will be introduced to some new circuits and will learn enough about power supplies to enable you to understand the purpose for which each part in a power supply is used. Once you know why the various parts are used and understand what each one is supposed to do, you should be able to service any power supply defect you encounter.

We will first take up the different rectifier circuits used in modern power supplies. The power supplied by power companies for home and industrial use is ac power, whereas the tubes and transistors used in electronic equipment require dc operating voltages. Therefore, in a power supply designed to operate from a power line, we must have some means of changing the ac to dc. The device used to do this is called a rectifier.

Once the ac is changed to dc by a rectifier, we have what is called a pulsating dc at the output of the rectifier. This is actually dc with ac superimposed on it. A power supply must therefore have some means of filtering or smoothing the pulsating dc to get pure dc. This is done by means of a filter network, which separates the ac and dc components of the pulsating dc at the rectifier output so that only the dc appears at the output of the filter network.

Many power supplies also have some type of voltage-divider network. Such a network is designed to provide several different operating voltages from one power supply. All the tubes or transistors in a piece of electronic equipment may not require the same operating voltage. It is more economical to use a single power supply and a voltage divider than to use a separate power supply for each voltage needed.

The power supplies in modern electronic equipment use solid state rectifiers in most low-voltage applications. Vacuum tubes are seldom used today as rectifiers in such devices as radio or television receivers or in other modern equipment. However, there are still millions of radios and television receivers in use today that do use vacuum-tube rectifiers. Therefore, you will probably have to work on this type of power supply as a service technician even though it is obsolete as far as its use in new equipment is concerned and you still should know how this type of rectifier works. For this reason, we will cover not only the new rectifier circuits using solid state rectifiers, but also a number of the older frequently-used rectifier circuits using vacuum tubes.

Rectifier Circuits

Any device that will pass current in one direction but not in the other direction can be used as a rectifier. You have already seen one example of this type of device: the vacuum tube. In a vacuum tube, as long as the voltage applied to the plate is positive with respect to the voltage applied to the cathode, the current will flow from the cathode to the plate of the tube. However, if the voltage applied to the plate is negative with respect to the voltage applied to the cathode, there will be no current flow through the tube because current cannot normally flow through the tube from the plate to the cathode. Thus, a two-element or diode tube was used for many years as the rectifier in the power supply of radio and television receivers.

The diode tube is entirely satisfactory as a rectifier, but it does have one big disadvantage. In order to handle the currents required in large radio receivers or in television receivers a rectifier tube with a rather heavy cathode or filament is required. Considerable power must be applied to the heater to heat the large cathode or filament, thereby bringing it to the temperature required for it to emit an abundant supply of electrons. Not only does this increase the power consumed by the equipment; also, a substantial amount of heat is given off by the diode and this, in turn, heats up other parts in the equipment. This often contributes to a shortened life of the other parts.

As we mentioned, diode vacuum tubes were used for many years as the rectifiers in radio and television receivers. However, a number of years ago the selenium rectifier began to replace the vacuum tube as the rectifier in entertainment-type equipment.

A typical selenium rectifier is shown in Fig. 1. A selenium rectifier is made up of a series of selenium discs with a coating of selenium oxide on the surface of one side of each disc. Electrons can flow from the selenium to the selenium oxide quite readily, but they cannot readily flow in the other direction, from the selenium oxide to the selenium. Thus, a selenium rectifier permits current to flow through it in one direction, but offers a high resistance to current flow through it in the opposite direction.

This type of rectifier is often called a dry-disc rectifier: "dry" to distinguish it from earlier rectifiers that used a wet chemical solution, "disc" because it is made up of discs. The square plates that are visible in Fig. 1 are cooling fins. The discs used are usually round and are

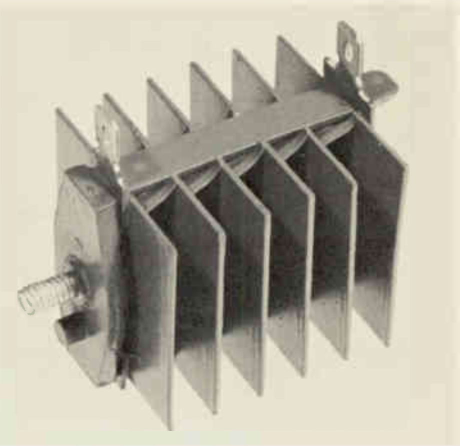


Fig. 1. A typical selenium rectifier designed for use in electronic equipment.

placed between the cooling fins, which are necessary because the rectifier does have some resistance and the current flowing through this resistance produces heat which must be dissipated.

The advantage of the selenium rectifier over the diode tube is that the selenium rectifier does not have a cathode that must be heated, and hence the power required to heat the cathode is saved. In addition, the total heat dissipated into the equipment from the selenium rectifier is somewhat lower than from a tube capable of handling the same current.

Both the vacuum tube rectifier and the selenium rectifier have been replaced in modern radio and television receivers by the silicon rectifier. The silicon rectifier, like the selenium rectifier, does not require any heater power; in addition, a silicon rectifier is much smaller than a selenium rectifier. It has a much lower forward resistance; that is, it offers far less opposition to current flow through it in the forward direction than does a selenium rectifier, and at the same time it has a higher reverse resistance (in other words it will permit a smaller current to flow through it in the reverse direction than a selenium rectifier).

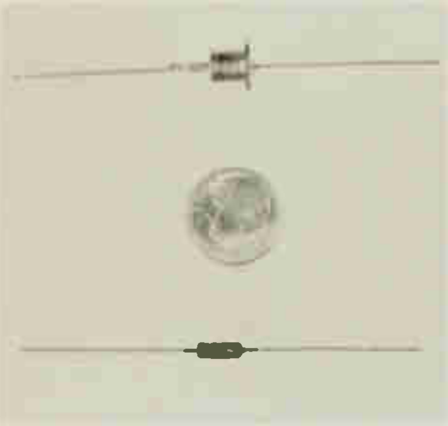

Fig. 2. Two typical silicon rectifiers with a dime between them to show their relative size.

Two typical silicon rectifiers are shown in Fig. 2. The rectifier at the top is called a top-hat rectifier because of its shape. A rectifier of this type and size is capable of handling currents several times those required in a color TV receiver. We have shown a photograph of the two rectifiers with a dime in between them so you can get an idea of the relative size of the two units. The lower rectifier is capable of handling currents of two or three amperes.

In addition to their small size and high current-handling capabilities, silicon rectifiers have another big advantage over selenium and vacuum tube rectifiers due to modern manufacturing techniques: they are relatively inexpensive to manufacture. Furthermore, unless they are overloaded, their life is almost indefinite.

Now, let's see how the various types of rectifiers are used in power supply circuits.

HALF-WAVE RECTIFIERS

You already know that the power supplied by most power companies is ac power and that the voltage supplied has a waveform that is called a sine wave. A typical single cycle is shown in Fig. 3A. A rectifier circuit using a diode tube is shown in Fig. 3B. Let's assume that the waveform shown at A represents the voltage at terminal A of Fig. 3 with respect to the voltage at terminal B. This means that for the first half-cycle (that is, the voltage waveform

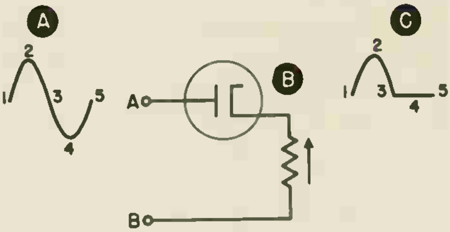

Fig. 3. How current flows in a half-wave rectifier circuit for one ac cycle. We have omitted the rectifier heater to simplify the diagram.

from point 1 to point 3), the plate of the tube will be positive. When the plate of the tube is positive, it will attract electrons from the cathode; therefore, current can flow through the tube.

Thus during the first half-cycle, as the plate voltage starts at point 1 and builds up to point 2, the current through the tube will increase from point 1 to point 2 as shown in Fig. 3C. As the voltage decreases during the first half-cycle from point 2 to point 3, the current through the tube will decrease as shown from point 2 to point 3 in Fig. 3C. When the voltage in Fig. 3A reaches point 3 there will be zero potential between points A and B in the rectifier circuit and current will stop flowing.

During the next half-cycle terminal A will be negative with respect to terminal B. This means that the plate of the tube will be negative; hence no current can flow through the tube. Therefore, the current will be zero (as shown in the waveform in Fig. 3C) as the voltage swings from point 3 to point 5.

The rectifier circuit shown in Fig. 3 conducts when the plate of the tube is positive. Since this occurs during one half the time of each cycle then the rectifier conducts during one half of the cycle but not during the other half. As a result, the rectifier is called a half-wave rectifier. If we operate this type of rectifier from a 60-cycle power line, we will get 60 current pulses through the rectifier during one half-cycle and 60 intervals during which there is no current flow through the rectifier.

Another half-wave rectifier is shown in Fig. 4. Here we have shown a solid-state rectifier in place of the tube. This could be either a selenium rectifier or a silicon rectifier -- the same symbol is used for both types.

Notice the schematic symbol used for the rectifier. Also notice that the arrows indicate that the direction of current flow through the circuit is opposite to the direction in which the arrow points in the schematic symbol. The reason for this is that in the early days of electricity, scientists thought that current flowed from positive to negative. Therefore, this symbol was designed to show the direction in which current flowed. But it was discovered later that current flow was actually electron flow and that it flowed from negative to positive, a direction opposite from that in which the early scientists thought it flowed. Although we know current flow is from negative to positive, we still use the same symbol; it has never been changed so that the arrow is actually pointing in the direction opposite to the direction of electron flow.

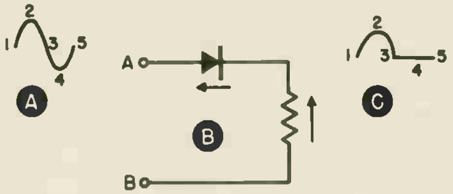

Fig. 4. A half-wave selenium rectifier circuit.

In a power supply of this type using a selenium rectifier, with terminal A positive with respect to terminal B, the selenium rectifier will offer only a low resistance to the flow of current through it; therefore, current flows in the circuit from B through the load and through the rectifier and back to terminal A. During the next half-cycle, when terminal A is negative with respect to terminal B, the selenium rectifier will offer a very high opposition to the flow of current through it so that there will be little or no current flow through the load (as shown in Fig. 4C).

We mentioned that the schematic symbol for the rectifier in Fig. 4 also represents a silicon rectifier. If a silicon rectifier is used, the rectifier will simply consist of a PN junction. The P-type material will be on the side represented by the arrow and the N-type material by the flat line. With a PN junction rectifier in the circuit when terminal A is positive and terminal B is negative, we will have a positive voltage applied to the P side of the junction and a negative voltage applied to the N side of the junction. The negative voltage will repel electrons from the N side of the junction across the junction into the P-type material. Electrons will be attracted through the P-type material by the positive potential applied to it. In other words, there will be a forward bias placed across the junction and current can readily flow through the rectifier because the carriers can cross the junction.

During the next half-cycle when the polarity reverses, terminal A will be negative and terminal B positive. Thus there will be a negative voltage, applied to the P side of the junction, which will repel electrons and prevent them from crossing the junction. At the same time there will be a positive voltage, applied on the N side of the junction, which will prevent any holes from the P side crossing the junction. In other words, there will be a reverse bias placed across the junction; hence the carriers cannot cross the junction and there will be no current flow through the circuit.

Of the three types of half-wave rectifiers, the silicon-type rectifier is the most widely used in modern equipment because of its small size, low cost and very low forward voltage drop.

Sometimes, in order to operate a piece of electronic equipment, a higher voltage is required than can be obtained directly from the power line. Under these circumstances a step-up transformer may be used to step up the voltage as shown in Fig. 5. The secondary-to-primary turns-ratio is simply adjusted to provide the required voltage step-up. A half-wave rectifier is then used as shown to rectify the ac and change it to pulsating dc. The operation of the half-wave rectifier is exactly the same in the circuit as

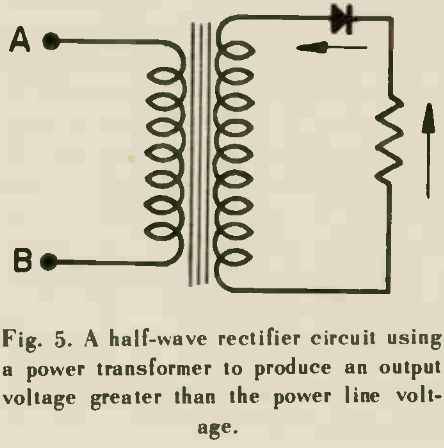

Fig. 5. A half-wave rectifier circuit using a power transformer to produce an output voltage greater than the power line voltage.

it was in the preceding circuits; however, the rectifier will have to have a higher voltage rating to make up for the fact that it is being used in a higher voltage circuit.

The disadvantage of the circuit shown in Fig. 5 is that power transformers are comparatively expensive. By means of the circuit shown in Fig. 6 a voltage approximately twice the voltage obtainable from the half-wave rectifier circuits shown in Figs. 3 and 4 can be obtained. This circuit can be operated directly from the power line and is known as a voltage-doubler circuit.

The operation of this circuit is quite simple. During one half-cycle terminal A will be negative with respect to terminal B. During this half-cycle electrons flow from A into the side of the capacitor C1 marked with the minus sign. The electrons flowing into this side of the capacitor force electrons out of the other side leaving a positive charge on this side of C1. The electrons leaving the positive side of C1 flow through the rectifier D1, back to side B of the power line which is positive and which will attract electrons. Thus, during this half-cycle, when terminal A is negative with respect to terminal B, capacitor C1 is charged with the polarity shown. The peak charge on C1 will be equal to the peak value of the ac input voltage.

During the next half-cycle, when terminal A is positive with respect to terminal B, we have a situation where the voltage between terminals A and B is effectively placed in series with the voltage charging capacitor C1. These series-connected voltages will cause a current to flow through the load and through D2. During this half-cycle terminal A is positive with respect to terminal B. This means that terminal B is negative. Electrons flow from terminal B through the load and through D2. They are attracted by a positive voltage which is equal to the voltage across C1 plus the line voltage. Thus the peak voltage that can be developed across the load will be equal to twice the peak line voltage.

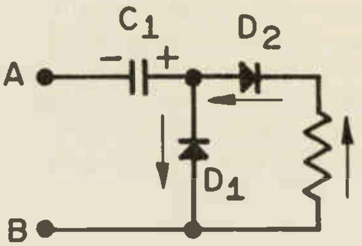

Fig. 6. A half-wave voltage-doubler circuit.

You might wonder why the current flows through only one rectifier during each half-cycle. During the first half-cycle, when terminal A is negative with respect to terminal B, the electrons flowing through D1 and charging C1 cannot flow through D2 because the diode is connected in such a way as to prevent current flow through them in that direction. Similarly, during the next half-cycle, when terminal B is negative and terminal A is positive, current cannot flow through D1 because it would have to flow through it in the reverse direction. Current can flow through the diodes only in the direction shown and it will flow through D1 during one half-cycle and through D2 during the other half-cycle.

This type of power supply is known as a half-wave doubler circuit. It is called a voltage-doubler circuit because the voltage across the load is effectively double the line voltage.

It is called a half-wave circuit because there is a current pulse to the load during only one half of each cycle. The half-wave voltage-doubler circuit is widely used in modern radio and television receivers. It's a very important circuit and you should be sure you understand how it works before leaving it.

When a half-wave rectifier is used in the power supply, the current will flow through the rectifier in a series of pulses. With a 60-cycle power supply line, there will be 60 pulses per second: one pulse during each positive-half cycle and nothing during each negative-half cycle. The net result is that you will have current flowing through the rectifier for no more than half the time. This results in a pulsating dc output from the rectifier that is rather difficult to smooth out to the pure dc required in most equipment to operate the tubes and/or transistors. A somewhat better arrangement is the full-wave rectifier that passes current during both halves of the ac voltage cycles.

FULL-WAVE RECTIFIERS

A typical full-wave rectifier circuit is shown in Fig. 7. Notice that the tube used is a twin diode tube. The tube has two plates and a single filament which is used with both plates. In operation, this tube acts as two separate diode tubes.

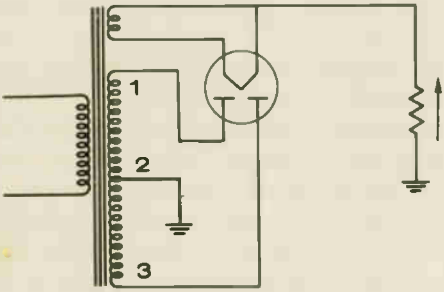

Fig. 7. A full-wave rectifier circuit using a single rectifier tube with two plates.

The power transformer used in the rectifier circuit has three windings. The primary winding is the winding that connects to the power line. A low-voltage winding is used to provide the current required to heat the filament of the rectifier tube. It serves no other purpose as far as the operation of the rectifier circuit is concerned. This winding is often referred to as the filament winding.

The high-voltage winding on the transformer is the winding that will supply the pulsating current to the load resistor. Notice that this winding has a center tap. In operation, one half of the winding first supplies the current and then, during the next half-cycle, the other half of the winding supplies current to the load.

We can see how this rectifier circuit works if we consider one half-cycle during which terminal 1 of the high-voltage secondary is positive. This means that terminal 2 will be negative with respect to terminal 1 and terminal 3 will be even more negative. Electrons will leave the center tap, terminal 2, and flow through ground to the load resistor. They will flow through the load resistor to the filament of the rectifier tube and then be attracted to the plate connected to terminal 1 because this plate has a positive voltage applied to it. No electrons will flow to the other plate because this plate is negative with respect to both terminals 1 and 2.

During the next half-cycle, the polarity of the secondary voltage will reverse. At this time terminal 3 will be positive, terminal 2 negative with respect to it, and terminal 1 even more negative. During this half-cycle electrons will leave terminal 2 and flow through ground to the load, through the load and to the filament of the rectifier tube, and then to the plate connected to terminal 3 because this plate now has the positive voltage applied to it. No electrons will flow to terminal 1 because terminal 1 is negative with respect to both terminals 2 and 3.

Notice that with the full-wave rectifier circuit we get a current pulse through the load resistor during each half-cycle. This means that for a 60-cycle power line we will get 120 pulses of current through the load. Since there is current flowing through the load during each half-cycle, this type of rectifier produces an output that is much easier to filter to a smooth dc than the output from a half-wave rectifier.

Either selenium rectifiers or silicon rectifiers can be substituted in this type of circuit in place of the rectifier tube. This type of circuit was widely used in older television receivers along with vacuum tubes. Modern TV receivers use silicon rectifiers and frequently use bridge-rectifier circuits or voltage-doubler circuits in place of this circuit.

BRIDGE-RECTIFIER CIRCUITS

One of the disadvantages of the full-wave rectifier circuit shown in Fig. 7 is that it requires a transformer with a center-tapped secondary. The total voltage across the entire secondary winding is actually twice the voltage between the center tap and either end of the secondary winding. This type of transformer is more expensive to manufacture than a transformer without a center tap because twice as many turns are required on the secondary to get the required voltage.

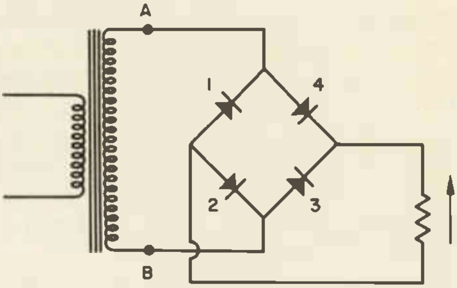

Fig. 8. A bridge-rectifier circuit.

A circuit that gets around the requirement of a center-tapped secondary is shown in Fig. 8. This is called a bridge-rectifier circuit; it is also often called a full-wave bridge-rectifier circuit because current flows to the load during each half-cycle.

A quick look at the circuit immediately shows us that four rectifiers are required in a circuit of this type. At one time this was a disadvantage because of the cost of rectifiers, but silicon rectifiers are comparatively inexpensive today and it is usually more economical to use the extra two silicon rectifiers and avoid the center tap on the secondary winding of the power transformer. The power transformer shown in Fig. 8 would be far more economical to manufacture than the one shown in Fig. 7.

The operation of the bridge rectifier is comparatively simple. When terminal A is positive and terminal B is negative, current will flow from terminal B through the rectifier marked 2 on the diagram and then through the load to the junction of rectifiers 3 and 4. It will then flow through rectifier 4 back to terminal A on the transformer. During the next half-cycle, when terminal A is negative and terminal B is positive, current will flow from terminal A on the transformer through the rectifier marked 1 on the diagram and then through the load back to the junction of rectifiers 3 and 4. This time the current will flow through rectifier 3 back to terminal B of the power transformer.

Notice that during each half-cycle current flows through two of the rectifiers. During one half-cycle it will flow through rectifiers 2 and 4 and during the other half-cycle it will flow through rectifiers 1 and 3. Also notice that current flows during both half-cycles; therefore, this bridge rectifier is a full-wave rectifier.

Bridge rectifiers have been used in television receivers where comparatively high operating voltages and high currents are required. The bridge circuit eliminates the need for the center tap on the power transformer secondary winding and thus reduces the cost of the transformer. The voltage regulation (the ratio of the full-load voltage to the no-load voltage) obtainable with this type of power supply is as good as the regulation that can be obtained from the full-wave rectifier circuit shown in Fig. 7.

FULL-WAVE VOLTAGE DOUBLERS

A full-wave voltage-doubler circuit is shown in Fig. 9. One advantage of this type of circuit is that we get the same load voltage as you have in a circuit like the bridge rectifier shown in Fig. 8, although only half as many turns are required on the secondary of the power transformer. This will result in a savings in the cost of the power transformer. Another advantage of this type of circuit is that only two rectifiers are required instead of the four required in the bridge-rectifier circuit.

The operation of the full-wave voltage-doubler circuit is quite simple. During one half-cycle terminal A of the power transformer secondary will be negative and terminal B will be positive. During this half-cycle current flows from terminal A through diode D2 to the capacitor C2 charging the capacitor as shown. Electrons flow into the negative side of the capacitor and out the positive side back to terminal B of the power transformer. During the next half-cycle, terminal B of the power transformer secondary will be negative and terminal A will be positive. During this half-cycle electrons leave terminal B of the power transformer and flow into capacitor C1. They flow into the side of the capacitor marked with the minus sign and force electrons out of the plus side. Electrons leaving the plus side flow through diode D1 back to terminal A of the power transformer, which is positive.

The capacitors C1 and C2 are connected in series and they supply the voltage to the load. The capacitors are charged by the current flowing

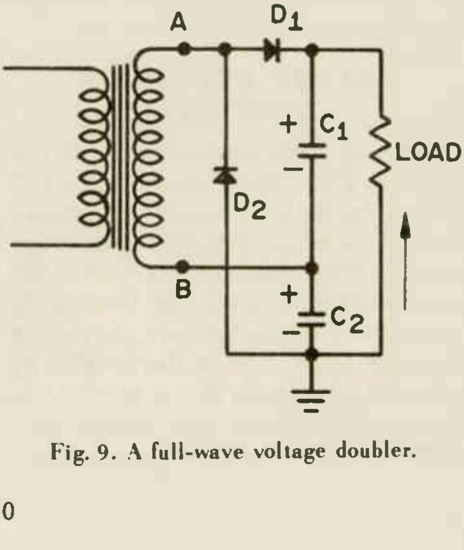

Fig. 9. A full-wave voltage doubler.

through the diodes, and since there is a charging pulse each half-cycle we will get 120 charging pulses from a 60-cycle power line. Since there is a charging pulse during each half-cycle, the circuit is a full-wave rectifier. The actual voltage that will be available across C1 and C2 in series will depend upon the power transformer secondary resistance, the resistance of the diodes when they are conducting, the size of the two capacitors, and the size of the load. As the resistance of the load increases, the current that will flow through the load decreases, and the charge on each capacitor becomes closer to the peak value of the ac voltage between terminals A and B.

Notice that in the diagram we have shown the direction of current flow through the load. The load current is supplied entirely by the charged capacitors C1 and C2. As the capacitors supply current to the load, electrons leave the negative plate of C2 and flow through the load in the direction shown. These electrons flow into the positive side of C1 forcing electrons out of the negative side into the positive side of C2. Thus the current flow through the load tends to reduce the charge across the capacitors. Of course, during each half-cycle one of the diodes conducts to build the charge across one of the capacitors up towards the peak value of the line voltage.

While this type of rectifier circuit offers some advantages over the circuits shown in Figs. 7 and 8, it does not have as good voltage regulation as they have. However, by using capacitors of large capacity for C1 and C2, and with modern silicon rectifiers that have a very low resistance when they are conducting, reasonably good voltage regulation can be obtained from this type of power supply. You will find the power supply widely used both in monochrome and color television receivers. Be sure you understand how it operates because you will run into it frequently.

In comparing this power supply with the half-wave doubler circuit shown in Fig. 6, we immediately see that the full-wave doubler circuit is best suited to equipment where a power transformer is used. The half-wave voltage-doubler circuit is widely used in equipment where no power transformer is used.

SUMMARY

The rectifier circuits that we have discussed in this section of the lesson are extremely important. As you know, the power supplied by the power companies is alternating current and the tubes and transistors in electronic equipment require direct current for their operation. Therefore, equipment designed to operate from the power line must use some type of rectifier to convert the alternating current to direct current. One of the circuits shown in this section of the lesson is likely to be found in any type of electronic equipment you will service.

The half-wave rectifier circuit shown in Fig. 5 is perhaps the most widely used. All table model radio receivers use this type of rectifier circuit without a power transformer so that the receiver can operate directly from the power line. The half-wave voltage-doubler circuit shown in Fig. 6 is widely used in television receivers where operating voltages higher than those that can be obtained directly from the power line are needed. In some of the older radio receivers and many older television receivers a full-wave rectifier circuit such as shown in Fig. 7 will be found. This type of circuit was used almost exclusively in television receivers before the development of low-cost selenium and silicon rectifiers.

The bridge-rectifier circuit shown in Fig. 8 is used in many television receivers, particularly large television receivers where fairly high voltages and high currents are required. This type of circuit is also used in some transistorized equipment where lower than line voltages are required. In this instance, instead of being a step-up transformer, the transformer will be a step-down transformer that steps the line voltage down to a low value. The bridge-rectifier circuit is then used so that good voltage regulation can be obtained and so that at the same time a comparatively large current can be taken from the power supply.

The full-wave voltage-doubler circuit has been used in many television receivers -- in those which use power transformers where voltages higher than the line voltage are required -- yet at the same time, the transformer serves primarily as an isolation transformer. In other words, the secondary voltage is approximately equal to the primary voltage. The higher voltage required is obtained by the voltage-doubling action. The output from the full-wave doubler circuit is somewhat easier to filter or smooth out than the output from the half-wave doubler circuit, because with the former we have 120 pulses per second through the load and with the latter we have only 60 pulses per second.

Before leaving this section regarding rectifier circuits, why not try to draw the circuits yourself? It would be worthwhile, and you don't have to draw them from memory -- copying them first from the book will help you to remember what they look like. Eventually, you'll be able to draw them from memory and recognize various circuits on the schematic diagram of any radio or TV receiver or piece of electronic equipment you may encounter.

After reviewing this section, do the following self-test questions.

SELF-TEST QUESTIONS

(a) In a half-wave rectifier circuit such as the circuit in Fig. 5, how many current pulses per second will there be through the load when the power line frequency is 60 pulses per second?

(b) What is the disadvantage of a half-wave rectifier circuit?

(c) What is the purpose of the diode marked D1 in the half-wave voltage-doubler circuit shown in Fig. 6?

(d) Why is the circuit shown in Fig. 7 called a full-wave rectifier circuit?

(e) What is the disadvantage of the full-wave rectifier circuit shown in Fig. 7?

(f) What are the advantages of the bridge-rectifier circuit shown in Fig. 8?

(g) What advantage does the voltage-doubler circuit shown in Fig. 9 have over the voltage-doubler circuit shown in Fig. 6?

(h) What are the advantages and disadvantages of the full-wave voltage doubler over the bridge-rectifier circuit?

Filter Circuits

The output from the rectifiers we discussed in the preceding section is not pure dc. Instead, it is pulsating dc: "direct" because it flows in only one direction, "pulsating" because it is varying in amplitude rather than flowing steadily. A pulsating dc voltage is a voltage that does not change polarity, but does change in amplitude. The voltage at the output of a half-wave rectifier will be zero during one half of each cycle and swing in a positive direction during the other half of each cycle.

Looking at the half-wave circuits shown in Fig. 3 and 4, you can consider the rectifier more or less as a switch. During one half-cycle the switch is closed so that the load is connected directly across the power line, and during the other half-cycle the switch is open so that no voltage is applied to the load. The voltage across the load in a half-wave rectifier circuit looks like Fig. 10A. The first half-cycle represents the cycle when the switch is closed and the load is connected directly across the power line, and the second half-cycle represents the cycle when the switch is open and there is no voltage applied across the load. We have shown what the voltage across the load will look like for four cycles in Fig. 10A.

In a full-wave rectifier circuit such as shown in Fig. 7, you have two switches. During one half-cycle one switch closes and connects the load across one half of the power transformer secondary; then, during the next half-cycle, the other switch closes and connects the load across the other half of the transformer secondary.

In the bridge rectifier shown in Fig. 8 two rectifiers act as switches and close to connect the load across the transformer secondary during one half-cycle; then during the next half-cycle the other two switches close, giving the effect of turning the load around so that the current flows through it in the same direction and the voltage applied across the load has the same polarity. The output from a full-wave rectifier circuit will produce a voltage across the load that looks like Fig. 10B.

As you can see from the waveforms shown in Fig. 10, the output taken directly from the rectifier is not a pure dc. There is a voltage, but the voltage drops to zero, builds up to the maximum value, and drops to zero again. In the half-wave circuit it remains at zero for a half-cycle and then builds up again in a positive direction. In the full-wave rectifier circuit the voltage builds up across the load during each half-cycle. In either case, this pulsating voltage will cause a pulsating current through the load which is entirely unsuitable for use in electronic equipment. Fortunately, there are convenient methods that can be used to filter or smooth this voltage to a pure dc voltage.

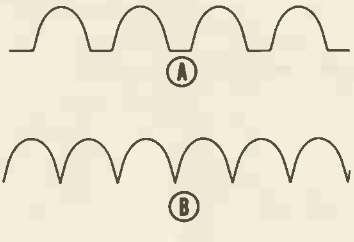

Fig. 10. Output voltage from half-wave and full-wave rectifier.

The pulsating dc voltage at the output of the rectifier is actually a dc voltage with an ac voltage, called a ripple voltage or a hum voltage, superimposed on it. The circuits used to get rid of this ripple or hum voltage are called filter circuits. There are a number of different types of filter circuits found in electronic equipment; in this section we will cover some of the circuits more commonly used.

THE SIMPLE CAPACITOR CIRCUIT

One of the simplest filters is the single capacitor filter shown in Fig. 11. In Fig. 11A we have shown a rectifier circuit using a tube and in Fig. 11B a rectifier circuit using a silicon rectifier. Notice that the circuits are practically identical -- we simply changed the rectifying devices in the two circuits.

The simple capacitor-type filter is sometimes used in circuits where the current drained or taken from the power supply is low. If the rectifier must supply high current to the circuit, this type of filter is generally unsatisfactory because there will be too much ripple or hum present across the load. In other words, the simple filter is simply not capable of eliminating all the ac or ripple voltage present at the output of the rectifier.

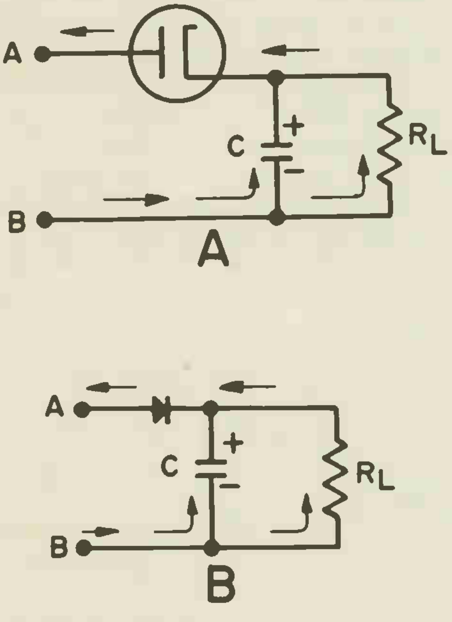

Fig. 11. A simple capacitor-type filter.

Both circuits shown in Fig. 11 work in the same way. Current flows through the rectifier during one half-cycle, as in the half-wave rectifier circuits we studied previously. When terminal A is positive, electrons will flow from terminal B through the load and through the rectifier back to terminal A. At the same time, electrons will flow into the negative side of the capacitor and out the positive side and through the tube or silicon rectifier back to terminal A. The capacitor eventually will be charged to a value almost equal to the peak line voltage. This will happen when the ac line voltage reaches its peak value with terminal A at its peak positive voltage with respect to terminal B.

Now, if the load on the rectifier circuit is light (that is, if the load resistor is a high resistance that draws very little current), as the ac input voltage between terminal A and B drops, capacitor C will begin to supply the current required by the load. Electrons will start to leave the negative side of the capacitor and flow through the load resistor back to the positive side of the capacitor. They will continue doing this as the ac voltage drops to zero and remains at zero during the next half-cycle and starts to build up again in the positive direction. The capacitor will continue to supply current to the load as long as the voltage across the capacitor is greater than the ac input voltage. Eventually, the input voltage will reach a value greater than the capacitor voltage; then we'll get a current flow into the capacitor and through the rectifier to recharge the capacitor.

In Fig. 12 we have shown the ac input voltage. Notice that during the first half-cycle between points 1 and 2 in Fig. 12A the ac voltage is increasing in a positive direction. Let's assume that terminal A in Fig. 11 is becoming positive with respect to terminal B. This explanation applies to both of the two circuits shown. During this first half-cycle the capacitor is charging and follows a curve as shown from point 1 to point 2 in Fig. 12B. Now, as the ac cycle drops from point 2 to point 3 on curve A in Fig. 12, the voltage drops faster than the capacitor discharges. During the interval from point 2 to point 5 and almost to point 6, as shown in Fig. 12A, the capacitor discharges very little. The discharge is shown on the curve from point 2 over to the number 5 on curve B. At this point the ac input voltage exceeds the capacitor voltage, so the capacitor is recharged again.

In circuits where the drain or load current is low, the capacitor will discharge very little between current pulses that recharge it so that the voltage across the capacitor and hence the voltage across the load remain almost constant. Of course, as the requirements of the load increase, the capacitor will discharge more so that there will be more of a voltage drop across the capacitor and across the load than in circuits where current drain is low.

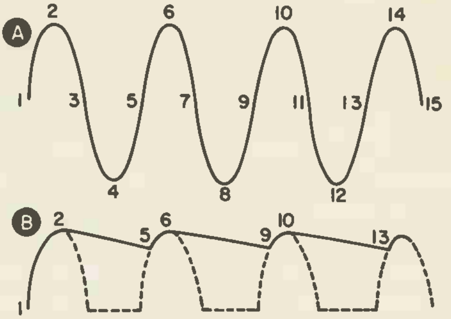

Fig. 12. Voltage waveshapes for a simple capacitor filter. (A) Input voltage; (B) output voltage.

There are several important points you should notice in the circuits shown in Fig. 11. Notice that the current does not flow during an entire half-cycle, but flows only when the line voltage exceeds the voltage across the capacitor. This may be for a very short interval if a load is a high resistance and draws very little current, or it may be for a sizable portion of a half-cycle if the current is a low resistance and draws a high current from the power supply. However, since the current flows through the rectifier in pulses, then the current pulse through the rectifier must be many times the average dc current flowing through the load. This is because the pulse or current that flows through the rectifier during the interval in which the rectifier is conducting must supply enough current to the capacitor to charge the capacitor and make up for the current it is going to supply for the remainder of the cycle.

When the rectifier is not conducting it is because the voltage across it is what we call a reverse voltage. In other words, it has a polarity opposite from that which the rectifier needs to conduct. In the case of the vacuum tube circuit this means that the plate of the tube is negative with respect to the cathode; in the case of the silicon rectifier, that there is a reverse bias across the junction.

One of the important characteristics of a rectifier is the maximum peak reverse voltage that can be placed across the rectifier before it breaks down. In the circuit shown in Fig. 11 the capacitor will be charged as shown and the charge can equal the peak line voltage. During the next half-cycle, when the polarity of the input voltage reverses, terminal A will be negative and terminal B will be positive. When this voltage reaches its peak, the peak reverse voltage across the rectifier will be equal to twice the peak line voltage. The rectifier must be able to withstand this voltage without breaking down. This important characteristic, by which rectifiers are rated, is usually referred to as "PRV" (peak reverse voltage), although it may also be called "PIV" (peak inverse voltage). The two are simply the maximum reverse or inverse voltages that can be applied across the rectifier without its breaking down. In circuits such as those shown in Fig. 11, the PIV should be considerably higher than twice the peak line voltage in order to allow a reasonable safety factor.

As we mentioned previously, the simple capacitor-type filter shown in Fig. 11 is usable only where a small current is required by the load. If the current required is small, the output capacitor can be made large enough so that it discharges very little between pulses. If the current required by the load is high, on the other hand, then the capacitor will discharge appreciably between charging pulses, resulting in a varying voltage applied to the load. This is essentially the same as applying dc mixed with ac to the load. Additional filtering is required in applications of this type in order to eliminate ac so that we will have pure dc across the load.

AN R-C FILTER

An improved filter, which is often called a pi filter because it looks like the Greek letter pi (π), is shown in Fig. 13. You will notice that this filter consists of two capacitors, C1 and C2, and a filter resistor, R1.

The operation of the half-wave rectifier and capacitor C1, which is called the input filter capacitor, is the same as in the simple capacitor filter shown in Fig. 11. The rectifier tube passes current pulses to charge capacitor C1 with the polarity indicated on the diagram. However, if the

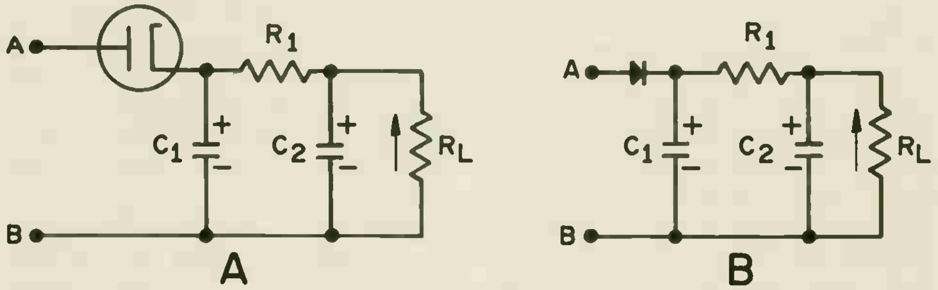

Fig. 13. An R-C pi-type filter.

load resistance R_L is low enough to draw appreciable current from the supply, then the voltage across C1 will discharge appreciably during the portion of the cycle when the rectifier tube is not conducting. Thus, we have dc with an ac superimposed on it across C1.

Now, to see the action of R1 and C2, let us first consider how the capacitor C2 reacts to ac and to dc. Remember that a capacitor is a device that will not pass dc -- it can be charged so that a dc voltage will exist across it, but applying dc to the plates of the capacitor will not cause a current to flow through it. Although electrons cannot cross through the dielectric of a capacitor, however, applying ac to the dielectric of a capacitor yields the effect of a current flowing through it. This is due to the fact that electrons will flow first into one plate and then into the other as the polarity of the ac voltage reverses.

You will remember from your study of capacitors that a capacitor offers what is called capacitive reactance (or opposition) to the flow of ac through it. The exact reactance that any capacitor will offer to the flow of ac through it is given by the formula:

$$Xc = \frac{1}{6.28 \times f \times C}$$

You can see from this formula that the larger the value of the capacitor, the lower the capacitive reactance will be to an ac voltage of a particular frequency. In Fig. 14A we have shown how the filter consisting of R1 and C2 reacts to dc; in Fig. 14B, we have shown how it reacts to ac.

As you know, a "perfect" capacitor will not pass dc -- although no capacitor is really perfect because there will always be a small dc current (called a leakage current). In other words, the capacitor offers a very high resistance to dc, so we have shown it as resistor R_{C2}. Most of the dc voltage applied to the input of this filter network will appear across the capacitor, and there will be very little dc dropped across the resistor R1. The exact drop across this resistor will depend upon the size of the resistor and the current drawn by the load.

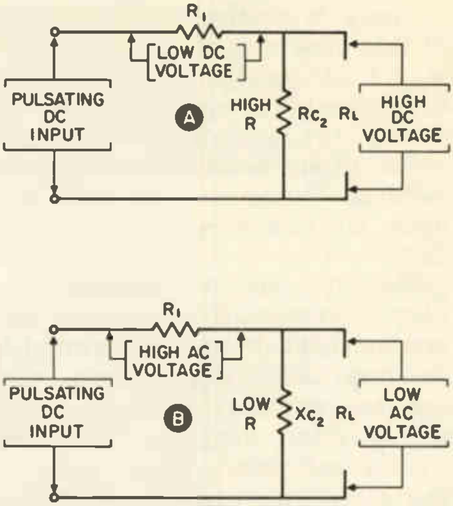

Fig. 14. Equivalent circuits showing the reaction of an R-C filter to dc at A, and to ac at B.

Now look at Fig. 14B which shows the reaction of the circuit to an ac voltage. The capacitor has a very low reactance to ac, so most of the ac voltage will be dropped across R1, because the resistance of R1 is much higher than the reactance (X) of C2. R1 and C2 act as a voltage divider network with most of the ac being dropped across R1 because its resistance is much higher than the reactance of C2.

There is another way of looking at this type of power supply which may help you see exactly what is happening in the circuit. Refer back to Fig. 13; the explanation applies to the circuit using the vacuum tube rectifier shown at A and to the one using the silicon rectifier shown at B.

When terminal A is positive with respect to terminal B, the diode will conduct and current can flow through the diode and through the load. During this part of the cycle electrons will flow into the plates of C1 and C2 marked with a minus sign. At the same time electrons will flow out of the other plate of both capacitors. Electrons leaving the positive side of C1 will flow directly through the diode being attracted by the positive voltage at terminal A. Because the resistance of the rectifier is low, C1 can charge up to a value almost equal to the peak ac voltage. However, the electrons leaving the positive side of C2 must flow through the filter resistor R1. Thus, capacitor C2 cannot charge to as high a voltage as capacitor C1.

When the ac input voltage drops so that the diode no longer conducts, capacitors C2 and C1 begin supplying the power required by the load. However, capacitor C1 is charged to a higher voltage than capacitor C2. Hence, capacitor C1 begins supplying power to the load and also tries to charge capacitor C2. Since electrons flowing from the negative side of C1 to the positive side must flow through filter resistor R1, the attempt of these electrons to charge C2 and flow through the load resistor will be somewhat restricted by R1. The net effect is that the resistor R1 prevents C2 from charging to as high a peak voltage as it would if R1 were not on the circuit. Because C1 charges to a higher voltage than C2, and while discharging tends to charge C2, the voltage across C2 is more nearly constant than the voltage across C1.

AN L-C FILTER

The disadvantage of the resistor-capacitor type of filter shown in Fig. 13 soon becomes apparent if you consider the size of the resistor and capacitor needed to obtain effective filtering and also the effect that the high value of resistance in the circuit has on the dc voltage present.

Consider Fig. 13 again for a minute. Suppose that the ac component of the pulsating dc across C1 is 10 volts and that the maximum ac component that can be applied to the load is only 1 volt. This means that the filter network consisting of R1 and C2 must produce a 9-to-1 voltage division. In other words, of the 10 volts ac appearing across C1 we must drop 9 volts across R1 and 1 volt across C2. This means that the resistance of R1 must be about 9 or 10 times the reactance of C2.

A 25-mfd capacitor (which is fairly large, particularly if it must be built to withstand high voltages), has a reactance of about 100 ohms at a frequency of 60 cycles. If we used such a capacitor for C2, then the resistance of R1 would have to be 10 times its reactance, or about 1000 ohms. If the current drawn by the load is 100 milliamperes, then the voltage drop across R1 due to the load current flowing through it will be 1000 ohms times .1 amp (100 ma), or 100 volts. This means that we will be losing 100 volts of our dc voltage across R1. Furthermore, the power being wasted by this resistor will be

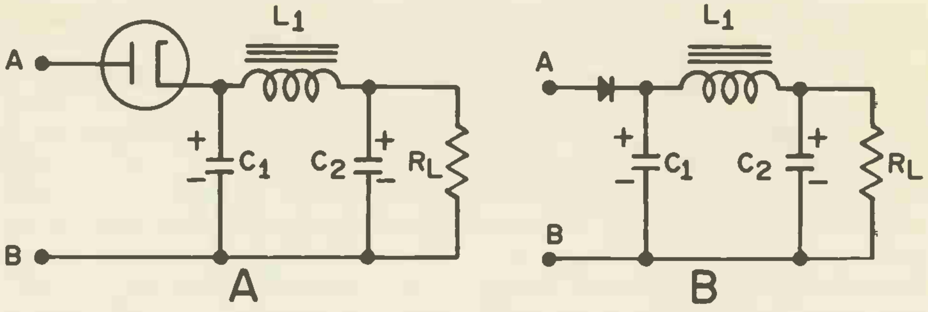

Fig. 15. An L-C filter.

equal to the voltage across it times the current flowing through it, which is 100 × .1, or 10 watts. You can see that we have an appreciable voltage drop and a sizable amount of power wasted by this resistor.

In some cases the current drawn through the filter resistor is not so high that the voltage drop across the resistor cannot be tolerated. Thus you will see this type of filter used in equipment when the current taken from the power supply is moderate. In equipment when the current drawn is high, a different type of filter is used. Such a filter is shown in Fig. 15. Notice that this circuit is identical to Fig. 13, except that we have substituted an iron-core choke for R1. The action of this filter network is quite similar to that of the filter network shown in Fig. 13. Again, capacitor C1 is charged by the rectifier and because there is no resistance in the circuit other than the rectifier resistance, it charges to a fairly high value. Just as before, however, the voltage across it will be pulsating (the equivalent of dc with ac superimposed on it).

Now consider the reaction of the choke to ac and dc. You will remember that a choke has inductance, and an inductance offers reactance to the flow of ac through it. At the same time the only opposition that the choke will offer to the flow of dc through it is due to the resistance of the wire used to wind the coil. By using a large size wire, this resistance can be kept quite low. The choke may have a dc resistance of 100 ohms or less and at the same time have a reactance of several thousand ohms to the 60-cycle ac applied to it.

The reaction of the L-C filter to dc is shown in Fig. 16A, and the reaction to ac is shown in Fig. 16B. In 16A we see that as far as the dc is concerned, the choke acts as a

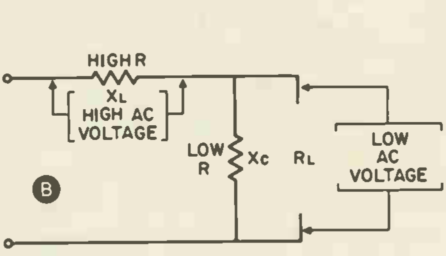

Fig. 16. Equivalent circuit showing the reaction of an L-C filter to dc at A, and to ac at B.

low resistance while the capacitor acts as a very high resistance. Thus, we have practically all of our dc voltage appearing across the capacitor and very little of it being lost across the choke. However, as shown in 16B, the choke acts as a high resistance to the ac while the capacitor acts as a low resistance. Thus, most of the ac voltage will appear across the choke and very little of it will appear across the capacitor.

There is another way of looking at the action of the L-C filter. We can consider the charging of the capacitors and the opposition offered by the choke more or less in the same way as we considered the action of the R-C filter in Fig. 13. During the first half-cycle, when terminal A of either rectifier circuit is positive and terminal B is negative, the rectifier will conduct. Electrons will flow from terminal B into the sides of C1 and C2 marked with a minus sign. These electrons will force electrons out of the positive side of C1 and they will flow through the rectifier with little or no opposition. However, the electrons leaving the positive side of C2 will encounter opposition in the choke. This is because at the instant when the electrons first try to get through the choke there is no magnetic field built up in the choke. You will remember that a choke is a device that opposes any change in current flowing through it. Therefore, the choke tries to keep the electrons leaving the positive side of C2 from flowing through it. Eventually this opposition offered by the choke is overcome, a magnetic field is built up in the choke, and some of the electrons can flow through the choke and capacitor C2 will be charged. However, the voltage to which C2 is charged will not be as high as the voltage to which C1 is charged because of the opposition of the choke.

When the ac input voltage drops below the voltage to which C1 is charged, the rectifier will no longer conduct and no current can flow through it. Now C1 and C2 and choke L1 must supply the current needed by the load. C2 does this by attempting to discharge. C1 also tries to discharge to charge C2 and to supply part of the current required by the load. At the same time there is a magnetic field built up in the choke L1 which does not collapse instantly but instead tries to keep current flowing in the direction it was flowing when the rectifier was conducting. It too helps to maintain the current flow through the load RL. Thus in this type of filter we have energy stored in three places: the capacitors C1 and C2 (as we did in the circuit in Fig. 13), and in the magnetic field of choke L1.

In the circuits shown in Fig. 15, the rectifier tube in Fig. 15A offers a certain amount of resistance to the flow of current through it. In addition, the rectifier tube has a cathode which must be heated by a heater. It takes some time for the cathode to come up to operating temperature; when a tube first starts conducting, the cathode is below normal operating temperature, and the tube offers a higher resistance to the flow of current through it than it does when the tube reaches its full operating temperature. Thus when the power supply is first turned on and the tube reaches a temperature at which the cathode begins to emit electrons, the tube offers considerable resistance to the flow of current through it. This limits the charging current through the tube that charges the input filter capacitor C1. In a matter of a few seconds capacitor C1 is charged and from then on the current that must flow through the tube is within the tube's capabilities.

In the circuit shown in Fig. 15B, however, the silicon rectifier does not have a cathode which must be heated -- as soon as the power is turned on the rectifier begins to conduct to charge the input capacitor C1. If you turn the equipment on at the peak of the ac cycle there will be a very high voltage immediately impressed across C1 and a very high current will flow through the rectifier. As a matter of fact, the current might be so high that it could burn out the rectifier. Even if the power is turned on when the ac voltage is at zero, a high current will flow through the diode to charge C1 as the voltage rises to a peak value with terminal A positive with respect to terminal B. If C1 is large enough, this could burn out the rectifier.

This problem of excessively high charging current can be overcome with the circuit shown in Fig. 17. Here a resistor is connected in series with the silicon rectifier to limit the current flow. In some equipment, this resistor is a fairly low resistance, fixed-value resistor. In other applications, the resistor may be a thermistor. You will remember that a thermistor is a resistor with a negative temperature coefficient. This means that the resistance of the thermistor decreases as its temperature increases.

With a thermistor for the resistor R1 shown in the circuit in Fig. 17, the thermistor will offer a fairly high resistance to current flow when the equipment is first turned on. This will limit the charging current that flows through the diode to charge C1 to a reasonable value. As the current flowing to the thermistor heats the thermistor and its resistance goes down, the charge across capacitor C1 will build up slowly so that the diode current never reaches an excessively high value. By the time the capacitor is fully charged, the thermistor temperature will have increased to a point where the resistance of the thermistor has dropped to a low value so that the thermistor has very little effect on the overall operation of the circuit.

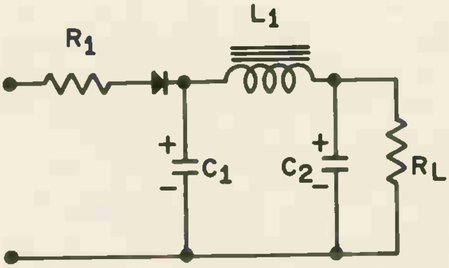

Fig. 17. Power supply with series-limiting resistor.

If you have to service a power supply of this type (where a resistor or a thermistor is used in the circuit in series with a silicon rectifier) and you find that the resistor or thermistor is opened, do not simply short the resistor or thermistor out of the circuit. If you do the chances are that the diode will burn out either the first time that you turn the equipment on or shortly thereafter.

The rectifier tubes used in low power equipment such as radio and television receivers are high vacuum rectifier tubes. However, in transmitters and in industrial applications where high voltages are involved you will often run into mercury-vapor rectifier tubes. Tubes of this type cannot be subjected to high peak currents through them without damaging the tube. A mercury-vapor rectifier tube in the circuit such as shown in Fig. 15A lasts only a short time. We can keep the peak current through the tube down to a safe value by using a somewhat different filter circuit known as a choke-input filter.

CHOKE-INPUT FILTERS

The filter circuits shown in Figs. 15 and 17 are called capacitor-input filters because the rectifier is connected directly to the input filter capacitor. A choke-input filter such as those frequently used with a mercury-vapor rectifier tube is shown in Fig. 18. Here, the rectifier tube is connected to a filter choke rather than a capacitor. Power supplies of this type will be found in radio and television transmitters and in industrial applications where comparatively high voltages are encountered.

It is easy to see how this type of filter works when we remember that the pulsating dc at the output of the rectifier tube is actually dc with ac superimposed on it. The choke offers little or no opposition to the flow of dc through it. On the other hand, the choke offers a high reactance to the flow of ac through it and at the same time the capacitor offers a low reactance to the ac across it. Thus the choke and the capacitor form a voltage divider network for the ac, so that most of the ac is dropped across the filter choke and very little of it appears across the load.

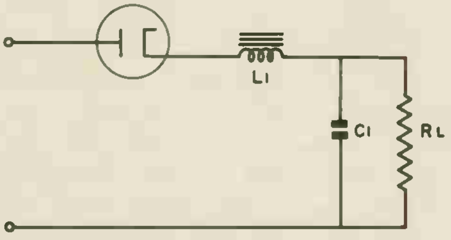

Fig. 18. A choke-input filter.

A more elaborate filter network is the two-section filter shown in Fig. 19. Again, it is a choke-input filter because the first element in the filter network is a choke. This type of filter network is frequently used in power supplies of radio and TV transmitters and of industrial electronic equipment where mercury-vapor rectifier tubes are used.

The choke-input filter has several advantages over the capacitor-input filter, even though the voltage obtained at the output of a choke-input filter is not quite as high as it is at the output of equivalent capacitor-input filters. In other words, if you feed the same pulsating dc into a choke-input filter you will not obtain as high an output voltage for a given load as you can with a capacitor-input filter. However, this type of filter has better voltage regulation than a capacitor-input filter. The voltage regulation of a power supply is the ratio of the full-load voltage to the no-load voltage. With a choke-input filter there is not as great a variation between the no-load and the full-load voltages as there is in the capacitor-input filter.

Another big advantage of the choke-input filter is that the peak current passed by the rectifier tube is held to a reasonable value. In a choke-input filter, the choke offers considerable reactance to any change in current flow through it. Thus, when the rectifier tube tries to conduct current heavily to charge C1 in Fig. 19, the input-filter choke L1 offers considerable reactance or opposition to the change in current flow through it. It tends to smooth

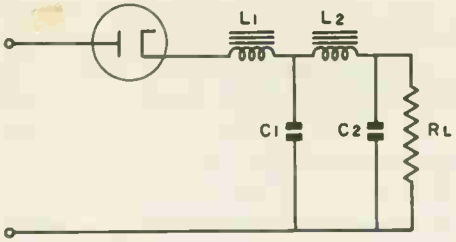

Fig. 19. A two-section choke-input filter.

out the pulses of current through the rectifier tube. The current pulse flowing through the rectifier tube flows for a slightly longer time than it would flow with an equivalent capacitor-input type of filter, and the peak amplitude of the current flowing through the rectifier tube is not as high as it would be with the capacitor input filter. This is a big advantage in a power supply using mercury-vapor rectifier tubes, because they can easily be destroyed by excessively high current pulses through them.

The filter network shown in Fig. 19 is quite effective in eliminating hum. Consider what would happen if the output of the rectifier had an ac voltage of 100 volts superimposed on the dc. If the two sections of the filter network are designed so that each choke has a reactance about 10 times as high as the reactance of the capacitors, each section will have approximately a 10-to-1 ripple voltage division; thus if there are 100 volts ac at the output of the rectifier, L1 and C1 will divide this voltage so that there will be only 10 volts appearing across C1. Now L2 and C2 act as a voltage divider network and divide this 10 volts further, so that the voltage across C2 would be only 1 volt. Thus, the two-section filter has reduced the ac hum or ripple voltage at the rectifier output from 100 volts to 1 volt.

The input filter choke, which is L1 in Fig. 19, is often a swinging choke. A swinging choke is designed so that it saturates rather easily and thus its inductance will vary appreciably as the current through the choke changes. When the current through the choke becomes high, the inductance and hence the inductive reactance of the choke decrease, but when the current through the choke is low, the inductance and hence the inductive reactance increase. Thus we have in effect a variable reactance between the rectifier tube and the input-filter capacitor; this variable reactance helps to improve voltage regulation at the power supply output. This type of choke is particularly useful in circuits where the load current goes through wide variations. If the load current goes down, the reactance of the choke increases. The increased reactance limits the charging action of the rectifier tube and keeps the output voltage from rising appreciably. On the other hand, if the load current increases, the reactance of the choke decreases, allowing the rectifier to charge C1 to a higher value so the capacitor can supply the increased current demand.

FACTORS AFFECTING THE OUTPUT VOLTAGE

In any filter network containing a filter choke or a filter resistor, the dc current flowing through the load must also flow through the filter choke or filter resistor. Thus, there will be a voltage drop across this choke or resistor; the exact value of the voltage drop will depend upon the dc resistance and the current flowing. We already pointed out that if a 1000-ohm filter resistor is used in the circuit and the current that is flowing is 100 milliamperes, the voltage drop across the filter resistor will be 100 volts. On the other hand, if a filter choke having a dc resistance of 100 ohms is used, a current of 100 milliamperes will produce a voltage drop of only 10 volts across it.

If the current drawn by the load changes, the output voltage at the output of the filter network will change. You can see why this is so--the current must flow through the filter resistor or filter choke. If the current flowing through the choke or resistor changes, the voltage drop across it will change, and hence the voltage at the output of the power supply will have some tendency to change.

The output voltage is also affected by the size of the filter capacitors used. If the filter capacitors used are small, then the rectifier is unable to keep them completely charged; if the filter capacitors are large, once the rectifier gets them charged, they will stay charged to a voltage near the peak ac voltage being applied to the rectifier tube.

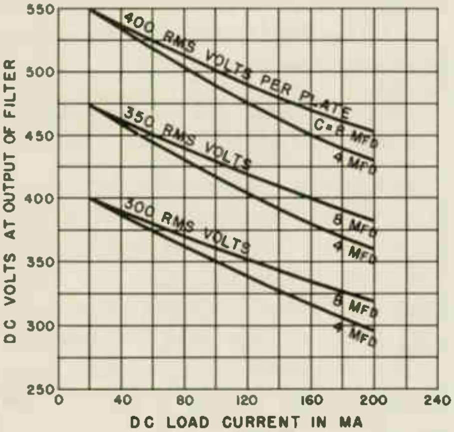

Fig. 20. How the size of the input capacitor of a filter affects the output voltage for different values of load current.

Of course, it is difficult to say whether a filter capacitor is large or small. Whether or not it is large for the particular circuit depends upon how much current is being drawn from the circuit. If the current drain is low, then a capacitor of 10 or 20-mfd will usually be sufficient to keep the power supply output voltage at or near the peak value of the ac voltage applied to the rectifier tube. However, if the current drain from the power supply is large, then the voltage across the power supply output will be considerably less than the peak ac value if the capacitors used are 10-mfd or 20-mfd capacitors.

To give you some idea of how the size of the input filter capacitor affects the output voltage, we have shown a graph in Fig. 20. The graph is for a full-wave rectifier. It shows how the output voltage varies with different load currents for both 4-mfd and 8-mfd capacitors. We have shown this for three separate input voltages. Notice that in each case when the current drain is low, the output voltage is substantially above the rms input voltage applied to the rectifier. Remember, of course, that the peak value of a 300-volt rms voltage is actually 1.4 times 300 volts.

Fig. 21 shows a comparison between a choke-input and capacitor-input type of filter. Notice that with a capacitor input the output voltage at low loads is substantially higher than it is for a choke input. However, as the load is increased, the output voltage from a capacitor-input type of filter drops rapidly. The output voltage from the choke-input type filter also drops as the load is increased, but it does not drop nearly as rapidly as it does with a capacitor-input type of filter.

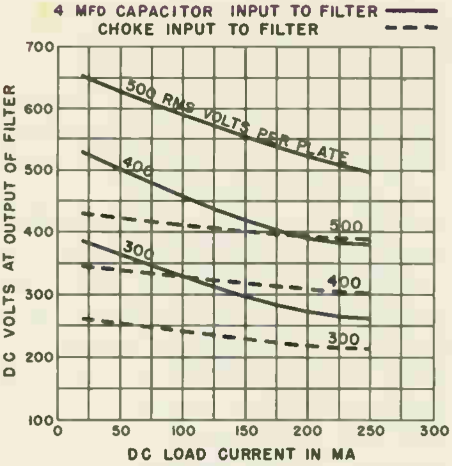

Fig. 21. How the output voltage of a filter network varies for different values of load currents and input voltages. The solid curves are for a capacitor-input filter; the dashed curves for a choke-input filter.

SUMMARY

In this section we have covered some of the more important types of filter networks you are likely to encounter in your career as an electronics technician. You have seen that these networks vary from comparatively simple filters consisting only of a capacitor up to networks containing two chokes and two filter capacitors.

Simpler types of filter networks can be used where the current drain is low and where the filtering does not have to be very good. The more elaborate filters are used in power supplies having a high current drain and in cases where good filtering is required to supply pure dc at the power supply output.

The circuits in this section of the lesson are shown with a half-wave rectifier. The same filter circuits are also used with full-wave rectifiers.

Study the circuits shown in this section. You should be familiar with each of these circuits. You might try drawing these circuits several times to get familiar with the circuit arrangement. Copy them from the book the first few times you try drawing them and then try to reproduce the circuit from memory. This will help you remember what the circuits look like, and if you can remember what they look like, the chances are that you'll be able to remember how they work.

SELF-TEST QUESTIONS

(i) To what value may the input filter capacitor charge in a simple capacitor filter such as shown in Fig. 11?

(j) In what type of application may a simple capacitor-type filter (such as shown in Fig. 11) be used?

(k) What advantage does an R-C pi-type filter (such as shown in Fig. 13) have over the simple capacitor-type filter shown in Fig. 11?

(l) What is the disadvantage of the R-C pi-type filter, and how can this disadvantage be overcome?

(m) What is the purpose of the resistor R1 in the power supply shown in Fig. 17?

(n) Why are choke-input filters used with mercury-vapor rectifier tubes?

(o) What advantage does a choke-input filter have over a capacitor-input filter?

(p) What is a swinging choke?

Typical Power Supplies

The two main sections of the power supply are the rectifier and the filter section. Now that we have discussed both these sections, let's examine some typical power supplies and see what they look like. First we'll look at some power supplies using tube-type rectifiers which might be found in equipment using vacuum tubes. Remember that in these circuits the rectifier operates in the same way as a selenium or silicon rectifier would operate. Insofar as the rectification action is concerned, it makes little difference whether a tube, a selenium rectifier, or a silicon rectifier is used. In the circuits where tubes are used, we will in some cases show how the tube heaters are connected. After looking at a few tube circuits we will look at some typical power supplies using silicon rectifiers and then at a more complex regulated supply.

UNIVERSAL AC-DC POWER SUPPLIES

The universal ac-dc power supply is so called because it can be operated from either an ac or a dc power line. When these power supplies were first used in radio receivers, manufacturers played this feature up, but actually this type of power supply is used to keep costs at a minimum.

The circuit of an ac-dc power supply for a 5-tube radio receiver is shown in Fig. 22. This supply not only supplies the dc voltages required by the plates and screens of the tubes in the receiver but also contains the heater supply for the heaters of the various tubes. First, let us look at the heater supply. Notice that the heaters of the various tubes are connected in series and that they are operated on ac. In this type of power supply you will always find that the heater of the rectifier tube, in this case a 35W4 tube, is connected directly to one side of the power line. The heater of this particular tube is tapped, and a pilot light is connected in parallel with one part of the heater. The pilot light will light when the set is turned on. The tube is designed to be operated with the pilot light connected in parallel with part of the heater, so if in servicing a receiver using a tube with a pilot light tap you should find that the pilot light is burned out, it is a good idea to replace it to keep the heater current in the rectifier tube within its rated value.

Next to the 35W4 rectifier tube in the heater circuit (or heater string, as it is usually called) you will always find the high-voltage power output tube. By a high-voltage tube we mean a tube that requires a high heater voltage. In the diagram we have shown, the tube is a 50B5 tube. As the 50 suggests, a heater voltage of 50 volts is required to operate the tube.

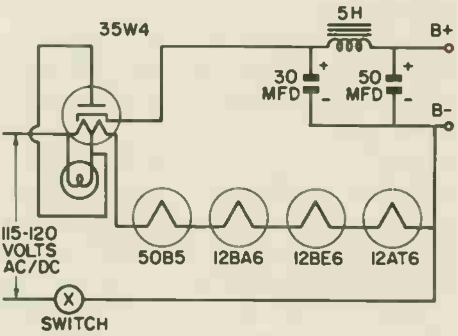

Fig. 22. A typical ac-dc power supply.

Next to the output tube you will usually find the i-f tube. In this diagram, the i-f tube is a 12BA6 tube. It is a tube with a 12.6-volt heater.

Next to the i-f tube you will find the converter tube. The 12BE6 tube is a converter tube designed so that the single tube performs two tasks: one part of the tube is the oscillator and the other part is the mixer.

The last tube in the heater string is always the first audio tube. In this circuit it is a 12AT6 tube. This tube is placed at the end of the heater string nearest B- to keep hum at a minimum, because hum picked up in the first audio tube will be amplified by the entire audio system and could be objectionable. The 12AT6 tube is a dual-diode-triode tube: it has two diodes and a triode inside the same glass envelope. As the 12 preceding the type designation suggests, the tube requires a heater voltage of about 12 volts--to be exact, 12.6 volts.

Now if we examine the rectifier circuit you will see that the plate is connected to a center tap on the rectifier heater. This means that the B supply current flowing through the plate of the tube must flow either through part of the rectifier heater or through the pilot light back to one side of the power line. The purpose of connecting the plate this way is to provide some protection in the event of a short in the receiver. If there is a short in the receiver, the rectifier tube will begin passing excessive current. If this current becomes too high, the pilot light and half the rectifier heater will burn out, opening the circuit and protecting the receiver and the house wiring.

The rest of the power supply is similar to the circuit you studied already. The filter network consists of a capacitor-input filter; the input filter capacitor is the 30-mfd capacitor, and the output filter capacitor is the 50-mfd capacitor. Usually these two capacitors are in a single container that has only three leads brought out from it. Since the negative leads are both connected to B-, a common negative lead and two separate positive leads are usually used. The capacitor is usually a tubular type of capacitor with a paper cover impregnated with wax. The capacitor is mounted on the receiver chassis by means of a mounting strap, or in a receiver with a printed circuit board, the leads are soldered directly to the circuit board. Often this is the only kind of mechanical mounting used.

Capacitors in this type of receiver are usually rated at 150 volts. The normal output voltage of this type of power supply under load is usually somewhere between 90 and 105 volts.

Not all universal ac-dc power supplies use a filter choke. In the circuit shown in Fig. 22, the plates and screens of all of the tubes are operated from the B+ output of this power supply. However, sometimes you will find a filter resistor used in the power supply in place of the filter choke. When this is done, the plate of the output tube is usually connected directly to the cathode of the rectifier tube so that the current drawn by the output tube plate will not flow through the filter resistor. This tube usually draws more current than all the other tubes in the receiver combined.

The output tube is normally a beam tube or a pentode tube, and the plate current depends very little on plate voltage. Therefore if there is some hum voltage applied to the plate of the tube, it usually does not cause any plate current variation and hence is not heard as hum in the output from the loudspeaker. The screen voltage for the output tube and the plate and screen voltages for the remaining tubes are obtained at the output of the power supply where the additional filtering obtained from the filter resistor and the output filter capacitor will reduce the ripple from the rectifier to a low value.

In some of the later table-model radio receivers only four tubes are used; a selenium rectifier or a silicon rectifier is used in place of a rectifier tube because either of these has a considerably longer life. In receivers of this type, tubes with higher heater voltage requirements are often used, so that the sum of the heater voltages required by the four tubes adds up to about 120 volts. If the heater voltage required by the tubes is less than the line voltage, a voltage-dropping resistor can be placed in series with the heaters to use up the leftover voltage. This will cause the total voltage drop across the series-dropping resistor and the tubes to be equal to the line voltage, thus allowing each of the tubes to have its required heater voltage.

Of course, in any heater string where tube heaters are connected in series, all the tubes must have the same heater current rating. Tubes designed for this type of service have what is called a controlled warm-up. This means that the tube heaters are made so that they all reach operating temperature at the same time. This prevents one tube from warming up too quickly and from having too high a voltage across its heater.

The voltage across the tube heater will depend upon its resistance, which changes with temperature. As long as all the tubes warm up at the same rate, their resistances change at the same rate. In this way, a high voltage across any of the tubes is avoided.

Before leaving our study of this type of power supply, it is worthwhile to consider what will happen if a tube such as the 12BA6 tube in Fig. 22 develops a cathode-to-heater shortage. The cathode will usually be connected either to B- directly or to B- through a low-value resistor; this will effectively short out the heaters of the 12BE6 and 12AT6 tubes and, as a result, these tubes will not light.

If you're called upon to service a receiver of this type and you find that one or more of the tubes is not heating, look for a cathode-to-heater short in either the tube which doesn't light that is highest up on the string, or the tube preceding it. If none of the tubes lights this is an indication, since the tubes are connected in series, that the series string is open -- chances are that the heater of one of the tubes has burned out.

A TYPICAL FULL-WAVE POWER SUPPLY

Fig. 23 illustrates a typical power supply using a power transformer and full-wave rectifier. This type is found in many radio and TV receivers and transmitting equipment, as well as in the equipment used in industrial electronics.

Notice that the power transformer has a primary winding to which the 115-volt ac power line is connected; a high-voltage secondary with its center tap grounded, and the two end leads connected to the plates of the rectifier tube; and the two filament

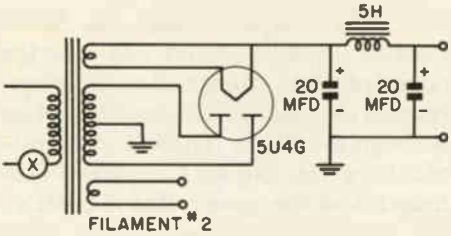

Fig. 23. A typical power supply using a transformer and full-wave rectifier.

windings. One filament winding is used to supply the heater voltage required by the rectifier tube, and one filament winding is used to supply the heater voltage for all the other tubes in the set.

In this power supply we have shown a 5U4G rectifier tube, which requires a heater voltage of 5 volts and a heater current of 3 amps. Thus the rectifier filament winding on the transformer must be capable of supplying 5 volts at a current of 3 amperes.

The winding marked filament number two is used to supply the heater voltage required by all the other tubes in the set. You will notice that this winding is called the filament winding, not the heater winding. This is a carry-over from the old days of radio when most of the tubes were filament-type tubes and few had a separate cathode and heater.

In an electronic device using this type of power supply, the heaters of the tubes (with the exception of the rectifier tube) are connected in parallel. Since the tubes are connected in parallel, you will find that all of the tubes are designed to operate from the same heater voltage. In most cases equipment using this type of power supply has tubes with heater voltage ratings of 6.3 volts. The filament winding must be capable of supplying the heater current required by all of the tubes. The tubes may require different heater currents since they are connected in parallel. You can determine the total current the winding must supply by looking up the heater current required by the individual tubes in a tube manual and adding these figures together.

Again, the filter network used in this power supply is a capacitor-input type. Notice that the capacitors have a lower capacity than those used in the circuit shown in Fig. 22. It is not as necessary to use large capacitors in a full-wave rectifier type of power supply as it is in a half-wave rectifier to obtain the same amount of filtering. Of course, in some power supplies in which it is essential to keep the hum voltage very low, you will find larger filter capacitors. You may also find a two-section filter using an additional choke and a third filter capacitor.

In a power supply such as the one shown in Fig. 23, the two capacitors will probably be mounted in a single container. If a cardboard tubular type is used, one common negative lead and two separate positive leads will be brought out of the container. The same color leads will probably be used for the two positive sections since they both have the same capacity. In some pieces of equipment a metal can-type capacitor might be used -- with this type the can is usually the negative terminal. Mounting the capacitor on the metal chassis automatically makes the connection between the negative terminal and the chassis. The positive leads are brought out of two separate terminals.

DUAL-VOLTAGE POWER SUPPLIES

A diagram of a typical dual-voltage power supply is shown in Fig. 24. This diagram is actually quite similar to the diagram of circuits used in a modern color-TV receiver. Notice that a voltage that is negative with respect to ground is developed by the diode D1 and its associated circuitry. Diodes D2 and D3 are used in a half-wave voltage doubler circuit.

In this circuit when terminal A is negative with respect to terminal B, current flows from A through R1 and D1 to charge capacitor C1. A simple pi-type R-C filter is used in this section of the power supply because the current requirements are low and there will be very little voltage drop across R2. At the same time with the two capacitors, small value capacitors can be used and adequate filtering obtained.

When terminal A is negative, current also flows through the thermistor R3 through R4 and into the negative plate of capacitor C3. Electrons flow out of the positive plate through the diode D2 back to terminal B of the power line. When terminal A of the power line is positive and terminal B is negative the voltage will be placed in series with the voltage built up across C3, so that capacitor C4 is charged to a value approaching twice the peak line voltage through diode D3. This provides an output voltage which is positive with respect to ground and approximately equal to twice the ac line voltage.

The thermistor R3 is put in the circuit to prevent high current surges through the silicon diodes D2 and D3 when the equipment is first turned on. R4 is used in the circuit to provide further protection. If the equipment is turned on and operating for some time, the resistance of the thermistor will drop to a low value. If the equipment is turned off for a

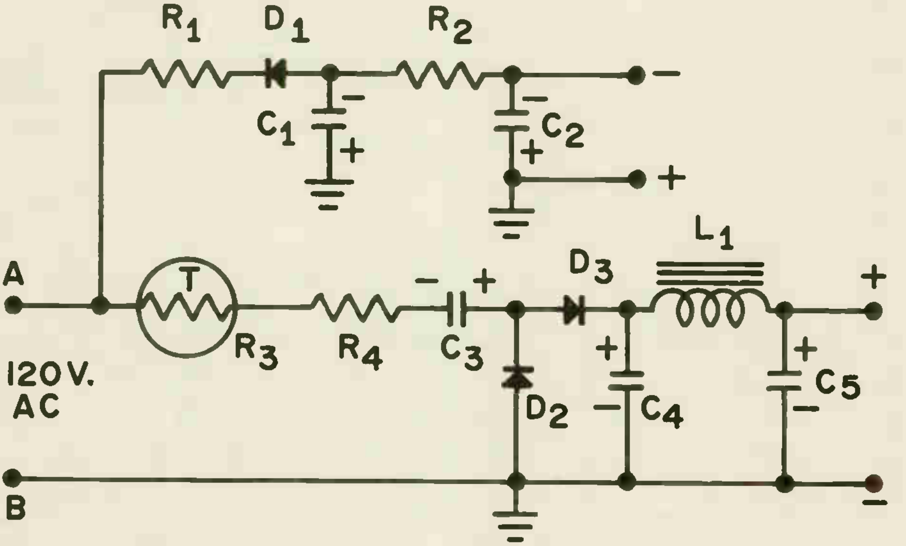

Fig. 24. A typical dual-voltage power supply.

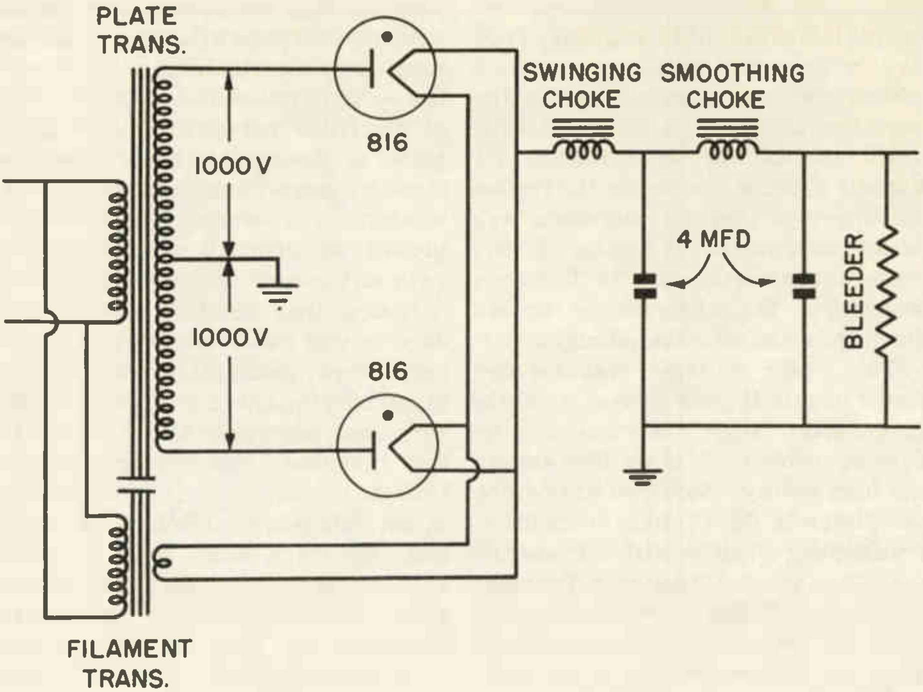

Fig. 25. A typical transmitter power supply.

few seconds and then turned back on, the charging current through the diodes could be quite high and damage them. R4 is put in the circuit; its value does not change and it limits the current through the diodes to prevent their damage under this circumstance.

The power supply shown in Fig. 24 is typical of the power supply you are likely to run into in both monochrome and color television receivers. A voltage-divider network may be used across the output of either supply to provide different value voltages. This power supply is comparatively inexpensive; it eliminates the need of a power transformer and with modern silicon diodes is comparatively trouble-free.

HIGH-VOLTAGE POWER SUPPLIES

Another power supply is shown in Fig. 25. This is the type of power supply you will find in transmitting equipment or in other equipment where high operating voltages are required. Notice that in this power supply, full-wave rectification is used. Also notice that it has two separate rectifier tubes. Separate rectifier tubes rather than a single tube with two plates are used in high-voltage supplies because the voltages are so high that they would simply arc across inside the tube. The type 816 tubes shown in this supply are mercury-vapor tubes designed for use in power supplies where the operating voltages are not too high and where the current requirements are not too great. They are often used in power supplies where the ac input voltage to the rectifier is between 1000 and 2000 volts, and the current drain does not exceed 250 ma. As far as the transmitting-type power supplies are concerned, an output voltage of 1000 volts across each half of the secondary of the high-voltage transformer is not considered high.

The high-voltage transformer found in this type of power supply is frequently called a plate transformer because it is used to supply the high voltage required to operate the plates of the various tubes in the transmitter. The rectifier tubes are operated from a separate filament transformer. In a power supply using type 816 tubes, the filament voltage required by these tubes is 2.5 volts and the current required is 2 amps. Therefore, this filament transformer must be capable of supplying a total of 4 amps at a voltage of 2.5 volts. The filament transformer must have good insulation between the secondary winding, the transformer core, and the primary winding; otherwise the high voltage will arc through the insulation either to the primary winding or to the transformer core.

At the input of the power supply filter network is a swinging choke. This is common practice in transmitter power supplies because it improves the voltage regulation, and also because it affords additional protection for the mercury-vapor rectifier tubes.

The second choke in the power supply is called a smoothing choke. This is the same type of choke shown in the power supplies in Figs. 22 and 23. It is called a smoothing choke in transmitting equipment because its primary purpose is to smooth out the ripple and also to distinguish it from the swinging choke used at the input of the filter network. A smoothing choke is designed to keep its inductance as nearly constant as possible, whereas a swinging choke is designed so that its inductance will vary as the current through it varies.

Notice that the filter capacitors used in this power supply are 4-mfd capacitors. Each of these capacitors is usually mounted in its own separate container. Occasionally you will find two small high-voltage capacitors in the same container, but this is not common practice. Also notice that the capacitors have a much smaller capacity than those in the two power supplies we discussed previously. These capacitors are oil-filled capacitors and it is quite costly to make this type of capacitor with a large capacity. On the other hand, capacitors used in circuits like those in Fig. 22, Fig. 23, and Fig. 24 are electrolytic capacitors and very large capacities can be obtained at a very moderate cost.

Effective filtering is obtained with the smaller-size capacitors in this supply, because two filter chokes are used. The inductance and hence the inductive reactance of these chokes are usually somewhat higher than that of filter chokes used in lower voltage equipment. The choice of using either large chokes or large filter capacitors is simply one of cost. At low voltages it is more economical to use large capacitors and low-inductance chokes, but at high voltages it is more economical to use high-inductance chokes and low capacities. The net result is the same as far as the filtering action is concerned. Another component that you will find in transmitting-type power supplies is a bleeder. A bleeder is a resistor connected across the power supply output. The bleeder serves two purposes: it improves the voltage regulation and is also used for safety.

A bleeder resistor connected across the power supply keeps the minimum current at a reasonable value. If the current drawn by the load connected to this power supply were to drop to zero, the two filter capacitors would be charged up to a value equal to the peak voltage across half of the secondary of the plate transformer. If the transformer had an rms voltage of 1000 volts across each half of the secondary, this would mean that the capacitors would charge up to a voltage of about 1400 volts. This may be high enough to destroy the capacitors. Also, the chokes have a definite maximum voltage that can be applied to them. If the voltage goes too high, the insulation between the choke winding and the core may break down. This will destroy the chokes. If either of the chokes or capacitors shorts, the rectifier tubes will pass such a high current that they may be ruined. There is also the danger of burning out the plate transformer. Furthermore, if the voltage reaches too high a value, the rectifier tubes may arc over internally. A bleeder connected across the power supply output can eliminate this danger. With the bleeder across the output, if the equipment current drops to or almost to zero, the bleeder current will continue to flow. If the output voltage starts to rise, the bleeder current will increase because the current flowing through any resistor increases if the voltage across it increases. The bleeder current will keep the voltage from climbing to an unsafe value.

Another important reason for using the bleeder is that an oil-filled capacitor such as those found in this type of power supply can hold a charge for a long time. If the two 4-mfd capacitors used in the supply were charged up to a voltage of 1000 volts or more and a technician servicing the equipment accidentally touched one of these capacitors, he could receive a very dangerous shock. Under certain conditions it could be fatal. This danger can be greatly reduced by connecting a bleeder across the power supply so that when the equipment is turned off the capacitors are discharged through the bleeder.

You may have occasion to work on high-voltage power supplies at some future date. Remember that a bleeder is connected across the power supply for safety as well as to improve the voltage regulation. Therefore if the bleeder in a power supply burns out, it should be replaced. However, never rely on a bleeder to discharge high-voltage filter capacitors. If you have to work on a high-voltage power supply, your first step should be to remove all voltages from the supply. To do this, turn the power supply off; if there are fuses in it, remove the fuses so that no one can accidentally turn it on; disconnect it completely from the source if you can. Often it is not possible or convenient to completely disconnect the equipment from the voltage source but if it is shut off and any fuse in the circuit is removed, it should be safe. Next, before you start to work on the supply, discharge all filter capacitors in the power supply. The capacitors should be discharged with a heavy metal rod that has a good insulated handle so that you will not come in contact with the metal rod. Use the metal rod to short together the terminals of the capacitor to discharge it. Touch the grounded terminal of the capacitor first and slide the rod over to touch the other terminal. Do this several times to be sure the charge is completely removed. After the capacitors have been discharged, the power supply should be safe to work on.

Keep this point in mind: high voltage capacitors, or for that matter any large capacitors, should be discharged before you start to work on a piece of equipment. Many technicians fail to do this. There are some technicians who can tell about the terrific shock they received when they failed to discharge a filter capacitor. There are others that did not survive the experience to tell about it.

A TRANSISTOR-REGULATED POWER SUPPLY

A regulated power supply employing transistor voltage regulators is shown in Fig. 26. This power supply is used in a TV receiver that is designed for operation from the power line and also from a 12-volt dc source. When the power plug is plugged into a 120-volt line and the switch is turned on, the receiver will operate from the power line. When the power plug is disconnected and switch S1 is closed, the receiver can be operated from a 12-volt battery.

The operation of the power supply from the power line is comparatively simple. Two diodes, D1 and D2, are used in a full-wave rectifier circuit. When the transformer T1, which is a step-down transformer, has a polarity such that the end of the secondary connected to D1 is negative, current will flow through the diode D1 to ground and into the negative plate of C3. Electrons flow out of the positive plate of C3 to the center tap of the power transformer which is positive with respect to the end connected to D1. During the next half-cycle, when the end of the secondary connected to D2 is negative, current will flow through D2 to ground, into the negative plate of C3,

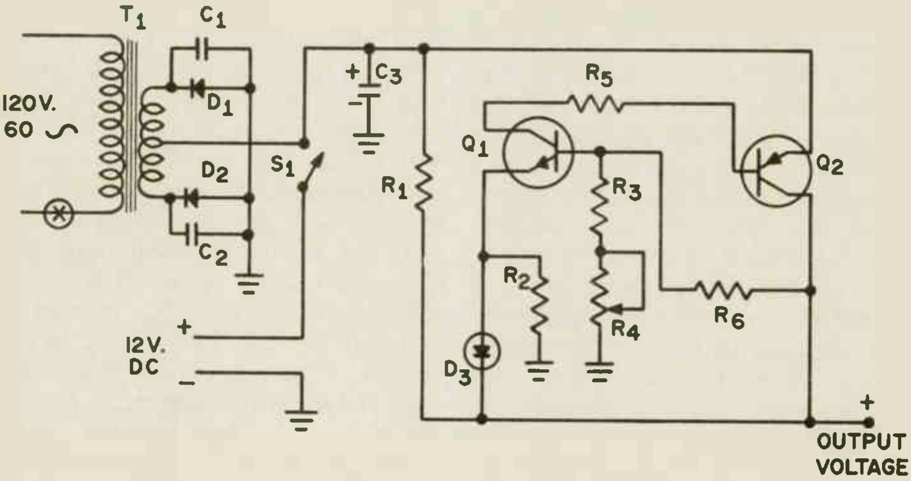

Fig. 26. A transistor-regulated power supply.

out of the positive plate of C3 and back to the center tap of the secondary winding on the power transformer.

The remainder of the components used for the power supply are used for the purpose of regulating the voltage. In other words, the power supply voltage is maintained constant at approximately 12 volts regardless of the load drawn from the supply. The transistor Q2 is a PNP transistor that is used as a series voltage regulator. Notice that the emitter of this transistor connects directly to the positive side of C3. You can consider this transistor as working more or less as a variable resistor: if the output voltage tends to rise, the resistance increases and if the voltage tends to fall, the resistance decreases.

The effective resistance of Q2 is varied by varying the forward bias across the emitter-base junction. Notice the zener diode D3. This diode is connected in series with R2. The zener has a constant voltage of 6.3 volts across it. Therefore, the voltage drop across R2 will be equal to the output voltage minus 6.3 volts. This is the emitter voltage applied to Q1. The base voltage is determined by the voltage division occurring between R4, R3 and R6. R4 is adjustable so that the output voltage can be adjusted to 12 volts. Under these circumstances a certain current will flow through Q1 and through R5 and this will set the forward bias on Q2. If the output voltage tends to rise, the base voltage on Q1 will rise but by an amount less than the emitter voltage. The divider network consisting of R4, R3 and R6 will prevent the base from rising the full amount of the output voltage rise. On the other hand, the voltage across the zener D3 remains constant so that the voltage across R2 will reflect the entire output voltage rise. This will reduce the forward bias on Q1 which, in turn, will reduce the emitter-collector current. The reduction in the emitter-collector current will reduce the voltage drop across R5 which, in turn, will reduce the forward bias on Q2; this has the effect of increasing its resistance. The increased resistance tends to keep the output voltage from increasing.

If the output voltage decreases, the opposite happens. The base voltage on Q1 falls, as does the emitter voltage. However, the emitter voltage falls more than the base voltage, so the forward bias is increased. This increases the emitter-to-collector current through Q1 which increases the forward bias on Q2. This has the effect of reducing the resistance on Q2 and tends to keep the output voltage from falling.

This type of power supply is one of the more complex power supplies that you are likely to encounter in electronic equipment. The voltage regulation is required in order to keep the voltage reasonably constant on the various transistors used on the TV receiver. In most cases, such precise voltage regulation is not required in entertainment-type equipment.

VOLTAGE DIVIDERS

We mentioned previously that more than one operating voltage is sometimes needed in the various stages of a piece of electronic equipment. Rather than use a separate supply for each voltage needed, the usual procedure is to use a single supply designed to give the highest voltage needed, and then obtain the lower voltages required by means of a voltage divider connected across the power supply output. A typical voltage divider is shown in Fig. 27.

In this voltage divider, R1 and R2 are voltage-dropping resistors; they drop the voltage from 300 volts to the required voltages of 200 and 100 volts. R3 is a bleeder used to stabilize the voltages at points B and C. With this type of network, terminal D is the ground or common terminal. Between D and C there is a voltage of 100 volts; terminal C is positive with respect to terminal D. Between D and B there is a voltage of 200 volts and terminal B is positive with respect to terminal D. Finally, between terminals D and A there is the full power supply output voltage of 300 volts, and of course terminal A is positive with respect to terminal D.

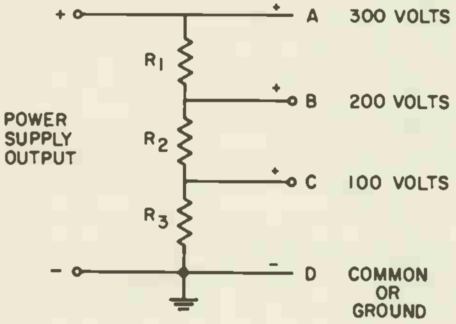

Fig. 27. A voltage-divider network.

The current flowing through R3 is called the bleeder current. It remains fairly constant and is determined primarily by the sizes of R1, R2 and R3. Usually, the size of R3 is chosen so that the bleeder current will be at least as great as the current drawn by the stages connected to terminals C and B. Choosing a value of R3 that will result in a reasonable bleeder current helps maintain good voltage regulation at terminals C and B.

The current flowing through R2 will be made up of the bleeder current plus the current drawn by the stages connected to terminal C. If this current varies, the voltage drop across R2 and hence the voltage at terminal C will vary. However, the bleeder current will remain essentially constant so that if a sizable percentage of the current flowing through R2 is bleeder current, variations in the current drawn by the stages connected to terminal C do not cause too much variation in the voltage drop across R2.

The current flowing through R1 is made up of the bleeder current plus the current drawn by the stages connected to terminals C and B. Again if the bleeder current through R1 represents a sizable part of the total current flow through R1, variations in the current drawn by the stages connected to terminals C and B do not cause too great a variation in the voltage drop across R1 so the voltage at terminal B will remain reasonably constant.

Bleeders are not used in modern midget radio receivers, but you will find them in many of the older sets. They are frequently used in TV receivers, in the low-voltage power supplies in transmitting equipment, and in industrial electronic equipment.

Sometimes one section of a tapped resistor will burn out. Often you can repair the equipment simply by connecting a resistor having the correct resistance and a suitable wattage rating across the defective section. Of course, if separate resistors are used in the voltage divider you can simply replace any defective one. If you do shunt a burned out section of a tapped resistor in a radio receiver and find the equipment is noisy after you have made this repair, the defective section may be making contact intermittently and creating the noise. Of course in this case you must replace the entire unit either with separate resistors connected in series or with a tapped resistor like the original one.

VIBRATOR-TYPE SUPPLIES

The radios installed in automobiles for years used a power supply known as a vibrator type of power supply. A schematic diagram of this type of power supply is shown in Fig. 28. The heart of this type of power supply is the vibrator, which is used to change the dc from the automobile storage battery to a pulsating current in the primary winding of the power transformer.

The vibrator consists of an electromagnet L, and a reed (R-K) placed between two sets of contacts. In the circuit shown in Fig. 28, when the switch is turned to the ON position, current will flow from the negative terminal of the battery through the switch and through the reed towards terminal M. Here it will flow from the reed to contact M, to coil L, through coil L back to the positive side of the battery. The current flowing through the coil creates a magnetic field. This magnetic field attracts the end of the reed K, pulling the reed over toward L and contact N. When the reed makes contact with terminal N, current flows through the upper half of the transformer primary winding. It flows from the top of the winding to the center tap, building up a magnetic field.

At the same instant that the reed is making its contact with terminal N, it will break its contact with terminal M so that the electromagnet will no longer be energized and the field about it will collapse. The reed is made of a spring type material so that it springs back until it makes contact with both terminal M and terminal O. At the instant contact is made with terminal O, current flows through the lower half of the primary winding of the transformer, flowing from the bottom of the winding towards the center tap. The current is flowing through the primary winding in the opposite direction to the direction in which it was flowing through the upper half of the trans-

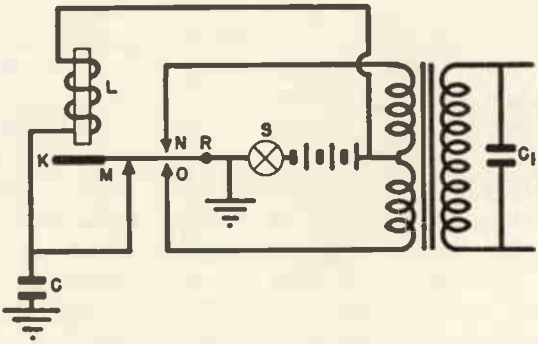

Fig. 28. A vibrator circuit.

former winding. Thus we have a field built up in one direction and then in the opposite direction. At the same time the fact that the reed makes contact with terminal M will once again complete the circuit through the electromagnet so the reed will swing over to the magnet again, making contact with terminal N. As you can see this action causes the reed to vibrate back and forth between terminals N and O. Thus we have a field built up in the primary first in one direction and then in the opposite direction. Building up this field, collapsing it, and then building up a reverse field and collapsing it, means that we have a continually changing magnetic field cutting the secondary of the transformer. By putting a large enough number of turns on the secondary, we can obtain whatever voltage we may require for the operation of the receiver.

A complete vibrator-type power supply is shown in Fig. 29. Notice that the secondary of the vibrator transformer is center tapped and that a full-wave rectifier is used. The capacitor C_2 is called a buffer capacitor. This is a high voltage paper capacitor that is used to keep sharp noise pulses out of the power supply. The size is usually quite critical and if it is necessary to replace the buffer capacitor in a receiver using this type of power supply, you should use a capacitor having the same capacity as the original.

In a vibrator-type power supply there is considerable sparking as the reed vibrates back and forth. This sets up a radio-frequency type of interference which could get through the rectifier and cause considerable interference in the receiver. In the power supply shown in Fig. 29, the choke L and the capacitor C are called hash suppressors. This rf interference or noise is called hash; the choke and the capacitor are put in the power supply in order to keep as much as possible of this hash or noise out of the power supply output. Capacitor C acts like a short circuit to these radio frequency pulses, and choke L acts like a very high impedance to them. Thus L and C form a voltage-divider network, with most of the voltage appearing across the high impedance L and little or no voltage across the low impedance C.

Vibrator-type power supplies were used in almost all automobile receivers in automobiles using 6-volt ignition systems. However, in newer cars, a 12-volt ignition system is used. The first receivers made for these cars also used vibrator type supplies, but tube manufacturers designed special tubes that will operate with plate and screen voltages as low as 12 volts. These 12-volt tubes were used in automobile receivers for a few years, but they too were replaced by transistors. Since transistors operate from low voltages, the vibrator type of power supply is no longer needed. These supplies were not only costly, but in addition they were one of the most troublesome sections of the automobile receiver.

SUMMARY

The power supplies we have shown in this section of this lesson are typical of the various types of power supplies you are likely to encounter as an electronics technician. You will find many variations of these circuits, but these are the basic circuits. Spend some time studying

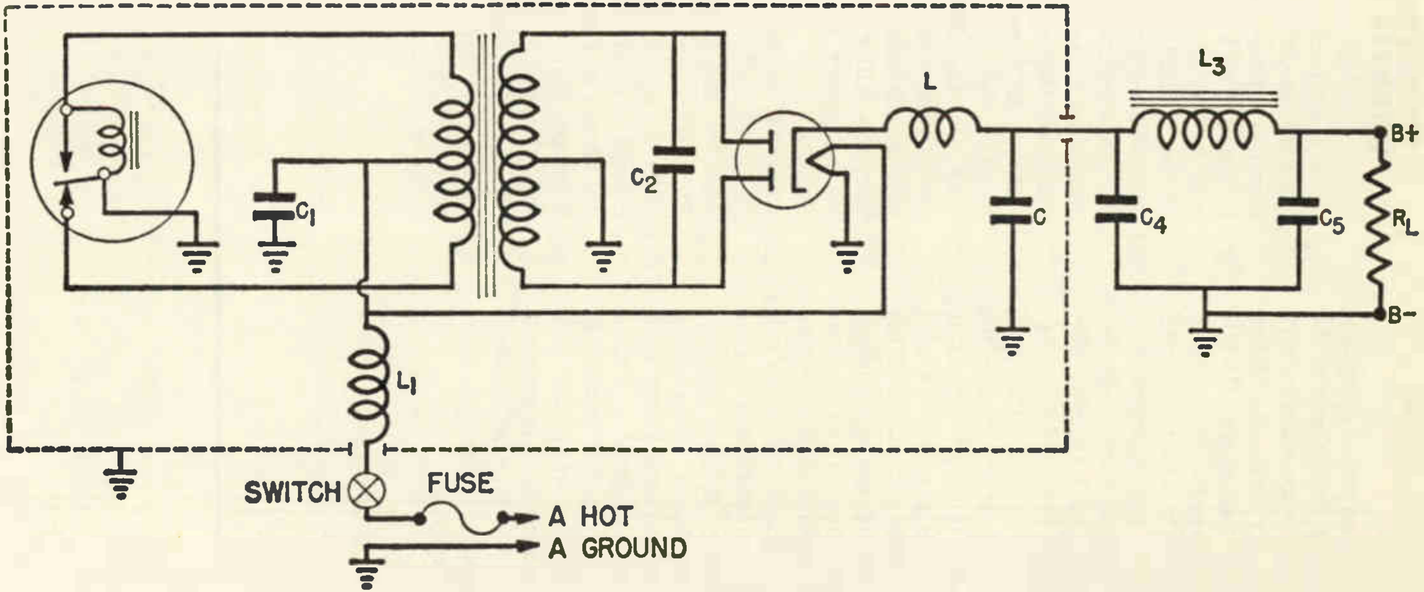

Fig. 29. A complete vibrator power supply.

these circuits so you will know what they look like.

In servicing these power supplies, keep in mind that the values of the various components used are generally not extremely critical. Manufacturers usually use as small a filter capacitor as they can in a circuit. It is more economical to use a small capacitor than to use a large one. Therefore, if you have an ac-dc receiver that uses a 20-40 mfd, 150-volt capacitor and you find it necessary to replace the filter capacitor, there is no reason why you could not use a 30-50 mfd, 150-volt capacitor in its place. Some variation of part values can be made without affecting the performance of the equipment.

It is also possible to use capacitors having a higher voltage rating than those used originally. This will simply provide an additional margin of safety. You may find that you cannot do this in large transmitter power supplies because there isn't room to mount a capacitor with a higher voltage rating, but usually in radio, TV, and most small pieces of industrial electronic equipment there is enough room to put in a capacitor of slightly larger physical size than the original.

SELF-TEST QUESTIONS

(q) Draw a schematic diagram of a typical ac-dc power supply found in a five-tube radio.

(r) In the circuit shown in Fig. 22, why is the 12AT6 tube placed at the B- end of the string?

(s) If in an ac-dc receiver in which the heaters of the tubes are connected in series and none of the tubes lights what would you suspect the cause of the trouble to be?

(t) Why are the filter capacitors used in the power supply shown in Fig. 23 smaller in capacity than the filter capacitors used in the power supply shown in Fig. 22?

(u) What is the purpose of R3 in Fig. 24?

(v) What is the purpose of R4 in Fig. 24?

(w) What type of voltage-doubler circuit is used in the power supply shown in Fig. 24?

(x) What purpose does the transistor Q2 serve in the power supply shown in Fig. 26?

(y) What is the purpose of the diode D3 in Fig. 26?

ANSWERS TO SELF-TEST QUESTIONS

(a) There will be 60 current pulses per second through the load.

(b) The disadvantage of the half-wave rectifier circuit is that current flows through the rectifier during one half-cycle and not during the other half-cycle. As a result, the output is somewhat difficult to filter and smooth out to pure dc.

(c) The diode D1 in the circuit shown in Fig. 6 is used to charge the capacitor C1 during one half of each cycle. Capacitor C1 is charged so that during the next half-cycle the voltage across it will be in series with the line voltage. This will place a voltage equal to twice the line voltage across the load and diode D2. Since diode D2 has a very low resistance when it is conducting, the voltage across the load is twice what it would be without the combination of C1 and D1 in the circuit: hence, the circuit is called a voltage-doubler circuit.

(d) The circuit is called a full-wave rectifier circuit because a current pulse flows through the load during each half-cycle. In other words, if the rectifier circuit is operating from a 60-cycle power line there will be 120 current pulses through the load (one for each half-cycle).

(e) The disadvantage of this circuit is that the high voltage winding on the power transformer must be center-tapped. This means that the high-voltage winding on the transformer must have twice the number of turns required to get the desired output voltage across the load. This circuit requires a rather expensive power transformer.

(f) The advantage of the bridge rectifier circuit is that there is a saving in the power transformer cost over that of a transformer that has a tapped high-voltage secondary winding; also, the circuit is capable of good voltage regulation.

(g) The voltage-doubler circuit shown in Fig. 9 is a full-wave voltage doubler. That is, there will be 120 current pulses per second in the output of the voltage doubling capacitor network consisting of C1 and C2. The circuit shown in Fig. 6 is a half-wave voltage-doubler circuit and there will be only 60 current pulses through the load in this circuit. It will be somewhat easier to filter and smooth the output voltage in the circuit shown in Fig. 9 than it will be in the circuit shown in Fig. 6.

(h) A full-wave doubler circuit requires a less expensive power transformer for a given load voltage than the bridge rectifier circuit requires. Also, the voltage-doubler circuit requires only two rectifiers whereas the bridge-rectifier circuit requires four rectifiers. The disadvantage of the full-wave voltage-doubler circuit is that it does not have as good voltage regulation as the bridge-rectifier circuit.

(i) The capacitor in a simple filter circuit such as shown in Fig. 11 may charge up to a value equal to the peak value of the ac input voltage. In the case of a power supply operating from a 120-volt line this is equal to approximately 1.4 times 120 volts.

(j) A simple capacitor-type filter may be used in applications where the current drain is low. With a low current drain the capacitor discharges very little between cycles so that the voltage across the capacitor, and hence the voltage across the load, remains essentially constant.

(k) The R-C pi-type filter is capable of better hum elimination than a simple capacitor-type filter. This type of filter is particularly desirable where the current drain is high enough to discharge the capacitor appreciably between charging cycles in a simple capacitor-type filter.

(l) The disadvantage of the R-C pi-type filter is that there is considerable voltage drop across the filter resistor. This problem can be overcome by using a filter choke such as in the L-C type filter shown in Fig. 15. A filter choke will offer a high opposition to any ac and thus effectively reduce the ac, while at the same time offering a low resistance to the passage of dc through it.

(m) R1 in the power supply shown in Fig. 17 is used to limit the current through the silicon rectifier when the power supply is first turned on. Without this resistance in the circuit, the charging current through the diode to charge C1 may be so high that the rectifier may be destroyed.

(n) To limit the peak current through the tubes. A mercury vapor rectifier tube is easily damaged by a high peak current. The peak current through the rectifier tube is much lower with a choke-input filter than it is with a capacitor-input filter.

(o) A choke-input filter will provide better regulation than a capacitor-input filter. This means that the voltage across the load will vary less with widely varying currents when the filter is a choke-input filter than it will when the filter is a capacitor-input filter.

(p) A swinging choke is a choke whose inductance changes as the current changes. As the current builds up the choke tends to saturate so that its inductance goes down. This tends to reduce the reactance of the choke and hence helps provide better voltage regulation.

(q) See Fig. 22. If you cannot draw this diagram from memory, copy it from the book. Simply drawing the diagram will help you to become familiar with the circuit and remember it in the future.

(r) The 12AT6 tube is the first audio stage. It is placed at the B- end of the heater string in order to keep hum pick-up in the tube as low as possible. Any hum picked up by this tube will be amplified by the entire audio system.

(s) The chances are that the heater of one of the tubes is open.

(t) The power supply shown in Fig. 23 uses a full-wave rectifier. Therefore there will be 120 pulses per second to charge the filter capacitors. The power supply shown in Fig. 22 is a half-wave power supply and there will be only 60 pulses per second to charge the filter capacitor; therefore, larger capacitors are needed to eliminate hum.

(u) R3 in Fig. 24 is a thermistor. A thermistor has a high cold resistance, but the resistance decreases as the thermistor heats up. The thermistor is used in this power supply to protect the diode rectifiers from high current surges when the power supply is first turned on.

(v) R4 is a fixed resistor that is used to protect the diodes in the event the equipment is turned off and then turned back on almost immediately. Under these conditions the resistance of the thermistor will be too low to provide the required protection for the rectifiers and hence R4, along with the hot resistance of the thermistor, limits the current through the diode rectifiers to a safe value.

(w) A half-wave voltage doubler.

(x) Q2 is in series with the B supply voltage. It operates essentially as a variable resistor and is used to regulate the power supply output voltage and keep it at essentially a constant value.

(y) The diode D3 is the zener diode. It provides a reference voltage so that the voltage variations on the emitter of Q1 will be greater than the voltage variations on the base. Thus, changes in output voltage affect the forward bias of the transistor and hence the conduction through it.

Lesson Questions

Be sure to number your Answer Sheet B201.

Place your Student Number on every Answer Sheet.

Most students want to know their grade as soon as possible, so they mail their set of answers immediately. Others, knowing they will finish the next lesson within a few days, send in two sets of answers at a time. Either practice is acceptable to us. However, don't hold your answers too long; you may lose them. Don't hold answers to send in more than two sets at a time, or you may run out of lessons before new ones can reach you.

1. What advantage does a silicon rectifier have over a vacuum-tube rectifier?

2. Draw the schematic symbol for a silicon rectifier, and indicate by an arrow the direction in which the current will flow through it.

3. How many pulses per second will you get at the output of a full-wave rectifier that is operated from a 60-cycle power line?

4. What is the purpose of C1 and D1 in the circuit shown in Fig. 6?

5. (a) In the circuit shown in Fig. 6, how many current pulses will there be through the load (60-cycle power line)?
   (b) In the circuit shown in Fig. 9, how many current pulses will there be through the load (60-cycle power line)?

6. In the circuits shown in Fig. 11, what part supplies current to the load when the rectifier is not conducting?

7. Explain the following things in connection with the L-C circuit shown in Fig. 15:
   (a) The action of the choke when ac flows through it.
   (b) The action of the choke when dc flows through it.
   (c) The action of the capacitor when ac flows through it.
   (d) The action of the capacitor when dc flows through it.

8. What type of filter network has better voltage regulation -- the capacitor input or the choke input?

9. If you are servicing a five-tube table model radio that uses a universal ac-dc power supply and you see that two of the tubes are not lighting, where would you look for trouble?

10. How does an increase in output voltage affect Q1 and Q2 in the regulated power supply shown in Fig. 26?

HOW TO START STUDYING

For some people, starting to study is just as hard as getting up in the morning. An alarm clock will work in both cases, so try setting the alarm for a definite study-starting time each day. Start studying promptly and definitely, without sharpening pencils, trimming fingernails or wasting time in other ways.

Beginning is for many people the hardest part of any job they tackle. So formidable does each task appear before starting that they waste the day in dilly-dallying, in day-dreaming, and in wishing they didn't have to do it. The next day and the next after that are the same story. Indecision brings its own delays, making it harder and harder to buckle down to work.

Are you in earnest? Then seize this very minute; begin what you can do or dream you can. Boldness in starting a new lesson is a great moral aid to mastery of that lesson; only begin, and your mind grows alert, eager to keep on working. Begin, and surprisingly soon you will be finished.

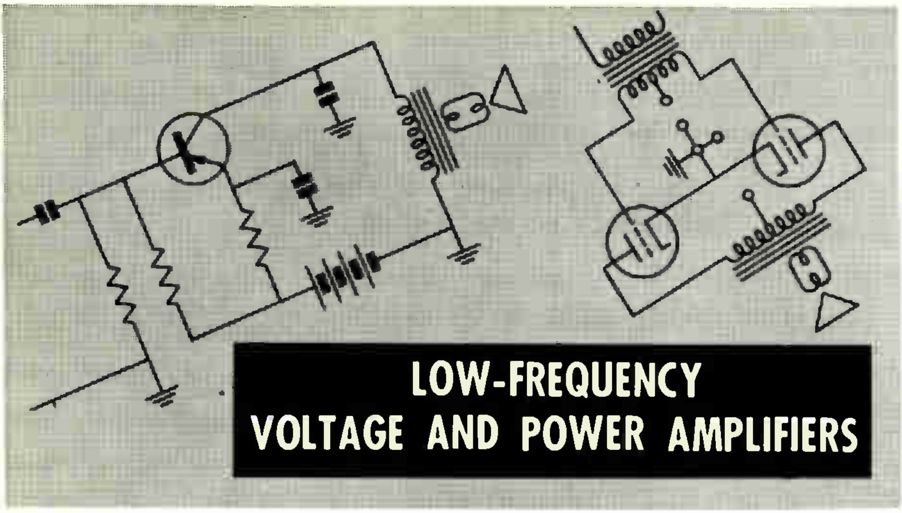
STUDY SCHEDULE

JDL5M372 1974 EDITION Litho in U.S.A.



LOW-FREQUENCY VOLTAGE AND POWER AMPLIFIERS

In this lesson and the next two, we will take up the study of amplifiers. For convenience in studying them, we have divided them according to the frequencies they are designed to handle.

You will study low-frequency voltage and power amplifiers in this lesson. These are the kinds used to amplify the sound or audio signal in radio and television receivers, and they are also used in high-fidelity and stereo equipment, in conjunction with amplifying audio signals that are received by means of a radio system from a broadcast station and also with audio signals from a phonograph or tape recorder.

In your next lesson you will study radio frequency amplifiers. These amplifiers are designed to amplify signals received directly from radio and television stations as well as signals within the receiving equipment itself that fall within the radio frequency range. You will study wide-band amplifiers in the third lesson; these are amplifiers that are designed to amplify a wide range of frequencies. For example, a wide-band amplifier might have to amplify signals that have few cycles per second, signals as high as several megacycles per second, and all the frequencies in between these two limits. Wide-band amplifiers of this type are used to amplify the picture signals in television receivers. They are also used in many other special applications.

The ability of tubes and transistors to amplify signals is essentially what makes many of our modern electronic devices possible. Therefore, if you understand how these amplifiers work and how they are put together to perform specific functions, you will be able to analyze the operation of many different types of electronic equipment that you might encounter. Since amplifiers are so important it is worthwhile to spend as much time as necessary on this lesson and on the next two to be sure that you have a complete understanding of them.

The low-frequency amplifiers that you will study in this lesson can be divided into two types: voltage amplifiers and power amplifiers. As you already know, a voltage amplifier is one that is designed to amplify a weak signal voltage and make it stronger. For example, the output voltage from a phonograph pickup in a record player might be only a few thousandths of a volt. This audio signal is too weak to do anything with directly so we feed it to a number of voltage amplifiers to build the amplitude of the voltage up to a usable value. We try to perform this amplification without changing the signal in any way. If we change the signal, we have introduced something called distortion because the amplified signal is no longer the amplified equivalent of the original signal.

Power amplifiers are used to drive the speaker in radio and TV receivers. The speaker requires a certain amount of power in order to cause the cone in the speaker to vibrate back and forth and set the air in front and in back of the speaker into motion. The power required to perform this function is supplied by power amplifiers. The exact amount of power required for the speaker will depend upon the design of the speaker, its size, efficiency and a number of other factors. You will study amplifiers that have a comparatively low power output of perhaps one or two watts and you will also study high-power amplifiers that are capable of putting out 50 or more watts of power.

When we speak of low-frequency amplifiers, we are generally concerned with amplifiers that are designed to amplify signals from about 50 to 100 cycles up to signals of about 10,000 or 20,000 cycles. There are no sharp dividing lines either at the low-frequency or high-frequency end of the range over which the amplifiers are supposed to work. Generally, a low-frequency amplifier is an amplifier that works in the audio range (in other words, within the limits of our hearing). Of course, these amplifiers will amplify signals beyond these frequency limits. The amplifier does not simply stop amplifying at a frequency above the highest frequency it is designed to amplify -- it just doesn't amplify higher frequency signals well. The same is true of low-frequency signals. If an amplifier is designed to amplify signals from about 100 cycles up, it will also amplify a signal having a frequency of 80 cycles, but the chances are that the 80-cycle signal will not receive as much amplification as the 100-cycle signal would.

In this lesson you will learn why the gain of an amplifier falls off as the frequency of the applied signal falls above or below the frequency limits of the amplifier. You will also see that the frequency limits of the amplifier are more or less arbitrarily fixed by design engineers.

In our study of low-frequency amplifiers we will begin with voltage amplifiers. We will study the resistance-capacitance coupled voltage amplifier first because it is the most widely used and hence the most important.

Resistance-Capacitance Coupled Voltage Amplifiers

Resistance-capacitance coupling, usually called R-C coupling or simply resistance coupling, is so named because resistors and capacitors are used to couple the signal from one stage to another.

This type of coupling is widely used between voltage amplifiers and between voltage amplifiers and class A power amplifiers in audio work. It is preferable to transformer coupling in modern equipment because it is more economical and, in addition, usually gives better frequency response. This means it comes closer than transformer coupling does to amplifying equally all signals in the audio range.

Transformer coupling has not been used for many years between voltage amplifiers using vacuum tubes. However, you may find transformer-coupled transistor amplifiers, and there is some advantage to this type of coupling in transistor circuits.

A TYPICAL TUBE CIRCUIT

Fig. 1 shows two typical resistance-capacitance coupled stages. V_1 is the first stage; the output signal from this stage is fed to the second stage (V_2) by means of R-C coupling. The R-C coupling components are R_2 (which is the plate load resistor of V_1), C_3 (which is the coupling capacitor) and R_3 (which is the grid resistance for the second stage, V_2).

Let's review again the operation of these amplifier stages and how the coupling network works. With no signal applied to V_1, a current will flow from the cathode of the tube to the plate because the plate is con-

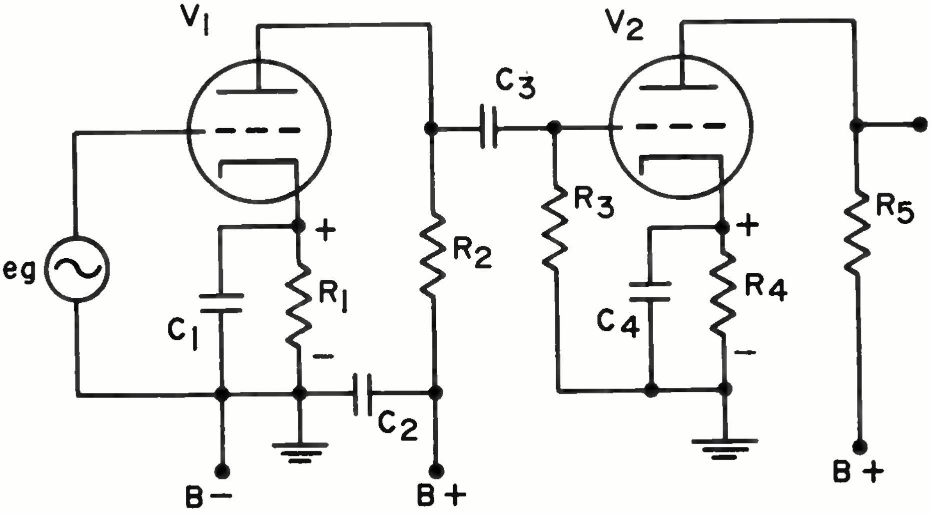


Fig. 1. Typical vacuum tube R-C coupled stage.

nected to the positive side of the B supply through R_2. The cathode is connected to the negative side through R_1. Electrons will leave the negative side of the B supply and flow through R_1 to the cathode. In flowing through R_1 they will set up a voltage drop across the resistor having the polarity shown. This voltage drop will make the cathode positive with respect to ground. The grid of V_1 is returned directly to ground through the generator and since there is no current flowing in the grid circuit there will be no voltage drop across the generator. Therefore the grid is at dc ground potential. This will make the grid negative with respect to cathode. The actual grid-cathode voltage will depend upon the size of R_1 and the current flow through R_1. The current flow through the tube can be determined from a tube manual and the required bias for the tube can be obtained simply by making R_1 large enough to produce the bias voltage needed.

Electrons reaching the cathode will be emitted by the cathode and flow through the tube to the plate. Then the electrons will flow from the plate through R_2 back to the B supply. In flowing through R_2 the electrons will produce a voltage drop across this resistor. The value of R_2 is usually quite high so there will be a substantial voltage drop across the resistor. Thus, although the plate will be positive with respect to ground, this positive voltage on the plate will be less than the positive voltage available at the positive terminal of the B supply.

The current flow through V_2 follows a path equivalent to the current path in V_1. The plate of V_2 is returned to the positive side of the B supply through R_5 so there will be a positive voltage on the plate of V_2. This will cause electrons to flow through R_4, producing a voltage drop across it (having the polarity shown) so that the cathode will be positive with respect to ground and the grid negative with respect to cathode. As before, there will be no current flow in the grid circuit and therefore no current flow through R_3. This means there will be no dc voltage drop across this resistor; consequently, the grid will be at dc ground potential.

When a signal voltage is applied by the generator e_g, the generator voltage will vary the voltage between the grid and cathode of V_1. The generator connects directly to the grid of V_1. The other side of the generator connects to the cathode through C_1. C_1 is chosen so that its reactance will be very low at the frequency of the signal to be handled. Thus we have the input signal from the generator applied directly between the grid and cathode of V_1.

When the polarity of the input signal is such that the grid end of the generator is positive and the other end is negative, the voltage applied between grid and cathode by the generator will subtract from the bias voltage across R_1. This will make the grid less negative with respect to the cathode and will cause the current flowing through V_1 to increase. This increase in current through V_1 will result in an increase in the voltage drop across R_2. Thus the voltage on the plate of the tube will become less positive with respect to ground; in other words, the plate voltage will swing in a negative direction.

When the signal applied by the generator reverses polarity, the grid will be made more negative and this will add to the bias voltage applied between the grid and the cathode of the tube. This will decrease the current flowing through the tube, which in turn will decrease the voltage drop across R_2. Therefore, the plate voltage on V_1 will swing in a positive direction.

Compare what we have in the plate circuit to the voltage applied to the grid by the generator. When the generator swings the grid positive, the plate voltage swings negative; when the generator swings the grid negative, the plate voltage swings positive. This means that the amplified signal voltage developed in the plate circuit of V_1 will be 180° out-of-phase with the input signal voltage eg.

The value of the coupling capacitor C_3 is chosen so that it has a low reactance within the range of signal frequencies we intend to amplify. As a matter of fact, the reactance of the capacitor is usually so low that for all practical purposes it acts like a direct connection for the signal voltages. Therefore, the voltage developed in the plate circuit of V_1 is applied directly to the grid of V_2 through the coupling capacitor C_3. The capacitor C_2 keeps the lower end of R_2 at signal ground potential. Often you will not find this capacitor in an amplifier; the actual capacitor is usually the output filter capacitor in the power supply. In any case, the signal voltage developed between the plate of V_1 and ground is coupled to the grid of V_2 through the coupling capacitor C_3 and to the cathode of V_2 through the cathode bypass capacitor C_4. Thus the amplified signal produced in the plate circuit of V_1 is coupled directly between the grid and cathode of V_2.

A TYPICAL TRANSISTOR CIRCUIT

Two R-C coupled transistor stages are shown in Fig. 2. Notice that both transistors are used in the common-emitter circuit and that both transistors are PNP transistors.

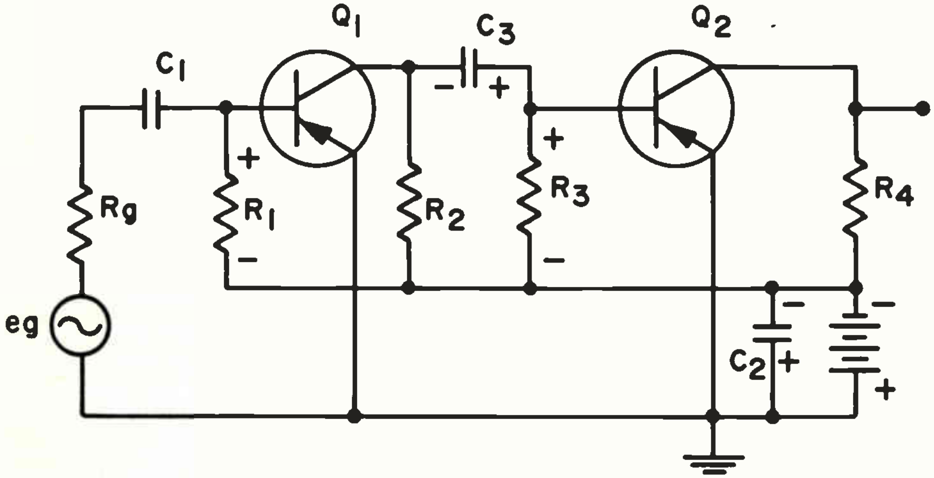

Fig. 2. Typical transistor R-C coupled stages.

The coupling components consist of R_2 (which is the collector load for Q_1), C_3 (the coupling capacitor) and R_3 (which is the base-bias resistor for Q_2).

Notice the capacitor across the battery. This is a large capacitor that effectively bypasses the battery as far as the signal is concerned, so that both the negative and positive sides of the battery are at ground potential in regard to the signal as well. In equipment designed for power line operation, the battery will be replaced by the power supply and C_2 will be the output filter capacitor.

Now let's review the operation of these two stages and see how a coupling network works. First, before any signal is applied, notice that the base of Q_1 and Q_2 connect to the negative side of the battery. The emitters of the two transistors connect to the positive side of the battery. This will place a forward bias across the emitter-base junction of the PNP transistor. However, the full battery voltage is not applied because there will be some small base current. A few of the holes crossing the emitter-base junction into the base will be filled by electrons that flow from the negative terminal of the battery through R_1 into the base of Q_1 and from the negative terminal of the battery through R_3 into the base of Q_2. Electrons flowing through resistors R_1 and R_3 will produce voltage drops across them having the polarity shown. The values of R_1 and R_3 are chosen so that the electrons flowing through them produce a voltage drop almost equal to the battery voltage. This will leave a forward bias across the emitter-base junction of only a few tenths of a volt.

Looking at the first stage, the emitter is connected to the positive side of the battery. This will pull electrons from the emitter, creating holes. The holes will be attracted by the negative potential on the base across the emitter-base junction, flow through the base and then across the base-collector junction and flow through the collector, where they will be filled by electrons coming from the negative terminal of the battery through R_2 to the collector. Thus we have a current flow through R_2 which will be governed by the number of holes reaching the collector of Q_1. This current flow through R_2 will result in a voltage drop across the resistor so that the negative potential on the collector of Q_1 will be somewhat less than the negative battery potential.

Holes and electrons move in the circuit for Q_2 in exactly the same way. Electrons pulled from the emitter of Q_2 create holes which flow through the transistor to the collector, where they are filled by electrons flowing through R_4.

When a signal voltage is applied by the signal source e_g the effective forward bias across the emitter-base junction of Q_1 is changed. Notice that we have shown a resistor in series with the generator. In the circuit for the vacuum tubes the generator will have some internal resistance, but since there is no current flow in the input circuit the resistance is of no consequence. However, in a transistor circuit there will be current flow in the input circuit and therefore the resistance affects the amount of signal actually reaching the transistor.

The capacitor C_1 is chosen to have a low reactance at signal frequency. Therefore the generator voltage is connected to the base of Q_1 through

R_g and C_1. The other side of the generator connects directly to the emitter.

When the end of the generator that connects to the base through the resistor and capacitor swings in a positive direction, the forward bias across the emitter-base junction of Q_1 will be reduced. This will cause the number of holes crossing the emitter-base junction and flowing to the collector to decrease. If fewer holes reach the collector then the number of electrons flowing through R_2 to fill these holes will go down. This means that the voltage drop across R_2 will decrease and the collector voltage will swing in a negative direction (in other words, closer to the negative battery potential).

When the generator polarity reverses so that the voltage applied to the base by the generator is negative, it will add to the forward emitter-base bias and cause the number of holes crossing the emitter-base junction to increase. This means that the number of holes reaching the collector will increase; therefore, the number of electrons flowing through R_2 to fill these holes must increase. The increase in current flow through R_2 will cause a greater voltage drop across this resistor. Thus, the potential at the collector of Q_1 will be less negative -- it will swing in a positive direction.

Notice the similarity between the transistor stage Q_1 and the vacuum tube stage V_1. In both cases, the signal is inverted; the amplified output signal voltage is 180° out-of-phase with the input signal voltage.

The amplified signal at the collector Q_1 is coupled to the base of Q_2, through the coupling capacitor C_3. This is similar to the arrangement used between the vacuum tubes in Fig. 1, but there is something quite different about the circuit. In the vacuum tube circuit shown in Fig. 1, there is no current flow through the grid resistor R_3 nor is there any current flowing between the cathode and grid of the tube. R_3 is a large resistor -- its purpose is to take care of any electrons that accidentally strike the grid of the tube and provide a path for these electrons back to ground. In most amplifier tubes this current flow through R_3 is so small it cannot be measured and we say for all practical purposes there is no current flow. This means that C_3 is coupling the signal into a very high impedance circuit.

In the circuit shown in Fig. 2, there is a current flow through R_3. However, the current flow through R_3 is small and the value of this resistor is comparatively large. Also, there is current flowing across the emitter-base junction. This is the movement of holes across this junction and since they flow across the junction with relatively little impedance with the forward bias on the transistor, we have, in effect, a low resistance circuit between the emitter and base. This is the circuit into which the capacitor C_3 must couple the signal. C_3 must be chosen so it has a low reactance compared to the input resistance of Q_2. Since the input resistance of Q_2 is quite low, the capacity of C_3 must be quite large in order to provide the low reactance coupling needed.

Often in transistor R-C coupled circuits, you will see electrolytic capacitors used as the coupling capacitor. In a circuit such as the one in Fig. 2 we have indicated the polarity with which an electrolytic capacitor should be connected.

The amplified signal from Q_1 is fed through C_3 to the base of the transistor. This causes the forward bias on Q_2 to vary, which in turn varies the number of holes flowing through the transistor and the electron current flow through R_4.

Q_2 will invert the signal 180° just like Q_1 did. Therefore, the signal voltage across R_4 will be in phase with the generator voltage. The signal voltage polarity will be inverted 180° by the amplifier stage Q_1 and will be inverted another 180° by the second amplifier Q_2 so that the output of the two-stage R-C coupled amplifier will be in phase with the input signal voltage. Of course, the same is true of the two-stage vacuum tube amplifier circuit.

When we discussed both the vacuum tube circuits shown in Fig. 1, and the transistor circuit shown in Fig. 2, we said that the coupling capacitor must have a low reactance. However, you know that the reactance of the capacitor varies with the frequency. Therefore, the reactance of these coupling capacitors must vary with the frequency; therefore, their effectiveness as coupling devices must also vary as the frequency varies. This fact has an effect on the limits of the frequencies which an amplifier of this type can amplify. There are other factors in the circuit which also limit the range of frequencies these amplifiers can handle and since these factors appreciably affect the performance of the amplifiers we will investigate them now.

FREQUENCY RESPONSE

When we talk about the frequency response of an amplifier we mean the ability of the amplifier to amplify signals of different frequencies. For example, if we say that the frequency response of an amplifier is flat from 100 cycles to 10,000 cycles we mean that signals from 100 cycles up to 10,000 cycles will receive the same amount of amplification. If we say that the frequency response of an amplifier falls off below 100 cycles and above 10,000 cycles we mean that signals having a frequency less than 100 cycles and signals having a frequency above 10,000 cycles do not receive as much amplification as signals between 100 cycles and 10,000 cycles receive.

Amplifiers can be designed to have a very wide frequency response -- in other words, they can amplify a wide range of frequencies. Often, however, it is not advantageous to have an amplifier that can amplify an extremely wide range of frequencies. For example, there is a limit to how low or to how high an audio frequency we can hear. Therefore, there is very little point in designing an amplifier that can amplify signals many times the frequency of the highest frequency we can hear. Certain economies can be realized by designing an amplifier that will amplify the desired or required frequency range and very little more. In addition to these economies, the design of the amplifier is usually simplified if we do not try to extend the frequency range it can amplify too much.

The factor that usually limits the frequency range of an amplifier most is the coupling network used between the various stages of the amplifier. In the circuits shown in Figs. 1 and 2 there are a number of factors that will limit the high-frequency and the low-frequency responses of these amplifiers. Let's look at these fac-

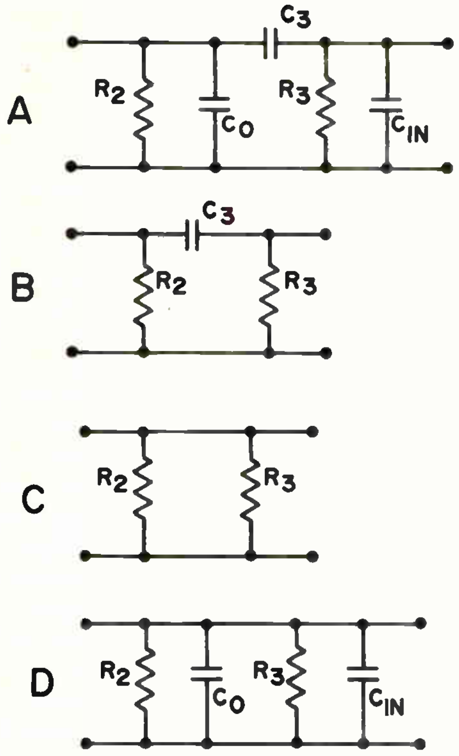

Fig. 3. Equivalent circuits of coupling network between V1 and V2 in Fig. 1.

tors and examine them in detail. We will consider the vacuum-tube circuit shown in Fig. 1 first.

In Fig. 3A we have shown a complete equivalent circuit of the coupling circuit used between V_1 and V_2. Notice that the plate resistor R_2 is shown in the circuit, as well as the coupling capacitor C_3 and the grid resistor R_3. In addition to these components we have also shown a capacitor marked C_O and a second capacitor marked C_{IN}. C_O represents the output capacity of V_1. This will be made up of the capacity in the tube itself plus wiring capacity in the circuit. C_{IN} is the input capacity of V_2. This will be the grid-to-cathode capacity plus any additional capacity added to the circuit by the wiring in the circuit. These capacitors are not shown on the diagram in Fig. 1, but they are present in the circuit and will affect the operation of the circuit.

At low frequencies, the output capacity of V_1 and the input capacity of V_2 are too small to appreciably affect the operation of the coupling network. We have shown the equivalent low-frequency circuit in Fig. 3B. Notice that the only components shown in this circuit are the plate resistor R_2, the coupling capacitor C_3, and the grid resistor R_3.

At some low frequency, the reactance of C_3 will be equal to the resistance of R_3. As you will remember, the capacitive reactance of C_3 increases as the frequency goes down. Even though the value of R_3 may be made quite large, if the frequency of the signal applied to the circuit is low enough a point will eventually be reached where the reactance of C_3 will be equal to the resistance of R_3. When this happens, C_3 and R_3 act as a voltage divider network so that only part of the voltage dropped across R_2 actually appears across R_3 and is fed to the grid and cathode of V_2.

By means of a vector diagram, we can see what happens to the voltage across R_3 when the reactance of C_3 is equal to the resistance of R_3. Remember that when a voltage is applied to a purely resistive circuit, a current will flow which will be in phase with the voltage. On the other hand, when a voltage is applied to a purely capacitive circuit, a current will flow that leads the voltage by 90°. When a voltage is applied to a circuit which has an equal resistance and an equal capacitive reactance, a current will flow in the

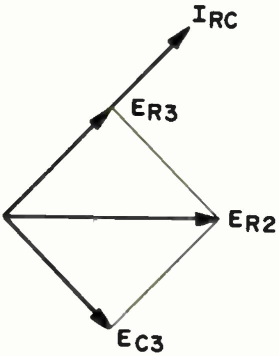

Fig. 4. Vector diagram of input and output voltages at low frequencies.

circuit that leads the voltage by 45°. From this information we can draw a vector diagram to show how the voltage across R_2 is divided across C_3 and R_3.

Fig. 4 is a vector representation of the voltage division. To draw this diagram the first thing we do is draw E_{R2}, which represents the voltage across R_2. Next, we draw the current I_{RC}, which represents the current that will flow through the network consisting of C_3 and R_3. We draw this current vector leading the voltage across R_2 by 45°. Now, we know that the voltage across C_3 will lag the current flowing through it by 90°. Therefore we can draw the vector E_{C3} lagging the vector I_{RC} by 90°. We also know that the voltage across R_3 will be in phase with the current flowing through it. This means that the voltage vector E_{R3} will fall on the vector I_{RC}. This will tell us the direction in which the vector representing the voltage across R_3 should point.

We know that the voltage across C_3 plus the voltage across R_3 must be equal to the voltage across R_2. Therefore, by drawing perpendiculars from the end of the vector representing the voltage across R_2 to the vectors representing the voltage across R_3 and C_3 we can determine the amplitude of the voltage across R_3 and across C_3. The perpendiculars are shown in Fig. 4. If we carefully measured the voltage vector E_{R3} we would find that it was equal to .707 × E_{R2}. Similarly, the voltage across C_3 will be equal to .707 times the voltage across R_2. Thus, even though the capacitive reactance is equal to the resistance, the actual voltage that will appear across R_3 and be fed to the second stage will be slightly over 7/10ths the input voltage, where at first we might think that the voltage would be only half the input voltage.

The frequency at which the reactance of the coupling capacitor is equal to the resistance of the input resistor of the second stage is called the half-power point. The reason for this is that the current that will flow through the grid resistor will depend upon the voltage applied to it.

If the voltage at some frequency where the capacitive reactance of the capacitor is so small it can be ignored is 1 volt, then with the same amplitude signal across R_2, at the frequency where the reactance of the capacitor is equal to the resistance of the grid resistor, the voltage across the resistor will be .707 volts.

In this case, the current that will flow through the grid resistor will be .707 times what it would be when the voltage across the resistor was 1 volt. Therefore the power of the signal fed to the resistor will be equal to the voltage times the current which will be $.707E \times .707I = .5P$. Thus the power fed to the resistor will be one half the power at frequencies where the coupling capacitor can be ignored.

The equivalent diagram of the coupling circuit at mid-frequencies is shown in Fig. 3C. Here, the reactance of the coupling capacitor C_3 is so small compared to the resistance of R_3 that it can be ignored. Therefore for all practical purposes R_2 and R_3 are connected directly in parallel. R_3 is usually many times the resistance of R_2 so that it has very little effect as far as reducing the size of the plate load of V_1 is concerned. In the mid-frequency range the output capacity of V_1 and the input capacity of V_2 are too small to affect the operation of the circuit so they can be ignored. In this mid-frequency range, essentially all of the output signal developed by V_1 is fed to V_2 so that the coupling circuit operates with maximum efficiency.

At high frequencies the reactance of C_3 will be even smaller and can therefore be omitted from the circuit. However, the effects of the output capacity of V_1 and the input capacity of V_2 must be considered. They are shown in Fig. 3D, the equivalent circuit for high frequencies. Notice that once again R_2 and R_3 are, in effect, in parallel; also C_O and C_{IN} are likewise in parallel. Therefore the circuit acts as if there is one capacitor connected across the parallel combination of R_2 and R_3.

As the frequency of a signal increases, you know that the capacitive reactance decreases. At low and middle frequencies the capacitive reactance of C_O and C_{IN} in parallel is so high that it has no effect on the performance of the circuit. However, as the frequency increases, the capacitive reactance of this parallel combination goes down. At some high frequency, the capacitive reactance will eventually be equal to the resistance of R_2 and R_3 in parallel. At this point the effective plate load resistance on V_1 will be reduced and the output voltage developed by V_1 will also go down.

When the capacitive reactance of the parallel capacity is equal to the resistance of R_2 and R_3 in parallel, then half of the signal current developed by V_1 will flow through the resistance combination and the other half will flow through the capacitors. This means that the voltage developed in the output of V_1 will be reduced. By means of the vector diagram shown in Fig. 5, we can see exactly what happens.

First, we draw the current vector I which represents the signal current from V_1. Then we draw a voltage vector E_R to represent the voltage developed across the parallel combination of R_2 and R_3. We draw this vector in phase with the current because we know that the voltage developed across these resistors will be in phase with the current. Now we draw a voltage vector that lags the current by 90°. This vector represents the voltage developed across the capacitors. Since half the current is flowing through the resistance and half through the capacitance, the two voltages must be equal; therefore, we draw the voltage vector E_C equal to the voltage vector E_R and lagging by 90°. Now we perform the vector addition of these two voltages as shown in Fig.

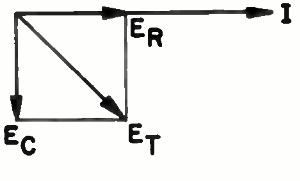

Fig. 5. Vector diagram of input and output voltages at high frequencies.

5. This gives us the total output voltage from V_1. Again, this voltage will be equal to .707 times the voltage developed in the mid-frequency range. This is the half-power point at the high-frequency end of the frequency range.

In addition to the amplitude of the signal voltage reaching V_2, dropping off both at high frequencies and at low frequencies, you should also notice that the phase of the voltage is changed. In the mid-frequency range, the voltage applied to V_2 will be in phase with the output voltage from V_1. However, at the low-frequency half-power point, the voltage fed to V_2 will lead the output voltage from V_1 by 45°. At the high-frequency half-power point, the voltage applied to V_2 will lag the output voltage from V_1 by 45°. In sound or audio amplifiers this phase shift is not particularly important, but in video amplifiers and television receivers this phase shift is important and can produce a smear in the picture. You will learn more about this later, as well as how this problem is overcome.

We have a somewhat similar situation in the transistor amplifier circuit shown in Fig. 2. However, here the situation becomes even more complicated because the transistors are low-impedance devices whereas tubes are high-impedance devices.

Fig. 6A illustrates the effective coupling circuit between Q_1 and Q_2 in Fig. 2. First, looking at Fig. 6A you see a resistor marked R_o. This resistance represents the output resistance of Q_1. In parallel with this we have shown R_2, the collector-load resistor. We have also shown C_O which represents the output capacitance of Q_1 plus any distributed capacitance that may be in the circuit. The coupling capacitor C_3 is shown as before; R_3 represents the resistance connected in the input circuit of Q_2. In parallel with R_3 we have shown another resistor marked R_{IN}. This resistance represents the input resistance or the base-emitter resistance of Q_2. In parallel with this combination we have capacitor C_{IN} which represents the input capacitance of Q_2. At some frequencies all of these parts affect the performance of the circuit.

Fig. 6B illustrates the equivalent low-frequency circuit of the coupling network. Here we have represented the output resistance of Q_1 and R_2 as a single parallel resistance. Since these two resistors are always in parallel we will use this representation in all of the equivalent circuits. Similarly, we have represented R_3

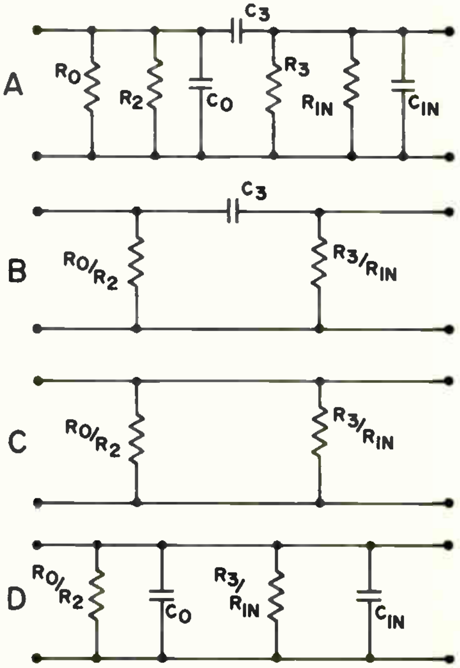

Fig. 6. Equivalent circuit of coupling network between Q1 and Q2 in Fig. 2.

and the input resistance of Q_2 as a single resistance. C_3 is the coupling capacitor and at low frequencies it will have a reactance that must be considered.

Since the input resistance of Q_2 is actually the parallel combination of R_3 and the input resistance to the transistor, we see that this resistance may be quite low. You already know that the input resistance of the transistor of a common emitter circuit is not particularly high; therefore, this resistance in parallel with R_3 will result in a comparatively low total resistance. Thus if we are to keep the half-power point at a reasonable frequency, we must use a large capacity for C_3. Capacitors many times those required for vacuum tube circuits are found in coupling networks between transistor stages. At some frequency the reactance of C_3 will be equal to the parallel resistance in the input circuit of Q_2 and then we will have the same voltage division we had in the vector circuit shown in Fig. 4. The amplitude of the voltage reaching the transistor Q_2 will be .707 of the amplitude reaching it in the mid-frequency range.

In Fig. 6C we have shown the effective mid-frequency range circuit. Here we simply have all of the resistances in parallel. Notice that since the input resistance of Q_2 is, in effect, in parallel with the output resistance of Q_1, the input resistance has an effect on the output resistance into which Q_1 is working. This means that in transistor R-C coupled amplifiers the input resistance of the second stage can actually affect the output that will be obtained from the first stage. This is not true in vacuum-tube coupled circuits because the input resistance of the second stage is so high it will not affect the output resistance of the first stage.

Fig. 6D shows the equivalent high-frequency circuit. We have shown the two resistances and capacitances separately, but actually they could be lumped together so that we have, in effect, a single resistance and a single capacitance. As in the case of the vacuum-tube circuit, at some frequency the capacitive reactance of the parallel capacity will be equal to the resistance of the parallel resistors. When this happens, the output voltage developed by Q_1 will fall to .707 of the voltage developed in the mid-frequency range. The vector representation will be the same as that given in Fig. 5.

We mentioned that the coupling capacitor in a transistor circuit must be larger than in a tube circuit in order to keep the low-frequency half-power point at a reasonably low frequency. In other words, we have an additional problem in the transistor circuit because of the low input resistance of the second transsistor. At the high frequency end we have a somewhat different situation. Since the transistors are already low-resistance devices, the value of the output and input capacitances can be somewhat larger than in a vacuum-tube circuit before they cause appreciable difficulty. If they happen to be the same as those in a vacuum tube circuit, then the high-frequency half-power point in a transistor circuit will be somewhat higher than the vacuum-tube circuit because the vacuum-tube circuits are high-resistance circuits and are quickly loaded by a capacitive reactance. The transistor circuits, on the other hand, are low-resistance circuits and the high-frequency half-power point will not be reached until a somewhat higher frequency.

CASCADE AMPLIFIERS

At the half-power point we say that the gain of an amplifier is .707 times the gain of the amplifier middle frequency. We also express this quite frequently as the percentage and say that the gain is 70.7% of the gain in the middle frequency range. This drop-off in gain due to the coupling network between a single stage is not too troublesome when only one network is concerned, but sometimes we have a number of amplifiers called cascade amplifiers and here the problem becomes much greater.

Cascade amplifiers are just a number of amplifiers connected together. A diagram of four cascade amplifiers is shown in Fig. 7. Here the input signal is fed to amplifier 1, amplified by it and then fed to amplifier 2, amplified further and fed to amplifier 3, where it is amplified still more, fed to amplifier 4, and amplified again.

We have not shown actual circuits in this diagram but we have presented each stage as a block to simplify the diagram. Each of these amplifiers could be either a vacuum tube amplifier or a transistor amplifier.

If the gain of each amplifier is 10 in the middle frequency range of about 100 cycles to 10,000 cycles, then the over-all gain of the first two stages is 10 × 10, or 100. The gain of the first three stages is 100 × 10 or 1000, and the gain of all four stages is 10,000. Thus, in the middle frequencies where the gain of each stage is 10, the total gain of this system is 10,000.

Now let's assume we are interested in amplifying signals as low as 75 cycles and at that frequency, the gain of the amplifier drops to 70.7% of what it is in the middle frequency range. Here the gain of each stage would be 7.07. Now the gain of the first two stages is 7.07 × 7.07 = 50. Now notice that the voltage gain of the two stages is only half of what it was at the middle frequencies.

The gain of the first three stages will be 50 × 7.07 or a little over 350, and the gain of all four stages will be 7.07 × 7.07 × 7.07 × 7.07 = 2500. Notice that whereas the gain of each stage has fallen to 70.7% of the gain at the middle frequencies, the over-all gain of the amplifier is only 25% of what it was at the middle frequencies! Thus, you can see that although the decrease in gain to 70.7% is not too big a problem in a single coupling network, if we have a number of stages used together, this fall-off in output is cumulative, so that in the four stages coupled as in Fig. 7, we have a gain of only 25% of the gain we had at the middle frequency. Of course, this much drop in response could not be tolerated and we would

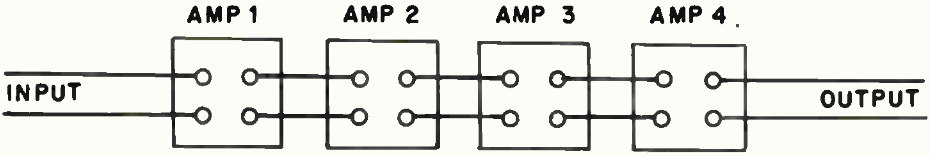

Fig. 7. Block diagram of cascade voltage amplifiers.

have to design each stage a little better so that within the range of frequencies we wanted to amplify, the gain in each stage would remain almost constant. In the example we have given, this problem can be overcome by using larger coupling capacitors.

SUMMARY

Resistance-capacitance coupled voltage amplifiers are the most important type of audio amplifier you will encounter. You should be able to draw from memory the circuits shown in Fig. 1 and in Fig. 2. You will use these circuits over and over again and the sooner you know exactly how the circuits are connected, the faster you'll reach a point where you'll understand their operation completely.

In the two circuits the first stage amplifies the input signal voltage. The amplified signal voltage is developed across the load resistor R_2. This amplified voltage is then fed through the coupling capacitor C_3 to the following stage. As long as the reactance of C_3 is low compared to the input resistance of the following stage all of the signal developed across R_2 reaches the input circuit of the following stage. However, at low frequencies the reactance of C_3 becomes appreciable compared to the input resistance of the following stage and then part of the signal is lost across C_3 so that the entire signal does not reach the input of the following stage. Thus in a low-frequency range the gain of the two-stage amplifier begins to fall off.

At some high frequency the output capacitance of the first stage and the input capacitance of the second stage begin to have a low enough reactance to effectively shunt the circuit and reduce the signal voltage developed across the load resistor R_2. When this happens, the gain of the amplifier begins to fall off as it does at low frequencies due to the reactance of the coupling capacitor. Because the input resistance of a transistor amplifier is much lower than that of a tube amplifier, a much larger coupling capacitor is required in the low-frequency region in the transistor circuit than is required in a tube circuit.

In the case of the transistor amplifier there was a tendency for the shunting capacity to have a less serious effect on the gain of the amplifier than it had in the case of the tube amplifier. This was due to the fact that the output resistance of the first transistor and the input resistance of the second stage were already low; therefore, a much larger capacitance was required to have the same loading effect. The input resistance of the second stage in a transistor amplifier had an appreciable effect on the gain of the first stage -- this is not true in the case of a vacuum tube amplifier; the input resistance of the second stage in the latter type is so high that it will not have any effect on the value of the load resistance in the plate circuit of the first stage.

Be sure that you understand resistance-capacitance amplifiers thoroughly before leaving this important section of the lesson. After you're sure that you understand the amplifiers, check yourself by doing the following self-test questions.

SELF-TEST QUESTIONS

(a) What is the purpose of R_1 in the circuit shown in Fig. 1?

(b) What is the purpose of C_1 in Fig. 1?

(c) With respect to the input signal voltage, what will the polarity of the amplified signal voltage across R_2 be?

(d) Is the voltage drop across R_1 in Fig. 2 used as the forward bias on Q_1?

(e) In the circuit shown in Fig. 2, do the holes reaching the collector flow through the collector load resistor R_2?

(f) When the input signal from the generator in Fig. 2 has a polarity which causes the end that connects the emitter to be negative and the end that connects to and through C_1 to the base to be positive, what happens in the transistor?

(g) Why does the input resistance of Q_2 in Fig. 2 have an effect on the gain of Q_1?

(h) In the circuits shown in Figs. 1 and 2, what part primarily limits the lower frequency limit of the two amplifiers?

(i) In the same circuits, what limits the high frequency limit to which the amplifiers can be used?

Transformer-Coupled Voltage Amplifiers

In the early days of radio, the vacuum tubes manufactured were relatively crude, and you couldn't get a great deal of gain from them. Voltage amplifiers with vacuum tubes frequently used transformer coupling between the tubes because the gain of the stage could be increased considerably by using a step-up transformer. For example, suppose the tube had a gain of five and you used a step-up transformer between the tube and the following stage, and suppose that the transformer had a turns-ratio of 1 to 3; this meant that the transformer would step-up the signal voltage fed to the primary by a factor of 3. Therefore, the total gain obtained with the tube and transformer would be equal to 5 × 3, or 15.

With modern vacuum tubes it is comparatively easy to obtain a gain of nearly 100 in R-C coupled circuits. Since R-C coupling is much more economical than transformer coupling, you will not find transformer coupling between voltage amplifier stages in modern equipment. Therefore, we'll take only a quick look at a vacuum-tube voltage amplifier using transformer coupling so you will know what it looks like, in case you run into it in any older equipment you might service, and also because transformer coupling is still used in some other applications.

In transistor circuits an entirely different situation exists. We have already pointed out that the input resistance of the second stage in a two-stage transistor amplifier has an effect on the output resistance of the first stage. We pointed out that the low input resistance of the second stage will, in effect, reduce the load resistance of the first stage, which in turn will reduce the amplitude of the output signal from the first stage. This problem can be overcome by using transformer coupling between the two stages. The transformer serves as an impedance-matching device and prevents the low input resistance of the second stage from reducing the load resistance of the first stage. Today, transformer coupling is much more important in transistorized circuitry than in vacuum circuity, so we'll spend more time discussing this type in transistorized circuits. However, let's go ahead and look at a transformer-coupled vacuum tube amplifier first.

VACUUM-TUBE CIRCUITS

Fig. 8 illustrates a typical two-stage vacuum-tube amplifier using transformer coupling between the stages. The operation of the circuit is comparatively simple. Resistor R_1 provides bias for V_1, and C_1 is the cathode bypass which provides a low-impedance bypass around the resistor for the signal. Resistor R_2 similarly provides bias for the second stage, V_2, and it is bypassed for the signal by capacitor C_2.

The input signal voltage causes the

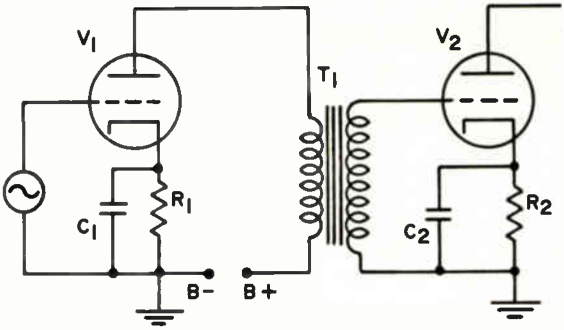

Fig. 8. Two transformer-coupled vacuum tubes.

potential between the grid and cathode to vary. This causes the plate current flowing through V_1 to vary. This varying current flows through the primary of T_1 and sets up a varying magnetic field which induces a voltage in the secondary of T_1. T_1 is a step-up transformer so that the voltage across the secondary will be greater than the voltage across the primary.

The amplified and stepped-up voltage appearing across the secondary of T_1 is applied between the grid and cathode of V_2 where it will receive further amplification.

At first glance it might appear that the transformer-coupled two-stage amplifier has many advantages over the R-C coupled amplifier. However, as we pointed out before, the step-up feature of the transformer is not needed with high-gain vacuum tubes available to use in modern equipment. In addition, a transformer is much more costly than the two resistors and capacitor needed for an R-C coupled network. Furthermore, most transformers are quite frequency-sensitive and therefore the signal voltage reaching V_2 will vary appreciably with frequency. Some of the problems of frequency discrimination in the transformer can be overcome by careful design, but this in turn increases the cost of the transformer. Because of the disadvantages of the transformer and the availability of high-gain tubes, this circuit is not used in modern equipment.

TRANSISTOR CIRCUITS

A transistor voltage amplifier using transformer coupling is shown in Fig. 9. Notice that both transistors are connected in common-emitter circuits.

From a standpoint of getting maximum gain from a transistor amplifier, transformer coupling is actually the best arrangement that can be used. You will remember that the input impedance of a transistor is quite low. We also pointed out that when two transistors are coupled together by means of resistance-capacity coupling, the low impedance of the second transistor actually loads the first transistor. The two transistors are not matched. By means of a transformer the first transistor can be matched to the second transistor so that the undesirable effect of having the input circuit of the second transistor load the output circuit of the first transistor can be avoided. The transformer serves as an impedance-matching device to match the comparatively high impedance of the first transistor to the low input impedance of the second transistor.

Looking at Fig. 9 we see that we have a transformer, T_1, in the input. This transformer is a step-down transformer and matches the low input impedance of the first transistor to the preceding circuit. C_1 is a blocking capacitor. It is needed to keep the transformer secondary from shorting out the forward bias placed across the emitter-base junction. The bias on the junction is obtained from the battery by means of a voltage divider network consisting of both R_1 and R_3. This network will bias the base negative with respect to the emitter. Notice that the 3K resistor R_1 is connected directly across the input circuit. As for the signal, it is connected directly from the base to the emitter. The 4 mfd capacitor C_3 provides an effective signal bypass between the emitter and ground.

The resistor R_2 is placed in the circuit to prevent thermal runaway. You will remember we mentioned previously that minority carriers crossing the collector-base junction may increase the forward bias across the emitter-base junction. This causes the current flow through the transistor to increase, heating the collector-base junction and its resistance, thereby causing still more minority carriers to cross the junction and increase the forward bias still further. R_2 prevents this from happening because if the emitter current increases, the voltage across R_2 increases, and this voltage subtracts from the forward bias across the emitter-base junction. This tends to keep the current through the transistor constant.

The signal is applied through the 4 mfd capacitor to the base of the first transistor and from the other end of the transformer through C_3 to the emitter. This causes the number of holes crossing the emitter-base junction to vary which in turn causes the number of holes reaching the collector to vary. Then the negative flow from the negative ter-

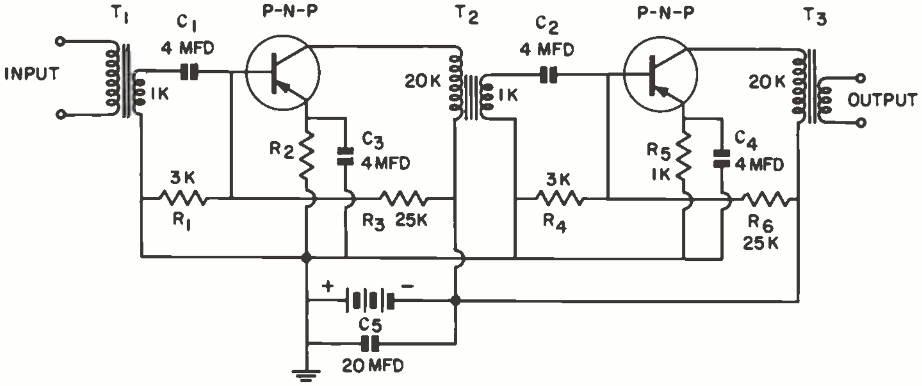

Fig. 9. Transformer-coupled voltage amplifier using transistors.

minal of the battery through the primary of T_2 will vary. The varying current through the primary of the transformer produces a magnetic field which induces a voltage in the secondary of the transformer. This in turn produces a varying voltage between the base and emitter of the second transistor.

Notice that the primary of T_2 is marked 20K and the secondary is marked 1K. The output impedance of a transistor in a common-emitter circuit is about 20K. The input impedance is about 1K. By means of a step-down transformer these impedances can be matched. You will remember that maximum power transfer from a generator to the load occurs when the load impedance is matched to the generator impedance. The first transistor acts more or less as a generator and maximum power is transferred from it to the second transistor when the input impedance of the second transistor is matched to the output impedance of the first transistor.

You might wonder why we are concerned about matching impedances to get maximum power transfer when the circuit shown in Fig. 9 is supposed to be a voltage amplifier. Remember, however, that transistors are current-operated devices. Therefore by matching impedances we can get maximum current variation in the emitter-base circuit of the second transistor. This in turn will result in maximum current variation in the collector circuit. The higher the current variation through the load of the second transistor the greater the voltage amplification obtained will be.

A two-stage transformer-coupled amplifier such as is shown in Fig. 9 will yield far more voltage gain than the two-stage R-C coupled amplifier shown in Fig. 2. This might at first lead you to believe that transformer coupling should be used in all transistor voltage amplifier circuits. However, this is not true because the transformers needed for the transformer coupling are much more expensive than the two resistors and capacitor needed in R-C coupled circuits. As a matter of fact, since transistors themselves are relatively inexpensive, it is usually more economical to use a three-stage R-C coupled voltage amplifier than it is to use a two-stage transformer-coupled voltage amplifier.

A three-stage R-C coupled amplifier is capable of giving about the same gain as a two-stage transformer-coupled amplifier. In addition, it is more difficult to get good frequency response using transformer coupling than it is using R-C coupling. Therefore, in applications in which we are concerned about the frequency response and in which we are trying to keep the cost down it is usually advantageous to use a three-stage R-C coupled amplifier. However, in some applications you will find transformer-coupled voltage amplifier circuits.

If you have to replace a transformer in a transformer-coupled voltage amplifier, it's important to use a replacement transformer having the same turns-ratio as the original transformer. The transformer is primarily an impedance-matching device and if you do not use a transformer with the same turns-ratio as the original, the output impedance of the first transistor will not properly match the input impedance of the second transistor.

SUMMARY

Since it is uneconomical, transformer coupling between voltage-amplifier vacuum-tube stages is no longer used. You will find it only in very old equipment. The transformer used between vacuum-tube voltage-amplifier stages is usually a step-up transformer. Transformer coupling is used in some transistor amplifiers. In this application, the transformer is a step-down transformer and it is primarily an impedance-matching device. By using a transformer in transistor voltage amplifiers, the high output impedance of the first transistor can be matched to the low input impedance of the second transistor. Transistor voltage amplifiers are capable of higher gain than R-C coupled amplifiers, but by using an extra stage the same gain can be obtained from R-C coupled amplifiers.

SELF-TEST QUESTIONS

(l) Why is it better to use transformer coupling in transistor-voltage amplifier stages?

(m) Why is transformer coupling seldom used between transistor-voltage amplifier stages?

(n) What must you watch if you have to replace a transformer in a transformer-coupled transistor-voltage amplifier?

Single-Ended Power Amplifiers

The primary purpose of most low-frequency amplifiers is to build up an audio signal to a sufficient amplitude to drive the loudspeaker. A loudspeaker must be driven by a power amplifier. The voltage amplifiers we have discussed previously are used to amplify a low-voltage audio signal to a sufficient amplitude to drive a power amplifier, which in turn will drive the loudspeaker.

There are a number of different types of power amplifiers that can be used to drive a loudspeaker: the single-ended power amplifier, which is always a Class A power amplifier, and the double-ended power amplifier, which may be a Class A, Class AB or Class B power amplifier. In this section of the lesson we are going to discuss single-ended power amplifiers. We will discuss both vacuum-tube power amplifiers and transistor power amplifiers.

Today, there are millions of radio and television receivers in use with low-frequency single-ended power amplifiers using vacuum tubes. You can be sure that you will run into this type of amplifier to service. In addition, there are many single-ended power amplifiers using transistors. This type of power amplifier is found in modern automobile receivers as well as in many portable receivers, in some table model radios and in some transistorized television receivers. It is quite likely that in the future there will be fewer vacuum tube stages around to service, but at the present there are probably many more power amplifiers using vacuum tubes than transistors. We will go into the vacuum-tube circuit first, and then into the transistor power amplifiers later.

VACUUM-TUBE CIRCUITS

A typical single-ended Class A power amplifier using a beam power tube is shown in Fig. 10. Practically all modern low-frequency power amplifiers use beam power tubes. This stage is driven by the amplified signal voltage from the last voltage amplifier applied to R_1 through C_1. It produces audio power to drive the loudspeaker. Notice that in general this circuit is not too different from that of a voltage amplifier.

The tubes made for use in power amplifier stages are designed especially for this type of service. These tubes normally draw a much higher plate current than the tubes in voltage amplifiers. A typical tube used in a voltage amplifier may draw a plate current somewhere between about 1 and 10 milliamperes, whereas tubes designed for use in power amplifiers will usually draw a plate current of 50 milliamperes or more.

In the circuit shown in Fig. 10, R-C coupling is used between the preceding voltage amplifier and the power amplifier. This type of coupling can be used between a Class A power amplifier and the last voltage amplifier because no grid current flows. The power amplifier shown in Fig. 10 is designed to operate as a

Class A amplifier by the voltage developed across the cathode-bias resistor R_2. You will remember that in a Class A amplifier, sufficient bias is applied to the tube so that the grid voltage is halfway between zero and cut-off voltage. In operation, the grid should not be driven positive, and it should not be driven into the region where plate current is cut off. As long as the grid is not driven positive, there will not be a grid current flow.

Notice that R_2 is bypassed by a capacitor, C_2. This capacitor is usually an electrolytic capacitor -- in many receivers you will find that this capacitor is in a common can along with the filter capacitors used in the receiver. It is usually a comparatively low-voltage capacitor because the voltage across it (which is equal to the voltage across R_2) is not too high. An electrolytic capacitor is used because the resistance of R_2 is usually only a few hundred ohms. A large capacitor is required to bypass this resistor -- otherwise, the reactance of the capacitor becomes so high at low frequencies that the resistor is not bypassed effectively. The purpose of this capacitor is to hold the cathode at signal ground potential, as we mentioned previously, so that the input signal is, in effect, applied directly between the grid and cathode of the tube.

You will remember that to get maximum power transfer from a generator to a load, the load impedance must be matched to the generator impedance. In this circuit, the tube acts as the generator. However, a beam power tube has a very high plate impedance. Therefore, it is not practical to try to match the plate impedance of the tube to the speaker. Instead, manufacturers of the tubes usually specify a load impedance into which a tube should work for best results. The output transformer is designed so that the tube will, in effect, see this load impedance. This is accomplished by means of a step-down transformer, T_1, which matches the load impedance of the tube to the low impedance of the speaker voice coil. Another way of looking at this transformer is from the speaker end of the circuit. Most speakers have a comparatively low impedance; the speakers in most radio and television receivers have a voice coil

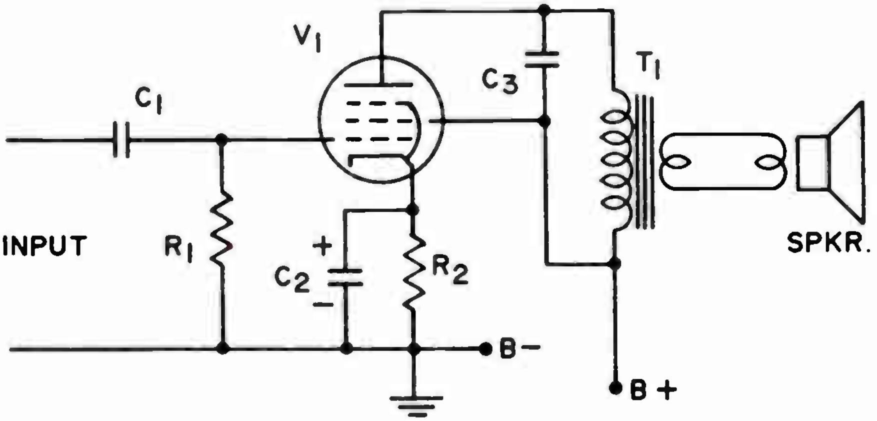

Fig. 10. Schematic diagram of single-ended Class A amplifier using a beam power tube.

impedance of 3.2 ohms at a frequency of 400 cycles. The output transformer is designed to step up this impedance so that the tube sees the load it works into best. Most beam power tubes work into a load of somewhere between 2,500 ohms and 10,000 ohms. Therefore, if we look at the circuit from the speaker end, the transformer is a step-up transformer because it steps up the low impedance of the speaker to the higher impedance of the tube. If we look at the circuit from the tube end, on the other hand, the transformer is a step-down transformer because it steps the high impedance of the tube down to the low impedance of the speaker. The important thing for you to realize is that the primary winding of the transformer, which connects to the plate circuit of the tube, has far more turns on it than the secondary winding that is connected to the voice coil of the speaker. Since the primary winding has more turns than the secondary, we usually refer to this as a step-down transformer.

Capacitor C_3 is called a plate bypass capacitor. This capacitor is used to prevent oscillation. Actually, the capacitor provides a low-impedance path for high-frequency signals and it reduces the possibility of a high-frequency oscillation in the stage. These high-frequency signals in the plate circuit of the tube are shunted to ground through the capacitor while low frequency signals must flow through the primary of T_1. You might wonder how the high-frequency signals are shunted to ground through C_3, since C_3 connects between the plate and screen of the tube. The screen of the tube connects directly to B+. The output of the power supply will have a large electrolytic capacitor as the output filter capacitor. This capacitor provides a low impedance path from B+ to ground as far as the audio signal is concerned. Therefore, B+ is effectively at ground as far as the signal is concerned. Hence the bypass capacitor C_3 (which connects from the plate to the screen of the tube) effectively bypasses the high-frequency signal to ground.

In some receivers you will find C_3 connected directly between the plate of the tube and ground. The disadvantage of this arrangement is that C_3 must then be capable of withstanding the high dc plate voltage applied to the tube. By using the circuit shown in Fig. 10 and connecting C_3 between the plate and screen of the tube, the only dc voltage the capacitor must be able to withstand is the voltage drop across the primary winding of T_1. This voltage is usually nominal (somewhat less than 10 volts) so that C_3 does not have a high dc potential placed across it.

Sometimes you will see a triode tube used as the power output tube. A triode tube has the advantage over a pentode or a beam power tube, in that it usually produces less distortion. However, the disadvantage of the triode tube is that it requires a very high driving power. The power gain in a triode tube is relatively low compared to that of a beam power or a pentode tube. As a result, triode tubes have in general disappeared as power amplifiers in favor of beam power and pentode tubes.

TRANSISTOR CIRCUITS

A schematic diagram of a single-ended Class A amplifier using a PNP

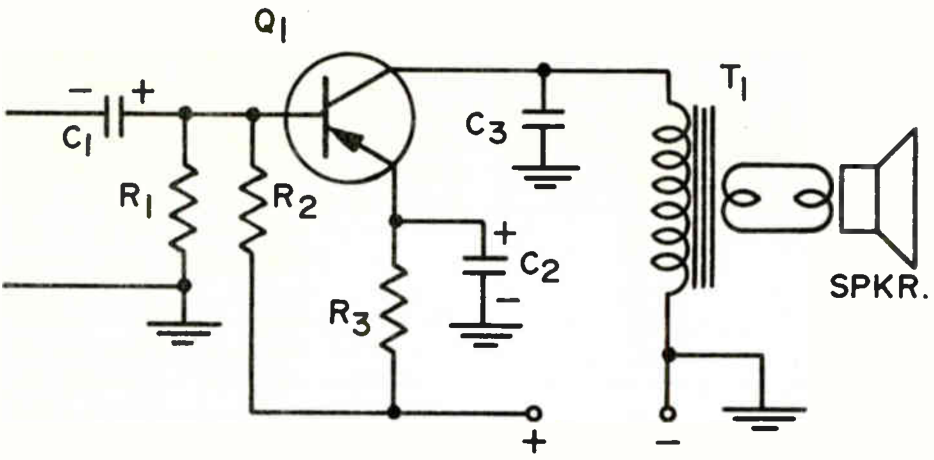

Fig. 11. Schematic diagram of single-ended Class A amplifier using a PNP transistor.

transistor is shown in Fig. 11. Notice that, in many respects, this circuit is similar to the vacuum tube circuit shown in Fig. 10.

The circuit we have shown in Fig. 11 is a common-emitter circuit and the output transformer is connected in the collector circuit. Again, the output transformer is an impedance-matching device. Its purpose is to match the speaker impedance to the output impedance of the transistor. Notice that capacitor C_2 is an electrolytic capacitor. The value of R_3 is comparatively low, so in order to hold the emitter at signal ground potential for all signal frequencies, the capacitor must be large. As in the case of a vacuum-tube circuit there will be some low frequency where the reactance of this capacitor becomes appreciable and reduces the gain of the amplifier at that frequency.

The input coupling capacitor C_1 (in the circuit shown) is an electrolytic capacitor. Again, remember that an electrolytic is required in the input of the stage because the input resistance of the transistor is very low and unless a large capacitor is used, there will be considerable loss in gain at low frequencies.

Once again, C_3 is a bypass capacitor. Its purpose is the same as that of the plate bypass capacitor in Fig. 10. It is used to prevent oscillation in the collector circuit and to provide a low-impedance path from the collector to ground for high-frequency signals in the collector circuit.

In a Class A stage of this type, the emitter-base junction is biased so that the transistor operates approximately in the midpoint of its characteristic curve. The bias is adjusted so that the signal does not overcome the emitter-base forward bias at any time and the current flow from the emitter to the collector is never cut off.

Transistor power amplifiers of this type are quite widely used in automobile receivers. In most automobiles the negative side of the battery is grounded. This means that the collector of the transistor is almost at ground potential. It is at ground potential less the voltage

Fig. 12. A power transistor.

drop across the primary of T_1. As a result, very little insulation is required between the collector and the receiver chassis. Power transistors resemble the transistor shown in Fig. 12. They are usually bolted to the chassis to provide a heat sink, or a means of getting rid of the heat dissipated by the transistor. Very little insulation is required between the transistor case and the chassis in a circuit of this type because there is very little voltage between the chassis and the collector. In most power transistors, the collector connects directly to the case of the transistor; therefore, the circuit provides a simple way of getting rid of the heat developed in the transistor and at the same time keeps the insulation requirements between the transistor case or collector to a minimum.

Of course, in a circuit of this type NPN transistors can be used as well as PNP transistors. For that matter, in automobile receivers where the battery voltage is only 12 volts, it is comparatively simple to insulate NPN transistor collectors from the chassis so that there will be no voltage breakdown, and at the same time provide adequate heat dissipation from the transistor.

Single-ended transistor amplifiers are also used in radio and television receivers that are operated from the power line. However, in portable-type equipment that operates from a dry cell-type battery, it is more economical to use push-pull transistors in Class B circuits. You will see this later.

SUMMARY

Class A power amplifiers are important because they are used in all types of equipment, especially in radio and television receivers. The power amplifier is a stage that converts the amplified signal to a signal with sufficient power to drive a loudspeaker. It consists of a tube or transistor, the output transformer, and the loudspeaker. The loudspeaker is the load; the output transformer is designed to match the speaker impedance to the output impedance of the tube or transistor.

You should be sure that you understand what a Class A power amplifier is and what it is supposed to do. If you go into radio and TV service work, you will run into an amplifier of this type in almost every radio or television set you will repair. If you plan to be a technician in a broadcast station you will find Class A power amplifiers in both radio and television equipment. If you intend to go into industrial electronics, you may be in a plant where a public address system is used. The chances are that you will find Class A amplifiers in this equipment. Regardless of what type of electronics work you do, you will encounter this type of amplifier.

SELF-TEST QUESTIONS

(o) What is the purpose of a power amplifier in a radio receiver?

(p) What type of tube can you expect to find in the power amplifier stage of most modern radio and television receivers?

(q) What is the purpose of the bypass capacitor used in the plate circuit of power amplifier tube circuits?

(r) In a circuit such as the one shown in Fig. 10, how can low-frequency distortion due to the reactance of the cathode bypass capacitor be kept to a minimum?

(s) What is the advantage of using a PNP transistor power amplifier (such as in Fig. 11) in an automobile receiver?

(t) Are you likely to find a single-ended or a push-pull power output stage in portable receivers which operate from batteries?

Push-Pull Power Amplifiers

In many applications it is impossible or at least uneconomical to try to obtain the required power from a single-ended stage. In such cases a double-ended power amplifier called a push-pull amplifier is used. A push-pull amplifier is particularly useful because it generates no second-harmonic distortion. Because of the circuit arrangement, any second-harmonic distortion produced is cancelled within the stage itself. Second-harmonic distortion is a signal having a frequency equal to twice the frequency of the signal to be amplified. Due to the curve in the characteristic curve of both tubes and transistors, single-ended stages produce a certain amount of second-harmonic distortion. However, in push-pull amplifiers, any second-harmonic distortion that is produced will be cancelled in the stage itself.

Push-pull stages may use either tubes or transistors, and you will study both types. Also, push-pull stages may be operated as Class A amplifiers or as Class B amplifiers. Often, you will find push-pull pentode or beam power stages operated as Class AB amplifiers. We will study and review some of the conditions of these various types of operations.

CLASS A AMPLIFIERS

A typical Class A push-pull amplifier using beam power tubes is shown in Fig. 13. Transformer T_1 can be a step-up transformer to provide additional drive between the grid and cathode of each tube. Notice that the cathode bias resistor R_1 is not bypassed. A bypass capacitor is not necessary because the current flowing through this resistor remains essentially constant. When the input signal drives the grid of V_1 in a positive direction so that the current flow through this tube increases, the signal will at the same time drive the grid of V_2 in a negative direction so that the current through that tube decreases. If the tubes are operated on the linear portion of their characteristic curves, the increase in plate current in V_1 should be offset by the decrease in plate current in V_2.

C_1 and C_2 serve as plate bypass capacitors for the two tubes. These capacitors prevent high-frequency oscillations which might cause the tubes to draw excessive current and burn out the primary of the output transformer.

Notice that the B+ for the screen of the tubes is obtained from the output filter capacitor. The B+ at this point will receive maximum filtering so that it is essentially pure dc. At the same time, the center tap of the output transformer, T_2, through which plate voltage is supplied to the two tubes, connects to the input filter capacitor. The dc voltage at this point will be somewhat higher than the voltage at the output filter capacitor due to any voltage drop that might occur in the filter choke or filter resistor used in the power supply. In addition, there will be considerably more hum voltage present at this point. At first, you might think that this would cause hum in the output. However, there are two factors which prevent hum in a circuit of this type. First, any hum current would flow through the two halves of the output transformer

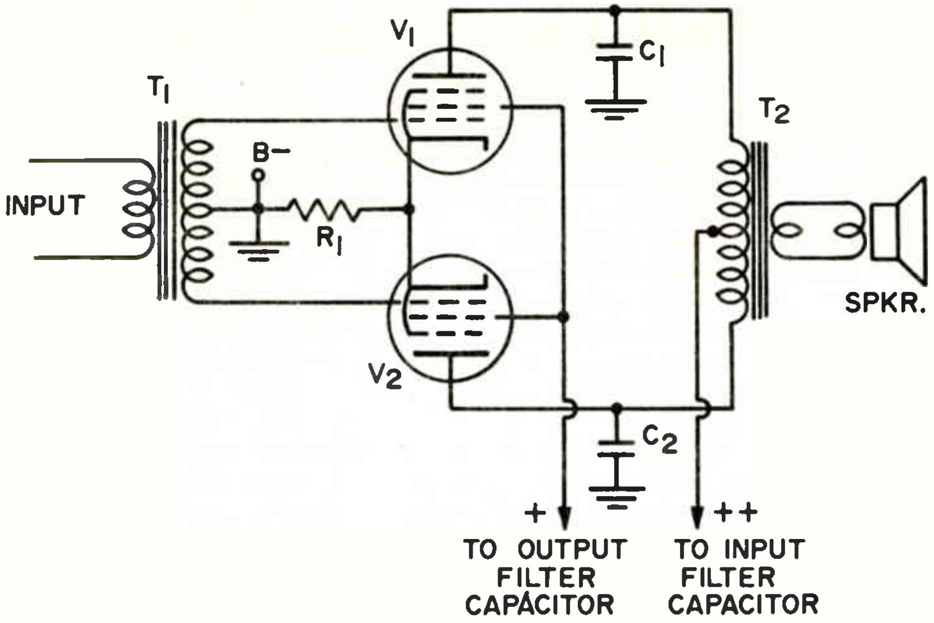

Fig. 13. Class A push-pull beam power tubes.

T_2 in opposite directions and hence tend to cancel. In addition, if there is some hum voltage on the plates of the two output tubes, remember that in pentodes and in beam power tubes the plate current depends very little on the plate voltage. It is determined primarily by the grid and screen voltages. Therefore, if there is some variation in the plate voltage on the tubes due to hum, this will not cause any appreciable change in plate current. Hence, the current flowing through the primary of T_2 remains essentially constant, and no hum will be fed to the speaker.

A push-pull Class A power amplifier using NPN transistors is shown in Fig. 14. Notice that, in many ways,

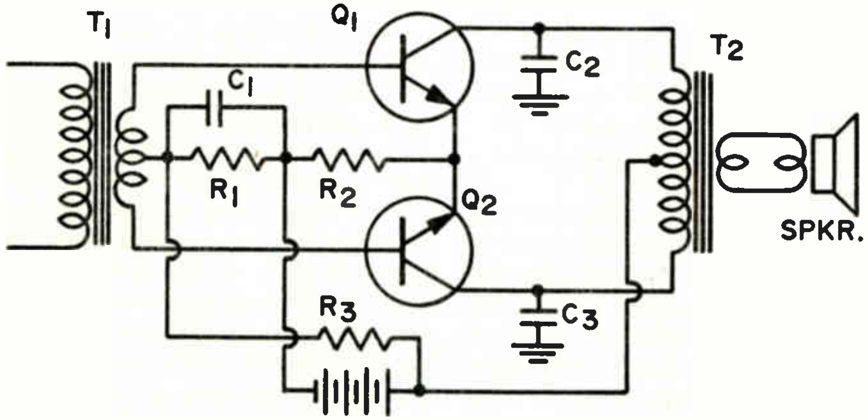

Fig. 14. Class A push-pull NPN transistors.

the circuit is similar to the vacuum-tube circuit in Fig. 13. The transformer T_1 is a step-down transformer; you will remember that the input resistance (or impedance, as it's more correctly called when referring to a signal) of transistors in a common-emitter circuit is quite low. Thus, T_1 serves as a matching device. Forward bias for the emitter-base junction is obtained by means of a voltage-divider network made up of R_1 and R_3 connected across the battery.

Resistor R_2, connected between the negative side of the battery and the emitter, is for bias stabilization purposes. In the event that the current through the transistor starts to increase due to a temperature rise in either transistor, the current through R_2 will increase and reduce the bias to hold the current through the transistors essentially constant.

Capacitors C_2 and C_3 are bypass capacitors that are used to prevent high-frequency oscillation in the output circuit. In some circuits the capacitors will be connected as shown, while in others a single capacitor connected directly between the two collectors may be used.

For simplicity, we have represented the power supply in the circuit as a battery. Of course, in a portable receiver or in an automobile receiver the actual power source will be a battery. However, in equipment designed for use in the home (where it will be operated from a power line) a power supply will replace the battery. The power supply will use a rectifier and a filter circuit similar to those you have already studied. It might also have a step-down transformer if the transistors are of the low-voltage type. However, many transistors are designed for high-voltage operation and equipment using this type of transistor will not require a transformer in the power supply.

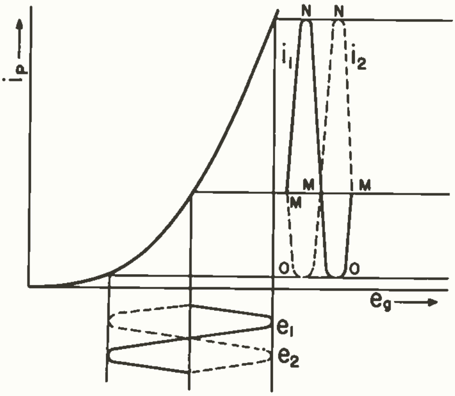

Fig. 15. When the operating point is on the lower bend of the tube characteristic curve, the plate current pulses i_1 and i_2 will be distorted.

Distortion Cancellation.

We mentioned previously that second-harmonic distortion generated within a push-pull amplifier is cancelled in the stage. Let's see how this distortion is produced and how it is cancelled.

First, we'll consider the beam power circuit shown in Fig. 13. Remember that the characteristic curve of a tube is not a straight line -- it is curved something like the line shown in Fig. 15. If the tube is operated on the bent portion of the curve shown in Fig. 15, distortion will be introduced.

Referring back to Fig. 13, let's consider the input signal across the primary of T_1 as "e" and in Fig. 15 consider the signals across the two halves of the secondary as e_1 and e_2. The plate current flowing through V_1 will be referred to as i_1 and the plate current flowing through V_2 as i_2. Let's look first at the signal e_1

applied to the tube V_1 -- this is represented in Fig. 15 as the solid line. When e_1 swings in a positive direction, i_1 increases as shown; when e_1 swings in a negative direction, then i_1 decreases as shown.

Notice, however, that the waveshape for the plate current is not equal in amplitude on the two sides of the zero axis -- that is, the alternation M-N-M is greater than the alternation M-O-M. This indicates that the stage has added second harmonics as well as other even harmonics to the original fundamental sine wave. In other words, it has added distortion (signals that were not present in the original signal).

At the same time, the other tube is getting the grid signal e_2, represented by the dotted line in Fig. 15. Notice also that the plate current i_2 is distorted on the M-O-M alternation. However, the plate current alternation of i_1 that is distorted occurs at the same moment as the portion of i_2 that is not distorted, and vice versa. This is due to the fact that e_1 and e_2 are 180° out-of-phase (when one is going positive, the other is going negative).

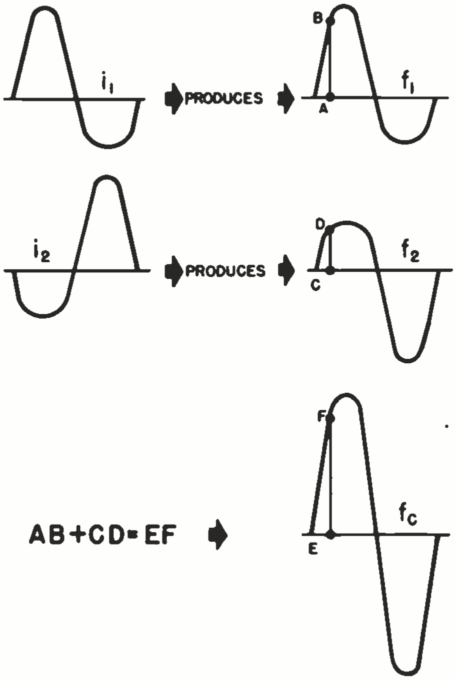

Fig. 16. The even-harmonic distortion cancellation occurs because of the manner in which the fluxes add in the output transformer.

In a transistor circuit such as is shown in Fig. 14, essentially the same thing happens. When the collector current of Q_1 is increasing, the collector current in Q_2 is decreasing. Similarly, when the collector current in Q_1 is decreasing, the collector current in Q_2 is increasing. Thus, if we have distortion in one-half of the output waveform produced by either transistor, we have exactly the same thing we have in the vacuum-tube stage, represented graphically in Fig. 15.

Now let's examine the action occurring in T_2 when the plate current of the two tubes (shown in Fig. 13) or the collector current of the two transistors (shown in Fig. 14) flows through the primary winding. This is shown in Fig. 16. Although the currents i_1 and i_2 are 180° out-of-phase, they now flow in opposite directions through the two halves of the primary T_2.

If i_1 produces flux f_1 and i_2 produces flux f_2 (as shown in Fig. 16), the fact that i_2 is flowing through the transformer in a direction opposite from that of i_1 means that flux f_2 will add to flux f_1, as if the two were being produced by a single current flowing through the entire primary winding. When f_1 and f_2 (in Fig. 16) are added, the resultant flux (f_c) is not distorted.

Because the resultant flux f_c is

not distorted even though the flux produced by the individual tubes or transistors is distorted, a push-pull amplifier will cancel out all even harmonics produced within the stage. In other words, if some second and fourth harmonic distortion is produced within the stage, it will be cancelled out in the stage because of the way in which the signals are recombined in the output transformer. This applies only to even-order harmonics produced within the stage because of a non-linear tube or transistor characteristic. A push-pull amplifier will not cancel even-order harmonics fed to it in the input, nor will it cancel out odd-order harmonics such as the third and fifth harmonics generated within the stage.

Push-pull amplifiers are not entirely distortion-free because a certain amount of third, fifth and higher odd harmonics will be produced within the stage. These harmonics are not cancelled out by another stage. Therefore, the amount of third harmonic distortion in the stage is usually what limits the amount of power we can get out of the stage without excessive distortion. The more power we try to get out of the stage, chances are the more third harmonic distortion there will be produced.

CLASS B AMPLIFIERS

A Class B push-pull amplifier using beam power tubes is shown in Fig. 17. Notice that this circuit is almost identical to the circuit shown in Fig. 13. The only difference is that the bias for the tubes is obtained from a separate source rather than from a cathode bias resistor. In Class B operation the tubes are biased approximately at cut-off. You cannot have current flow in the cathode circuit to develop this bias if the tubes are at cut-off and therefore grid bias for the tubes must be obtained from another source. It is usually obtained by placing a resistor in the negative side of the power supply.

In the Class B amplifier with the tubes biased to cut-off, when the in-

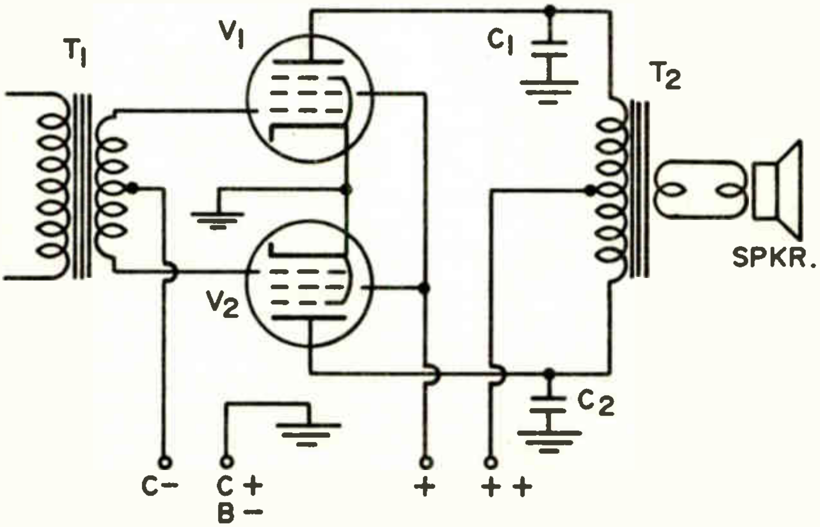

Fig. 17. Class B push-pull beam power tubes.

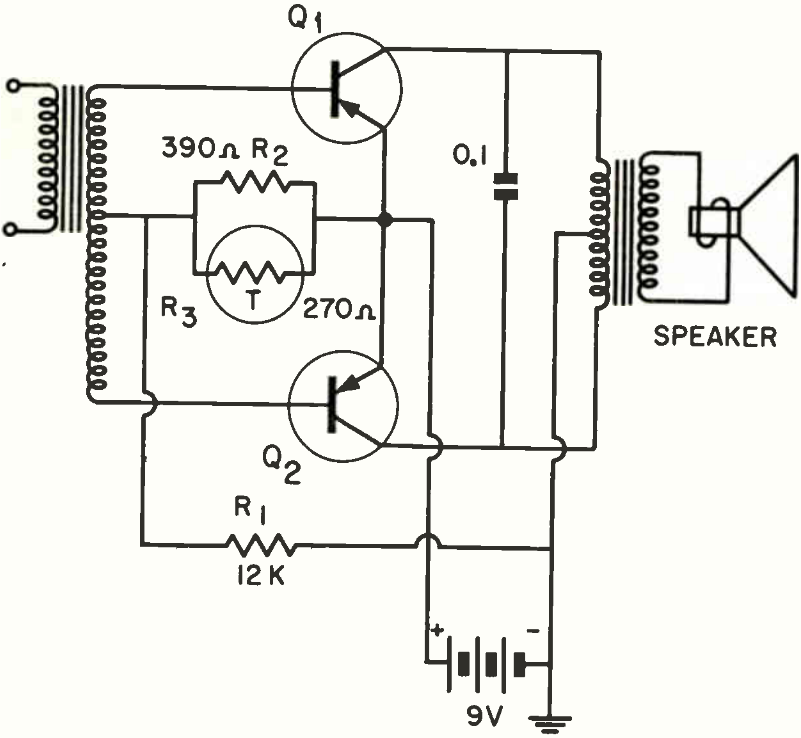

Fig. 18. Class B push-pull PNP transistors.

put signal swings the V_1 grid in a positive direction the tube will conduct. At the same time, the grid of V_2 will be driven in a negative direction so that no current will flow through V_2. During the next half-cycle, the opposite happens; the grid of V_2 is driven in a positive direction so that this tube conducts and no current flows through V_1.

Notice that we have indicated the plate and screen going to different voltage sources. As in the circuit shown in Fig. 13, the screen is returned to the output filter capacitor and the plate to the input filter capacitor in order to get the higher voltage on the plate.

Class B push-pull amplifiers using PNP transistors are shown in Fig. 18. Notice that the circuit is not too different from the tube circuit. The transistors are used in a common-emitter circuit. Bias is obtained by means of a voltage divider consisting of R_1 in series with the parallel combination of R_2 and R_3. The divider network is connected across the battery. When the input signal drives the base of Q_1 in a negative direction, Q_1 will conduct quite heavily. Holes will cross the emitter-base junction and flow over to the collector. At the same time as the base of Q_1 is driven in a negative direction, the base of Q_2 will be driven in a positive direction so that the base will be positive with respect to the emitter. Thus there will be reverse bias across the emitter-base junction of this transistor, and no current will flow through it. During the next half-cycle when the signal is reversed, the base of Q_1 will be driven in a positive direction so that a reverse bias will be placed across the emitter-base junction of this transistor and hence no current will flow through it. The base of Q_2 will be driven in a negative direction, increasing the forward bias so that the current flow through the transistor is increased. The number of holes crossing the emitter-base junction increases, and therefore the number of holes reaching the collector will increase.

The resistor R_3 in the emitter circuit is for bias stabilization purposes. This resistor is a thermistor. If the temperature is high, the resistance of R_3 will go down. This will reduce the forward bias across the emitter-base junction of the transistors and prevent the current from becoming excessive.

CLASS AB AMPLIFIERS

Quite frequently, vacuum tubes are not operated as Class B power amplifiers, but rather as Class AB power amplifiers. This is particularly true of amplifiers using beam power tubes. You can obtain almost as much power out of a Class AB vacuum tube as you can from the Class B circuit and the distortion is usually somewhat less with the Class AB operation. You will remember that for Class AB operation, bias on the tubes is about halfway between the bias used for Class A operation and the bias used for Class B operation. If the grids are driven positive at any time during the input cycle, we refer to the operation as Class AB_2 operation. If the grids are not driven positive then it is referred to as Class AB_1 operation.

When the power amplifier is operated as a Class AB_2 amplifier or a Class B amplifier where the grids of the tube are actually driven positive, the tubes consume power in the grid circuit. In an application of this type, the input transformer must be a step-down transformer in order to provide the power needed in the grid circuit. In addition, instead of using a voltage amplifier in the preceding stage, a power amplifier stage is required. In other words, in a circuit such as is shown in Fig. 17, the stage driving the push-pull Class B power amplifiers would probably be a single-ended Class A power amplifier. The Class A power amplifier produces the power required in the grid circuit of the two tubes. In Class A or Class AB_1 operation where the grids are not driven positive, the tubes do not require grid power and can be driven by a voltage amplifier stage.

SELF-TEST QUESTIONS

(u) In Fig. 13, why is the cathode resistor R_1 not bypassed?

(v) In Fig. 13, what purpose do C_1 and C_2 serve?

(w) In Fig. 14, is T_1 a step-up or a step-down transformer?

(x) What is one of the primary advantages of a push-pull type of power amplifier circuit?

(y) What is the difference between the Class A power amplifier in Fig. 13 and the Class B power amplifiers in Fig. 17?

(z) In Fig. 18, how are the transistors biased?

Reducing Distortion

Distortion is one of the most serious problems in low-frequency amplifiers. There are three kinds of distortion with which we must contend: amplitude distortion, frequency distortion, and inter-modulation distortion.

Amplitude Distortion.

Amplitude distortion results from the creation of irregularities in amplifying the signal. For example, one-half of a sine wave does not receive the same amplification as the other half, and harmonic distortion is produced. This means that signals that are multiples of the original signal frequency are produced. If the signal has twice the frequency of the original signal, it is called second harmonic distortion; if the signal is three times the frequency of the original signal, it is called a third harmonic distortion, and so on.

A small amount of distortion of this type is hardly noticeable, but the quality of the amplified signal usually suffers if you get a certain amount of second harmonic distortion plus some third (and higher) harmonic distortion.

Sometimes, in amplifying a sine wave, a small pip or irregularity may appear on the sine wave that was not present in the original signal. This type of distortion is also called amplitude distortion.

Frequency Distortion.

You already know that the gain of an amplifier falls off at low frequencies due to the reactance of the coupling capacitor used between the stages of an amplifier. Thus, low-frequency signals in some amplifiers do not receive the same amount of amplification as the middle-frequency signals receive. Similarly, at some high frequency, the various capacities in the circuit begin to reduce the gain of the amplifier at high frequencies so that high-frequency signals do not receive the same amount of amplification as middle-frequency signals receive. This failure to amplify signals at all frequencies equally is known as frequency distortion.

Inter-Modulation Distortion.

If an amplifier is not operated on the linear portion of its characteristic curve, mixing of two or more signals in the amplifier sometimes occurs. For example, suppose that two signals are fed to an amplifier at the same time. This might happen when an amplifier is amplifying musical notes of two different frequencies. If the two signal frequencies beat together to produce new signals equal to the sum and difference of the original signal frequencies, we have what is called inter-modulation distortion. In this case, the two signals have mixed together.

Inter-modulation distortion can be kept to a minimum by operating the amplifier on the linear portion of its characteristic curve and by avoiding operation of the amplifier at or near its maximum amplification capabilities.

There are several methods used to keep distortion to a minimum. One of these, of course, is careful design; another is making sure that the tube or transistor used in the amplifier is operated as it should be. This, however, is not enough to get what we would call good high-fidelity reproduction, although it is good enough for most table-model radio receivers (where we do not expect extremely high-quality output) and for television receivers (where we are primarily interested in sound to accompany the picture). In quality sound-reproducing equipment (high-fidelity or stereo, for example), on the other hand, steps must be taken to keep distortion as low as possible. One of the simplest steps in reducing distortion is the use of inverse feedback.

INVERSE FEEDBACK

Fig. 19 illustrates two simple examples of inverse feedback. The circuit at A shows a vacuum tube; the circuit at B, a transistor.

Looking first at the vacuum-tube circuit, we see that it is exactly the same as the circuit you studied previously, but in this case the bias resistor (R_2) in the cathode of the circuit of the tube is not bypassed.

The purpose of the cathode bypass capacitor is to bypass signals around the cathode resistor, R_2. We pointed out previously that all capacitors have a certain reactance, and that at low frequencies this capacitor may not be a good bypass. As a result, there will be some attenuation of low-frequency signals. By completely eliminating the capacitor, we can eliminate the problem. Now all signals will receive some reduction in amplification because there is a

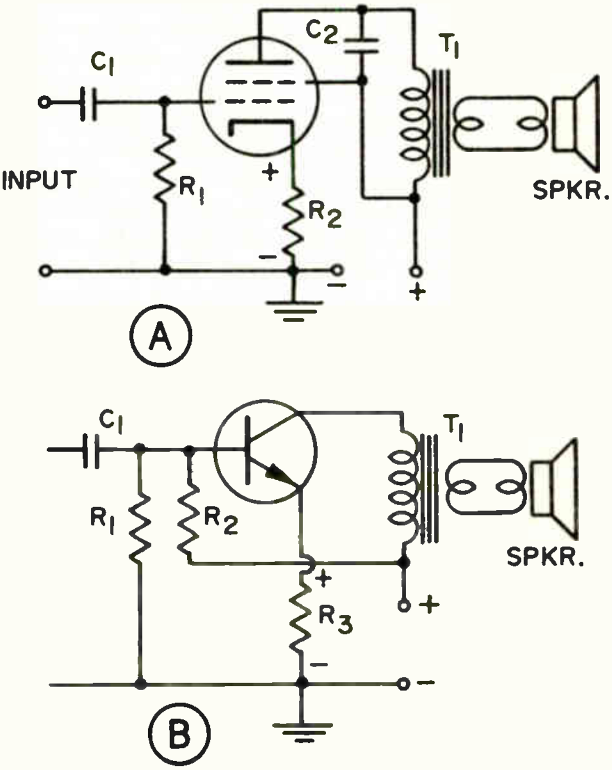

Fig. 19. Simple inverse feedback circuits.

certain amount of feedback in the circuit.

Let's consider what happens when a signal drives the grid of a tube in a positive direction. This causes the current flow through the tube to increase; hence the voltage drop across R_2 (which has the polarity shown on the diagram) increases. Thus the cathode swings in a positive direction. The signal voltage developed across R_2 is subtracted from the grid voltage. We then have a certain amount of feedback; in other words, the signal from the output circuit is fed back into the input circuit. We call this feedback "inverse" because the signal subtracts from the input signal.

In the transistor circuit shown in Fig. 19B, the resistor R_3 is put in the emitter circuit for temperature stabilization. It is usually bypassed, but the bypass capacitor acts in exactly the same way as the cathode-bypass capacitor in the tube circuit. At low frequencies, the capacitor is not an effective bypass. By eliminating the capacitor a certain amount of inverse feedback is introduced into the circuit. When the input signal drives the base in a positive direction, the forward bias across the emitter-base junction increases and the current flow through the transistor increases. This causes the voltage across R_3 to increase and the increase in voltage subtracts from the positive base voltage, thus reducing the net base-emitter signal voltage.

The feedback signal will be developed at all signal frequencies and will tend to make the gain of the amplifier more constant over a wider frequency range. You can see why this is so if you consider that at some frequency the signal reaching the amplifier has a higher amplitude than at other frequencies. This signal in the case of the circuit at A will cause a higher cathode current through the tube. Hence the voltage across R_2 will be higher than at other frequencies and will tend to reduce the input signal more than at other frequencies. Similarly, if the signal applied to the base is greater at some particular frequency, it will tend to develop a higher feedback signal across R_3. This, in turn, will tend to reduce it more, keeping it closer to the amplitude of the other signal frequencies.

We sometimes call this type of feedback "degeneration". Degeneration and inverse feedback are essentially the same thing. When the signal fed from the output circuit back to the input circuit reduces the input signal, we say this is degenerative feedback or inverse feedback. When the signal fed from the output circuit back to the input circuit adds to or aids the input signal, we call it regenerative feedback. Regenerative feedback is never used to improve the response of an amplifier.

The example of inverse feedback shown in Fig. 19 is in both cases contained within a single stage. Inverse feedback can be used over more than one stage as shown in the example in Fig. 20. Here a signal is fed from the plate of the output tube back to the cathode of the voltage amplifier tube.

In the circuit shown in Fig. 20, when the input signal drives the grid of V_1 in a positive direction, a negative-going signal will be developed in the plate circuit. This signal is fed to the grid of V_2 through the capacitor C_3 and this in turn causes a positive-going signal in the output circuit of V_2. The positive-going

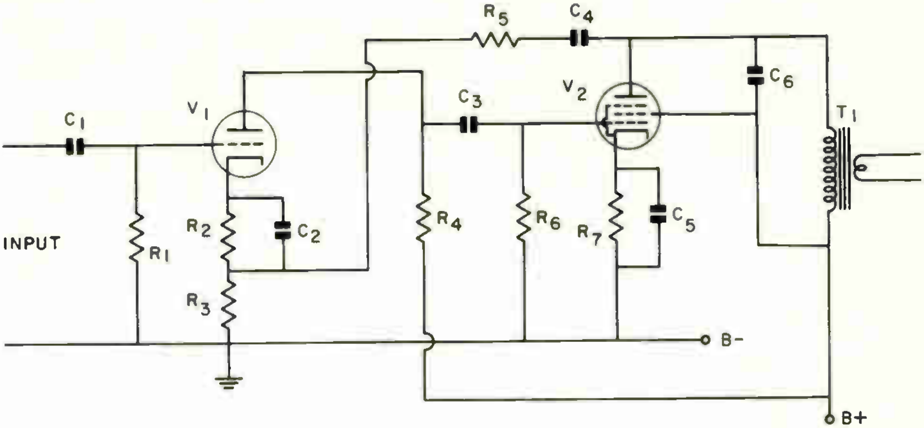

Fig. 20. Inverse feedback from the plate of the power output tube to the cathode of the voltage amplifier tube.

signal is fed through C_4 and R_5 back into the cathode circuit of V_1 where it subtracts from the input signal fed to V_1. The advantage of two-stage feedback of this type is that it tends to equalize the gain of the amplifier over both stages rather than in just a single stage as in the circuits shown in Fig. 19.

PHASE INVERTERS

One of the causes of distortion in push-pull power amplifiers (such as in Fig. 13) is the input transformer. Transformers that respond equally to a wide range of frequencies are difficult and expensive to manufacture. The transformer in this circuit can be eliminated by means of a phase inverter stage as shown in Fig. 21.

In this circuit the input signal is applied between the grid and cathode of V_{1A}. It is amplified by this tube and the signal phase is inverted. The signal is fed through C_3 to the grid

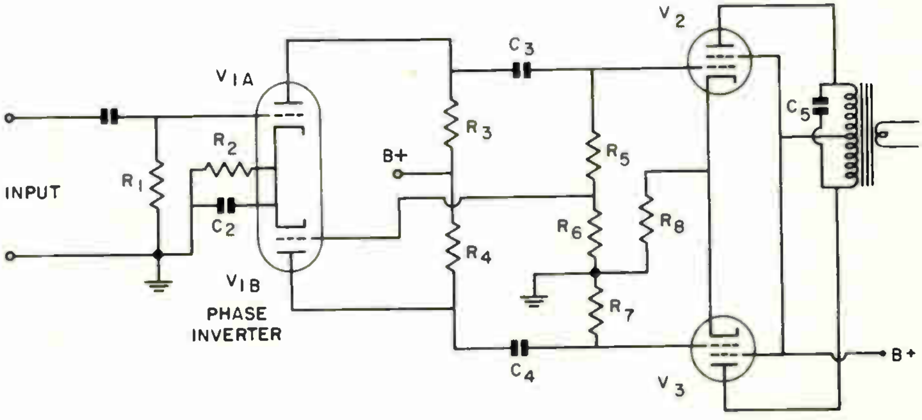

Fig. 21. A typical circuit using a phase inverter to drive one stage of a push-pull amplifier.

of V_2. Meanwhile, the amplified signal is divided by the resistors R_5 and R_6. Usually, R_5 is considerably larger than R_6 so that only a small part of the amplified signal is taken and fed back to the grid of V_{1B}, the phase inverter stage. Remember that this signal will be in phase with the signal fed to the grid of V_2. The signal is amplified by V_{1B}; its phase is inverted and then fed through C_4 to the grid of V_3. Thus V_2 and V_3 are driven by signals 180° out-of-phase.

If the ratio of R_5 and R_6 are selected correctly, the amplified signal fed to the grid of V_3 will be equal to the amplified signal fed to the grid of V_2. This type of circuit provides the two signals equal and 180° out-of-phase to drive the push-pull power amplifier. At the same time, better frequency response can be obtained with this type of circuit than with the circuit shown in Fig. 13 using an input transformer.

A circuit similar to the one shown in Fig. 21 could be used with transistor push-pull stages, but here the input transformer is primarily an impedance-matching device and usually there is more to be gained by using the input transformer than by attempting to use the phase-inverter type of stage found in push-pull vacuum-tube amplifiers. There are other things that can be done with transistor circuits to get improved results that cannot be done with vacuum-tube circuits. We will look at these circuits now.

TRANSISTOR CIRCUITS

A two-transistor amplifier which uses a PNP transistor and an NPN transistor is shown in Fig. 22. This amplifier makes use of the characteristics of the two different transistors to eliminate the coupling capacitor usually found between amplifier stages, and in so doing also eliminates distortion due to the capacitor.

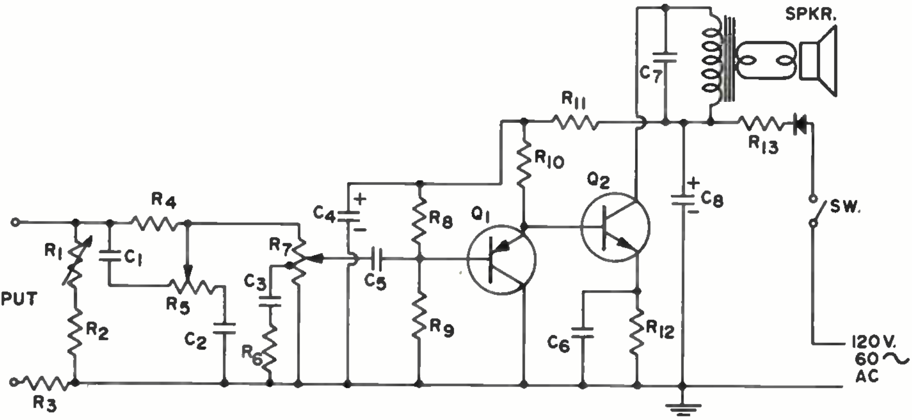

Fig. 22. Two-stage transistor amplifier.

In the circuit shown, the input impedance is controlled at high frequencies by R_5. C_1 and C_2 have a low reactance at middle and high frequencies, so the total impedance across the input at high frequencies will be equal to the resistance of R_5. At low frequencies, R_1 varies the input impedance. By varying the setting of R_1, the input impedance (and hence the amplitude of any low-frequency input signal) can be varied. Thus R_1 serves as a bass or low-frequency tone control. R_4 is in the input circuit between the input and the volume control. It can be bypassed at high frequencies by the setting of R_5. When the sliding contact is up towards C_1, C_1 provides an effective bypass around R_4 at high frequencies. When the sliding contact is down at the other end, R_4 and R_5 are essentially in parallel at high frequencies, and this tends to reduce the amplitude of the high-frequency signals. Thus, R_5 serves as a high-frequency tone control, which is usually called a treble control.

R_7 is the volume control. Notice that this control has a tap on it, and that C_3 and R_6 are connected between the tap and ground. This type of circuit is referred to as automatic bass compensation. When you turn the volume control to the low-volume position, the low-frequency sounds appear weaker than the high-frequency sounds. The higher-frequency signals are attenuated by means of C_3 and R_6, so that there is a tendency to equalize the loudness of the high-frequency and low-frequency signals. Actually, the low-frequency signals are given greater amplification to compensate for the fact that they are less noticeable at low volume levels. The transistor Q_1 is used in a common collector circuit. The input signal is fed to the base through C_5. The output is taken across the emitter resistor (R_{10}) and is fed directly to the base of Q_2. Q_2 is a power transistor which is used in a common-emitter circuit.

The two-stage amplifier is designed to operate directly from a 120-volt power line. Notice that a half-wave rectifier circuit using a silicon rectifier is shown. Resistor R_{13} is a series resistor to limit the charging current through the rectifier when the equipment is turned on. C_8 is the input filter capacitor; C_4, the output filter capacitor. R_{11} is the filter resistor. The supply voltage applied to the collector of Q_2 is not filtered as well as the voltage fed to Q_1. The voltage fed to Q_2 does not require the filtering because if there is hum voltage present with the dc, it does not receive any amplification. However, any hum voltage on the dc applied to Q_1 will be amplified and will result in an objectionable hum in the output.

Another transistor circuit of interest is the one shown in Fig. 23. This circuit is referred to as a complementary-symmetry push-pull amplifier. Here an NPN transistor and a PNP transistor are used. When the input signal drives the base of Q_1 in a positive direction, the current through Q_1 will decrease because this transistor is a PNP transistor and the positive voltage applied to the base of the transistor tends to decrease the forward bias applied to it. At the same time, the positive input signal is fed to the base of Q_2 and this increases the emitter-base forward bias and causes the current through this transistor to increase. This current is represented by i_2 and flows through the output transformer primary in the direction shown. In the next half-cycle, when the signal swings negative, this will subtract from the forward bias across Q_2, reducing the

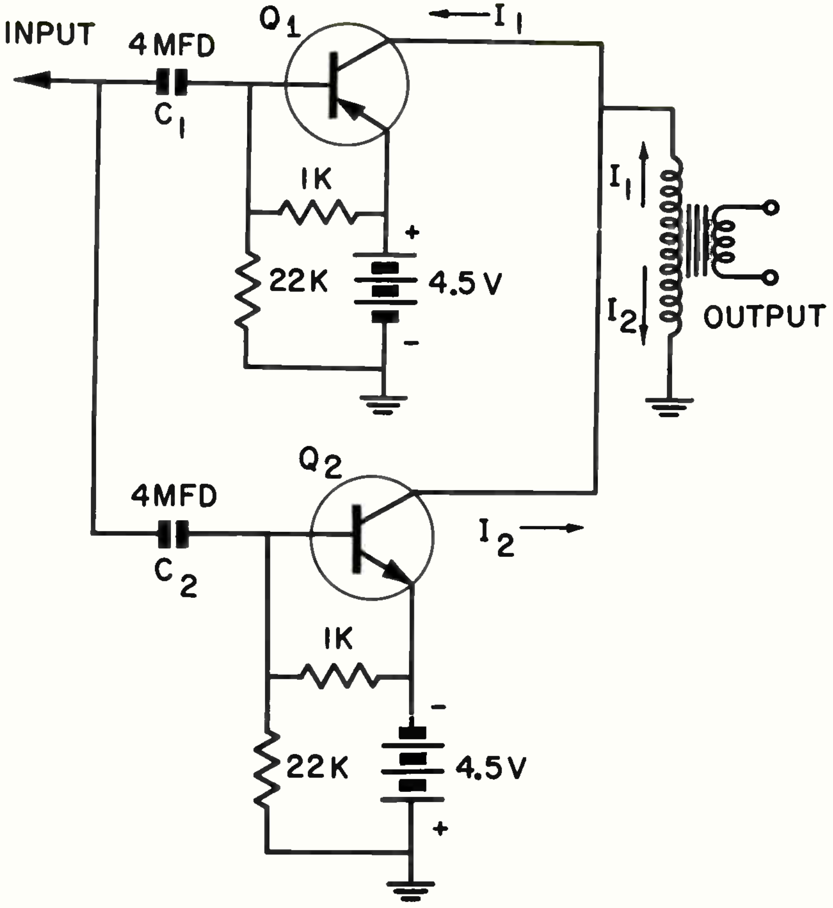

Fig. 23. Complementary symmetry push-pull amplifier.

current flow through it, and increase the forward bias across the emitter-base of Q_1, causing the hole flow through it to increase. The increase in hole flow through the transistor results in an increase in current flow i_1 through the primary of the output transformer in the direction shown.

If the transistors shown in Fig. 23 are balanced and biased essentially so that they are cut off without any signal flow, there will be no current flow through the primary of the transformer until a signal is applied. Then the current will flow through the transformer; the direction of flow will depend upon whether the signal is positive-going or negative-going. During one half-cycle the current will flow through the primary of the output transformer in one direction and during the other half-cycle it will flow through the primary of the transformer in the opposite direction.

Notice that this type of circuit eliminates the input transformer,

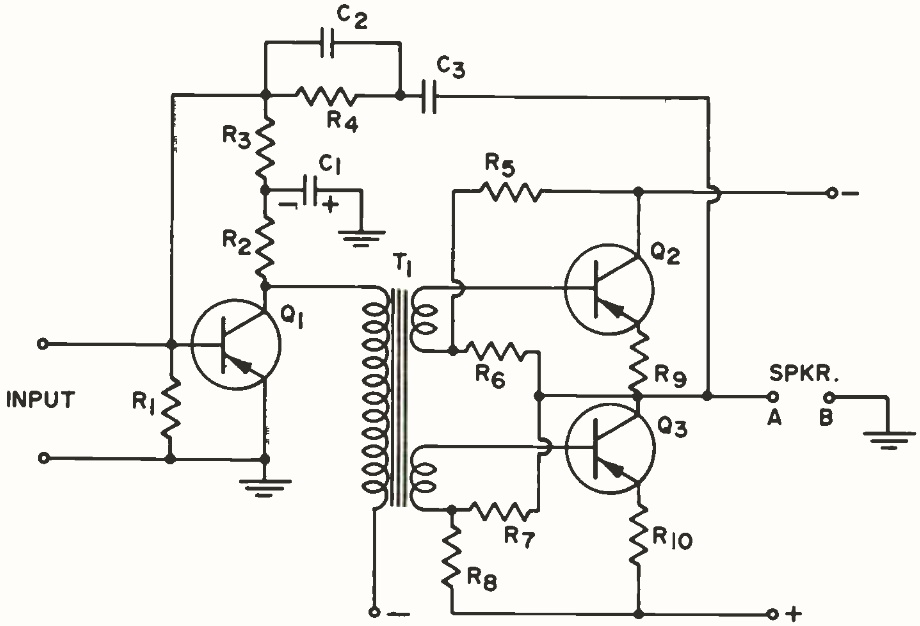

Fig. 24. Three transistor amplifiers where there is no output transformer.

yet we still have a push-pull power amplifier. In a circuit designed for power line operation, batteries would not be used and a single power supply capable of supplying the required positive and negative voltages would be used.

Another transistor circuit of interest is shown in Fig. 24. In this circuit the need for an output transformer has been eliminated. Notice that a negative voltage has been supplied to the collector of Q_2 and a positive voltage to the emitter of Q_3 through R_{10}. The negative voltage has the same value as the positive voltage with respect to ground. The resistors R_5 plus R_6 are equal in value to resistors R_7 and R_8 so that the junction of R_6 and R_7 will be at ground potential. Similarly, R_{10} is equal to R_9, and Q_2 and Q_3 are similar transistors so that there is an equal voltage drop across the emitter resistor and transistor in each case. The junction of the collector of Q_3 and resistor R_9 are also at ground potential. The junction of R_6 and R_7 and the collector of Q_3 and R_9 are connected together at terminal A. The speaker is connected between terminals A and B.

With no signal the transistors are biased essentially at cut-off so that there is little or no current flow through the transistors or through the speaker. When a signal is applied to the input circuit, it is amplified by Q_1 and fed to the transformer T_1. For example, suppose that the input signal drives the base of Q_1 in a positive direction. Since the transistor is a PNP transistor, this will reduce the forward bias across the emitter-base junction. This means that the number of holes reaching the collector will decrease and hence the current flowing through the primary of T_1 will decrease. The two secondary windings on T_1 are phased so that when this happens the voltage applied to the base of Q_3 will swing in a positive direction and the voltage applied to the base of Q_2 will swing in a negative direction. If Q_3 is already biased close to cutoff the positive voltage on the base will reduce the emitter-base junction forward bias still further so that if there is any current flowing through this transistor, it will drop even lower. On the other hand, the negative voltage applied to the base of Q_2 will increase the forward bias across the emitter-base junction. This will cause the number of holes crossing the junction to increase; the number of electrons flowing from the emitter of Q_2 through R_9 to terminal A and through the speaker to ground will also increase.

The current flowing through the speaker will develop a voltage drop across it so that the end connected to terminal A will be negative. This negative signal voltage will be fed through C_3 and the parallel combination of C_2 and R_4 back to the base of Q_1, where it will subtract from the input signal. Thus, this is an inverse feedback path.

When the signal swings in the opposite direction and drives the base of Q_1 in a negative direction the number of holes crossing the emitter-base junction will increase and hence the electron current through the primary of T_1 will increase. This will cause the base of Q_3 to swing in a negative direction. When this happens the number of holes crossing the emitter-base junction of Q_3 must increase. Therefore the number of electrons flowing from terminal B through the speaker to terminal A to the collector of Q_3 must increase. In flowing through the speaker in this direction, the electrons will develop a voltage so that terminal A is positive. This voltage is fed back to the input of Q_1 and will once again subtract from the input voltage.

The circuit is interesting in that the output transformer has been eliminated. The output transformer is one of the primary causes of distortion in low-frequency power amplifiers. Usually, there is more distortion developed in the output transformer than in the input transformer, because dc current flowing through the output transformer will be much higher than the dc current flowing through the input transformer. Also, there is more of a tendency to produce core saturation, which in turn produces more nonlinearity in the output transformer than in an input transformer.

A circuit of the type shown in Fig. 24 is not possible with vacuum tubes because of the high output impedance encountered in tubes. However, transistors are comparatively low-impedance devices, which makes this type of circuit practical.

SUMMARY

The circuits shown in this section of the lesson are all practical circuits. They are the type of voltage and power amplifiers you are likely to encounter in radio and television receivers and in high-fidelity and stereo equipment which you will be called upon to service. You should be familiar with the operation of these circuits so that when you come across them you will know how they work and be able to proceed to the cause of the trouble in a logical manner.

SELF-TEST QUESTIONS

(aa) What is distortion?

(ab) Name the three types of distortion.

(ac) What is inverse feedback?

(ad) In the circuit shown in Fig. 19, how does omitting the cathode bypass capacitor introduce inverse feedback?

(ae) In the circuit shown in Fig. 21, what is the purpose of the phase inverter stage?

(af) In Fig. 22, what purpose does R_1 serve?

(ag) In the circuit shown in Fig. 22, what purpose does R_5 serve?

(ah) In the circuit shown in Fig. 22, why is there a tap on the volume control on R_7? What purpose does this tap and the associated components serve?

(ai) In the circuit shown in Fig. 22, in what type of circuit is Q_1 used?

(aj) What is the primary advantage of the circuit shown in Fig. 24?

(ak) In Fig. 24, what purpose does the circuit serve which connects terminal A through C_3 and the parallel combination of C_2 and R_4 back to the base of Q_1?

ANSWERS TO SELF-TEST QUESTIONS

(a) R_1 is placed in the cathode circuit of V_1 to develop an operating bias for the tube. Current flowing from B minus through R_1 will develop a voltage having the polarity shown on the diagram. This makes the cathode positive with respect to ground. The grid of V_1 connects to ground through the generator and, since there will be no dc current flow through the grid circuit, there will be no voltage drop; therefore, the grid will be at dc ground potential. This will make the cathode positive with respect to the grid. In other words, the grid is negative with respect to the cathode.

(b) C_1 is a cathode bypass capacitor. Its purpose is to provide a low impedance path for the signal around the cathode bias resistor R_1. The value of C_1 is selected so that its reactance is much lower than the resistance of R_1 at the frequency of the signals to be amplified. Often, C_1 is an electrolytic capacitor; a large capacitor is required in this circuit because the resistance of R_1 is usually small and a large capacitor with a low reactance is required to bypass it effectively.

(c) In Fig. 1, the amplified signal voltage developed across R_2 will be 180° out-of-phase with the input signal voltage.

(d) No. The voltage drop across R_1 has the wrong polarity to provide a forward bias across the emitter-base junction of Q_1. The forward bias across the emitter-base junction is provided by the battery. The small current flowing through R_1 develops a voltage across this resistor having the polarity shown. This voltage subtracts from the battery voltage so that the net forward bias across the emitter-base junction is equal to the battery voltage less the voltage drop across R_1. Usually, the forward bias of only a few tenths of a volt is required across the emitter-base junction and R_1 is selected so that the base current flowing through it will develop a voltage drop, and when it is subtracted from the battery voltage the forward bias will be only a few tenths of a volt.

(e) No. The holes flow to the collector, where they are filled by electrons. These electrons come from the negative terminal of the battery and flow through R_2 to the collector. The movement of the holes is contained entirely within the transistor. In the external circuits, all current flow is electron flow.

(f) The forward bias placed across Q_1 makes the base negative and the emitter positive. When the input signal tends to swing the base in a positive direction it reduces the forward bias across the emitter-base junction. When this happens the number of holes crossing the junction decreases. When the number of holes crossing the emitter-base junction goes down, the number of holes reaching the collector will go down. This means that fewer electrons will flow through R_2 to fill the holes reaching the collector. When the number of electrons flowing through R_2 decreases, the voltage drop across R_2 will go down, so that the polarity of the collector end of R_2 will swing in a negative direction. In other words, the negative voltage on the collector of Q_1 will increase.

(g) In the circuit shown in Fig. 2, the value of C_3 is selected so that it will have a very low reactance over the frequency range of the signals to be amplified. Therefore, as far as the signal is concerned C_3 acts as a short circuit. In other words, the circuit functions as though there is a direct connection from both ends of R_2 to the end of R_3. The input resistance of Q_2 is equal to R_3 in parallel with the resistance across the emitter-base junction. The resistance across the emitter-base junction is comparatively low; therefore, the input resistance of Q_2 is low. The signal voltage developed in the collector circuit of Q_1 will depend upon the size of the load resistor. Thus, even though R_2 may be made large in order to develop a fairly high signal voltage, since the input resistance of the second stage is directly in parallel with this resistor it will pull the effective value of the collector load resistance down. As the net result, the gain of Q_1 is affected appreciably by the input resistance of the second stage, Q_2.

(h) The coupling capacitor C_3.

(i) The high frequency limit of the amplifiers is controlled primarily by the capacity in the output of the first stage and the input of the second stage. In Fig. 1 the output capacity is made up of the plate-to-ground capacity of V_1 plus wiring capacity and the grid-to-cathode capacity of V_2 plus wiring capacity. In Q_1 the output capacity of the transistor plus wiring capacity limits the frequency response along with the input capacity of Q_2 plus wiring capacity in this circuit.

(j) The early vacuum tubes were not capable of giving a very high gain. By means of a step-up transformer between stages the gain obtainable from the stage could be increased by the turns ratio of the transformer.

(k) The high gain available with modern vacuum tubes makes transformer coupling no longer necessary. In addition, R-C coupling is more economical and yields better frequency response.

(l) The transformer serves as an impedance-matching device. It matches the high output impedance of the first stage to the low input impedance of the second stage. Thus, maximum power transfer is possible and a higher voltage gain can be obtained.

(m) Modern transistors are relatively inexpensive. By using a three-stage R-C coupled voltage amplifier you can obtain as much gain as with a two-stage transformer coupled amplifier. The R-C coupled amplifier will be less expensive and also capable of better frequency response.

(n) You must obtain a replacement transformer having the same turns-ratio as the turns-ratio of the original transformer.

(o) The power amplifier in a radio receiver is designed to supply the power required to drive or operate the loudspeaker from the signal voltage applied to it.

(p) A beam power tube or a pentode tube. Triode tubes have been used as power amplifiers but they require considerable driving power. Therefore, it is not likely you will find a triode tube in modern equipment.

(q) The bypass capacitor in the plate circuit of a power amplifier is used to bypass the high-frequency audio signals and prevent high-frequency oscillation.

(r) Low-frequency distortion can be kept to a minimum by using a large value capacitor for C_2, the cathode bypass capacitor. This will reduce the frequency at which the reactance of the capacitor becomes large enough to stop acting as an effective bypass.

(s) The collector which is connected to the case of the transistor must dissipate a fair amount of heat. Since the collector is operated at almost ground potential, very little insulation is required between the collector and ground. Thus a good heat contact can be made between the collector and receiver chassis so that the chassis can aid in dissipating the heat from the transistor.

(t) You are more likely to find a push-pull output stage where the transistors are operated in a Class B circuit.

(u) The cathode bias resistor is not bypassed because the current through it remains essentially constant. Any increase in current through V_1 is compensated for by an equal decrease in current through V_2 and vice versa.

(v) C_1 and C_2 are plate bypass capacitors. They prevent high-frequency oscillation.

(w) T_1 is a step-down transformer. A step-down transformer is required to match the low input impedance of Q_1 and Q_2 to the high output impedance of the driver stage.

(x) In a push-pull power amplifier, even-order harmonics generated within the stage are cancelled within the stage so that the distortion is kept quite low.

(y) The circuits are practically identical except that a higher bias is used in Fig. 17 in order to bias the tube essentially at plate current cut-off. In addition, T_1 will be a step-down transformer in the circuit shown in Fig. 17, although it can be a step-up transformer in the circuit shown in Fig. 13.

(z) Forward-bias across the emitter-base junctions in the circuit shown in Fig. 18 is provided by the voltage divider consisting of R_1 in series with the parallel combination of R_2 and R_3. This will bias the base slightly negative with respect to the emitter.

(aa) Distortion is the introduction of a signal in the output that is not present in the input or the loss of a signal in the output that is present in the input.

(ab) Amplitude distortion, frequency distortion and intermodulation distortion.

(ac) Inverse feedback is a signal fed from the output of a circuit back to the input, with a polarity such that it subtracts from the input signal. With inverse feedback, the feedback signal reduces the amplitude of the input signal.

(ad) With the cathode bypass capacitor omitted, the signal current flowing through the tube will develop a voltage across R_2. Since this voltage has the same polarity as the grid voltage producing it, it reduces the net grid-to-cathode voltage. The voltage thus subtracts from the input voltage.

(ae) The phase inverter eliminates the need for an input transformer to the push-pull output stage. It takes part of the signal fed to V_2, one of the output stages, and inverts it so that it can be used to drive V_3.

(af) R_1 serves as a low-frequency tone control. This type of control is called a base control.

(ag) R_5 serves as a high-frequency tone control. It is usually called a treble control.

(ah) The tap on the volume control along with capacitor C_3 and R_6 form an automatic bass compensation circuit. At low volume levels, low-frequency sounds sound weaker than high-frequency sounds. To balance the relative loudness between the two, the high-frequency signals are bypassed through C_3 and R_6 so that the low-frequency signals receive greater amplification.

(ai) Q_1 is used in a common-collector circuit.

(aj) The elimination of the output transformer.

(ak) This circuit provides inverse feedback to improve the frequency response of the amplifier.

Lesson Questions

Be sure to number your Answer Sheet B202.

Place your Student Number on every Answer Sheet.

Most students want to know their grade as soon as possible, so they mail their set of answers immediately. Others, knowing they will finish the next lesson within a few days, send in two sets of answers at a time. Either practice is acceptable to us. However, don't hold your answers too long; you may lose them. Don't hold answers to send in more than two sets at a time, or you may run out of lessons before new ones can reach you.

1. When considering the action of the coupling network at middle frequencies, why can we ignore the coupling capacitor C_3 in Figs. 1 and 2?

2. In Fig. 2, what percentage of the signal voltage appearing across R_2 will appear across R_3 at the low-frequency half-power point?

3. Why is more gain obtained from the two-stage transformer-coupled voltage amplifier shown in Fig. 9 than from the two-stage voltage amplifier circuit shown in Fig. 2?

4. If transformer coupling between transistor voltage amplifiers provides maximum gain, why is R-C coupling more frequently used?

5. What is the difference between a voltage amplifier and a power amplifier?

6. In Fig. 14, will the voltage drop across R_2 add to or subtract from the forward bias across the emitter-base junction of Q_1 and Q_2?

7. Why are push-pull Class B power amplifiers preferred over push-pull Class A power amplifiers or single-ended power amplifiers in transistor portable receivers?

8. What is the advantage of using inverse feedback in low-frequency voltage and power amplifier stages?

9. In the two-stage amplifier shown in Fig. 22, in what type of circuit are the transistors Q_1 and Q_2 used?

10. What will be the polarity of the voltage at terminal A, in the circuit in Fig. 24, when the input signal drives the base of Q_2 in a positive direction and the base of Q_3 in a negative direction?

CONVERSATIONALLY SPEAKING

Conversation is a give-and-take proposition, and listening is the "take" part. Talk only when you can say something of interest. Otherwise, remain silent. Let your silence be eloquent enough to show that you derive pleasure from listening--that you consider the words of your companion far more valuable than anything you could say. This kind of silence can make just as many friends as good conversation.

Talk about things which will interest and please your listeners. Their hobbies, their work, their children and their homes are all good opening topics for conversation. Don't talk about yourself, your troubles or your work, unless asked.

Avoid expressing definite opinions on controversial subjects, for they often lead to unpleasant arguments. Ridicule of another person is likewise taboo at all times. If you can't say pleasant things about others, keep quiet. Finally, reserve technical discussions for technically minded listeners.

HOW RADIO-FREQUENCY AMPLIFIERS WORK

A radio-frequency amplifier is an amplifier designed to amplify signal frequencies above the sound or audio range. Some radio-frequency amplifiers are designed to operate at frequencies as low as 20 or 30 kilocycles; you will find amplifiers of this type in very low-frequency communications equipment. Other radio-frequency amplifiers are designed to operate at frequencies of several hundred megacycles. The radio-frequency amplifier found in the vhf tuner of a television receiver must be able to operate at frequencies over 200 megacycles in order to amplify signals from TV Channels 11, 12 and 13. As you will see in this lesson, the operation of low-frequency radio-frequency amplifiers is essentially the same as those designed to operate in the very high-frequency regions although some of the problems encountered in amplifiers operating at several hundred megacycles or more are not encountered in amplifiers operated at low frequencies.

Radio-frequency amplifiers are usually referred to as rf amplifiers. RF amplifiers are found in all types of electronic equipment. Modern radio and television receivers all contain rf amplifiers. RF amplifiers are used in all types of communications equipment designed to transmit or receive information by means of radio waves ranging from simple inexpensive portable receivers up to the complex radio systems designed to keep in touch with satellites and relay information about the earth or other planets from the satellite back to earth.

RF amplifiers perform two important functions. They amplify weak radio-frequency signals and they help select the desired signal while rejecting undesired signals.

The signal transmitted by a radio or television station is comparatively weak by the time it reaches the antenna of the radio or television receiver. Before the information contained in that signal can be extracted from it, the strength of the signal must be built up. Radio and television receivers have rf amplifiers in them to build up the weak signal picked up by the receiving antenna.

As you probably already know, in this country there are hundreds of radio stations sending out signals in the standard radio broadcast band; there are several hundred television stations sending out television signals; and in addition there are thousands of stations used for commercial communications. A radio or television receiver must be able to select the one signal you are interested in from all these and reject the others. The various radio broadcast stations in one locality all operate on different frequencies. Your receiver has rf stages in it that can be tuned to respond to one frequency while rejecting signals of other frequencies. Thus, in addition to amplifying the weak signals picked up by your receiving antenna the rf amplifier helps to select the one signal you want and reject the others.

In modern superheterodyne receivers you will remember that the incoming signal is mixed with the signal generated by a local oscillator (in the set) and a new signal frequency is produced. This frequency is called the intermediate (i-f) frequency. This i-f is actually an rf frequency and the amplifiers designed to amplify it are rf amplifiers. However, to distinguish between these amplifiers and the ones that amplify the incoming signal before its frequency is changed, they are usually called i-f amplifiers. Our discussion in this lesson will cover both the rf amplifiers that amplify the signal before the signal frequency is changed and the i-f amplifiers that amplify it after the signal frequency has been changed.

Because rf amplifiers are so widely used in both transmitting and receiving equipment, they are considered a basic circuit and all technicians should be familiar with and understand their operation. You will run into this type of amplifier regardless of what branch of the electronics field you work in. Before we go further into the subject let's see what a basic rf amplifier looks like.

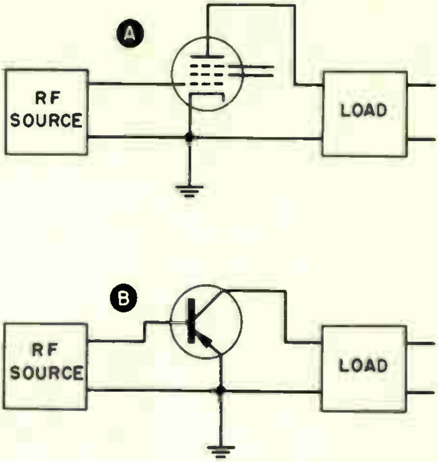

Fig. 1. Two basic rf amplifiers are shown above. Notice that they are similar to the low-frequency amplifiers you have already studied.

A BASIC RF AMPLIFIER

Two basic rf amplifiers are shown in Fig. 1. In Fig. 1A we have shown a circuit using a vacuum tube. We have not shown the screen-grid or suppressor-grid connections to the tube nor have we shown any bias on the tube, because they do not enter into our consideration of the basic rf stage. Notice that the rf source signal is applied between the grid and the cathode of the tube, and that there is a load in the plate circuit of the tube. The amplified rf signal voltage is developed across this load.

In the circuit shown in Fig. 1B we have shown a transistor using a common emitter circuit. Again, the rf signal source is applied between the base and the emitter, and the load is placed in the collector circuit of the transistor. The amplified signal voltage appears across the load.

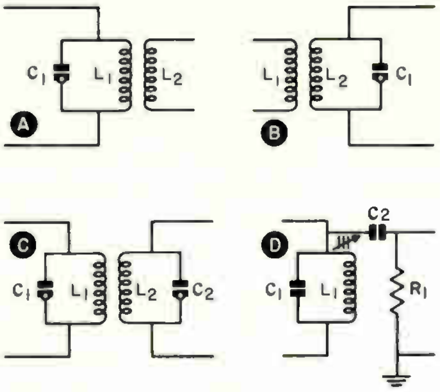

Fig. 2. Four basic loads which might be found in rf amplifiers.

At first glance it may appear that these circuits do not differ appreciably from the low-frequency amplifiers that you have already studied. However, there is a big difference, and that difference is in the load used in the output circuit of the rf amplifier. RF amplifiers almost always use some type of resonant circuit as the load.

Four basic loads which might be found in rf amplifiers are shown in Fig. 2. In the circuit shown in Fig. 2A we have an rf transformer. Coils L_1 and L_2 are inductively coupled together. The primary L_1 is tuned to resonance by the capacitor C_1. The parallel resonant circuit thus formed is connected into the plate circuit of the rf amplifier.

In Fig. 2B we have another type of rf transformer. Here L_1 and L_2 are again inductively coupled together. In this circuit, however, the secondary, L_2, is tuned to resonance by C_1. Thus, instead of having the resonant circuit in the output circuit of the rf amplifier we simply have L_1 in the output circuit, and the resonant circuit is in the input of the following rf stage.

In the circuit shown in Fig. 2C we have another type of rf transformer. Again, L_1 and L_2 are inductively coupled together, but in this circuit both L_1 and L_2 are tuned to resonance. L_1 is tuned to resonance by C_1, and L_2 is tuned to resonance by C_2. This type of rf transformer is found in the i-f amplifiers of most radio receivers and some TV receivers.

Another load that might be found, particularly in TV receivers, is shown in Fig. 2D. In this circuit C_1 is a fixed capacitor and L_1 a variable inductance. The circuit is tuned to resonance by adjusting a slug which moves in and out of L_1 to vary the inductance of the coil. This method of varying the inductance in the circuit rather than the capacity could also be used in circuits like those shown in Figs. 2A, 2B, and 2C. L_1 and C_1 form a parallel resonant circuit. The signal appearing across this parallel resonant circuit is coupled to the following stage through capacitor C_2. In some high-frequency circuits, C_1 in Fig. 2D is omitted. The output capacity of the tube or transistor and the wiring capacity in the circuit take the place of C_1.

This brief look at the basic rf stage and the loads that you are likely to find in the plate circuit of this type of stage should immediately point out to you the importance of resonant circuits in rf amplifiers. The operation of an rf amplifier stage is quite similar in many respects to that of the low-frequency amplifiers that you have already studied. The big difference is in the use of resonant circuits in rf amplifiers. Therefore, before going ahead with our study of the rf amplifier let's learn more about resonant circuits.

For many years we have used the expressions cycles per second, kilocycles per second and megacycles per second to describe the frequency of repetitive waves. For example, a sine wave is a repetitive waveform; it simply repeats itself over and over again. The frequency of the power line voltage, which is a sine wave, is 60 cycles per second.

In place of the expression, cycles per second, a new term, the Hertz, is now being used. Hertz was a physicist who many years ago studied radio wave propagation. No unit in electricity has been named after him and hence the term Hertz was designated as an honor to him and also as a unit of frequency measurement. One Hertz is equal to one cycle per second. 60 Hertz is equal to 60 cycles per second. We usually abbreviate the word Hertz Hz, thus instead of writing the power-line frequency as 60 cps we can write it as 60 Hz.

In addition to the unit Hertz we have the kilohertz and the megahertz. The kilohertz is abbreviated KHz and is equal to 1000 cycles per second or 1 kilocycle per second. The term megahertz is usually abbreviated MHz and is equal to 1,000,000 cycles per second or 1 megacycle per second. Notice that the term Hertz not only identifies the number of cycles, but also the time as one second. Thus to properly describe the power line frequency we can say 60 Hz, but if we use cycles, we must say 60 cycles per second.

You'll find the term cycles per second, kilocycles per second and megacycles per second used in all the older textbooks and magazines. Even some later textbooks still use these units. However, the general trend is toward adopting the new terms Hz, KHz, and MHz. Since you need to be familiar with both sets of units, we will use both in the following lessons. It will be worthwhile to take time now to memorize the equivalents.

1 Hertz (Hz) = 1 cycle per second (1 cps)
1 Kilohertz (KHz) = 1 kilocycle per second (kc ps)
1 Megahertz (MHz) = 1 megacycle per second (1 mc ps)

Practical Facts about Resonant Circuits

In an earlier lesson on resonant circuits you learned that there are two types of resonant circuits, series resonant circuits and parallel resonant circuits. In Fig. 3 we have shown these two resonant circuits. A series resonant circuit is shown in A and a parallel resonant circuit at B.

At this time it might be well to point out again that whether a circuit is a series resonant circuit or a parallel resonant circuit depends not on how the components are connected, but on how the voltage is applied to the circuit. If the voltage is applied in series with the coil and capacitor, as in Fig. 3A, the circuit is a series resonant circuit, but if it is applied across the coil and capacitor in parallel as in Fig. 3B, then the circuit is a parallel resonant circuit. Keep this point in mind; you will run into both series resonant and parallel resonant circuits in all types of communications equipment. It is not always easy to tell whether the circuit is a series resonant or a parallel resonant circuit simply by looking at it, but if you consider how the voltage is applied to the circuit, you can usually tell which type it is without too much difficulty.

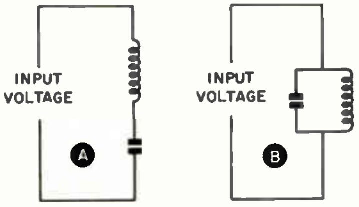

Fig. 3. A series resonant circuit is shown at A; a parallel resonant circuit at B.

Now let us quickly review what we already know about resonant circuits. We know that a circuit will be at resonance when the inductive reactance (X_L) of the coil is exactly cancelled by the capacitive reactance (X_C) of the capacitor. You know that this will occur for any given coil and capacitor at one frequency and only one frequency. The circuit will be resonant at this one frequency. In other words, if we take any coil and connect a capacitor across it, at some frequency that circuit will be resonant because the inductive reactance of the coil will be exactly cancelled out by the capacitive reactance of the capacitor.

The fact that a resonant circuit is resonant at only one frequency does not mean that it will respond only to that exact frequency. In fact, it will respond to a band of frequencies around the resonant frequency. For example, if we apply a voltage to a series resonant circuit and change the frequency of the voltage source, we will find that at resonance we get a maximum current flow through the resonant circuit. If we increase the frequency slightly above the resonant frequency, we will find that the current drops slightly. If we increase the frequency of the voltage source still more, the current will drop a little more. If we increase the frequency still further, the current will drop still further. Similarly, if we reduce the frequency below the resonant frequency, we will find that the current flowing in the circuit is slightly less than the current flowing at resonance. If we reduce the frequency still more, the current will be still less. In other words, at resonance we get a maximum current flow through the resonant circuit and at frequencies either above or below the resonant frequency, the current is somewhat less than it is at the resonant frequency. The further we get away from the resonant frequency, the lower the current will be.

Actually, instead of responding to a single frequency, the resonant circuit will respond to a band of frequencies around the resonant frequency. How wide a band of frequencies it will respond to depends upon the Q of the circuit. If the Q of the resonant circuit is high, any appreciable deviation from the resonant frequency will cause an appreciable change in output. However, if the Q of the resonant circuit is low, there must be a substantial deviation from the resonant frequency before the output of the resonant circuit changes appreciably.

You might at first think that the fact that a resonant circuit will respond to a band of frequencies rather than a single frequency is a disadvantage. However, this is not the case. In fact, if a resonant circuit would pass only a single frequency or a very narrow band of frequencies, then the radio and TV systems that we have today would not be practical. To see why this is so and to help us get a better understanding of what a resonant circuit in an rf amplifier must do, let's once again consider the type of signal that is actually transmitted by a radio or television broadcast station.

SIDEBAND FREQUENCIES

In a radio or television broadcast station, one section of the transmitter generates a radio-frequency signal which is known as the carrier or carrier wave. This is the radio-frequency signal that travels through space and carries either the sound or picture signals being transmitted by the broadcast station. However, a radio-frequency carrier itself is of no value unless we add intelligence to it. The earliest method of using this carrier signal was by interrupting it in a series of dots and dashes to send messages by code. However, even though this is useful in communications work, it is of no value in transmitting radio and television programs for entertainment purposes.

In order to transmit a radio program, the sound or audio signal must be superimposed on the radio frequency carrier. We call this process of superimposing the sound signal on the carrier, modulation.

In the modulation process certain additional frequencies other than the original carrier frequency are produced. For example, let us consider a radio station broadcasting on a carrier frequency of 1000 KHz. If we modulate this signal with a 1000-cycle (1 KHz) signal, we will produce two new frequencies in the modulation process. The 1 KHz audio signal when it is used to modulate the 1000 KHz carrier will produce two new signals, one equal to the sum of the carrier frequency and the audio frequency, and a second signal equal to the difference between the carrier frequency and the audio frequency. In other words, we will produce a signal of 1001 KHz and a signal of 999 KHz. The 1001 KHz signal and the 999 KHz signal are called the sideband signals. The higher of the two sidebands is called the upper sideband and the lower of the two is called the lower sideband.

Now, if we wish to be able to receive this modulated signal on a radio receiver, we must be able to receive not only the original 1000 KHz carrier, but also the two sideband frequencies. The sideband frequencies are the frequencies that actually carry the 1000-cycle audio signal superimposed on the carrier. Therefore, if we had a resonant circuit in our receiver that would respond only to a frequency of 1000 KHz and no other signal frequencies, we would not be able to pick up the 999 KHz and the 1001 KHz signal along with the 1000 KHz signal, and hence we would not be able to receive the modulation on the 1000 KHz carrier.

Fortunately resonant circuits have what is called a bandwidth. This simply means that the resonant circuit will respond to a band of frequencies around the resonant frequency and hence we would have no difficulty designing a resonant circuit that would respond not only to the 1000 KHz carrier signal, but also to the 999 KHz and the 1001 KHz sideband frequencies.

As you will see later, the resonant circuits in radio and television receivers must be able to respond to frequencies substantially above or below the resonant frequency. We will go into this shortly, but first let's look into what we mean by the bandwidth of a resonant circuit and some of the factors that affect the bandwidth.

BANDWIDTH

As we pointed out in the preceding section, a resonant circuit will pass a band of frequencies rather than a single frequency. However, if we move away from the resonant frequency the output that will be obtained from the resonant circuit decreases. In other words, if we are 50 KHz away from the resonant frequency you will not obtain as high an output from the resonant circuit as we would at the resonant frequency.

In Fig. 4 we have shown a voltage response curve of a typical resonant circuit that is resonant at a frequency of 1000 KHz. A response curve is simply a curve that shows how the circuit responds to signals at or near the resonant frequency. Notice that at the resonant frequency of 1000 KHz, the circuit peaks; in other words, the output voltage from the circuit is at its maximum value at a frequency of 1000 KHz. As the frequency is increased or decreased from the resonant frequency, the voltage produced across the circuit begins to go down. Notice, however, that although the circuit is resonant and the voltage is highest at a frequency of 1000 KHz, there is some voltage developed across it when the frequency is as low as 900 KHz and also when it is as high as 1100 KHz. This means that this circuit tuned to 1000 KHz when used in a receiver, will pass, to some extent, frequencies as low as 900 KHz and as high as 1100 KHz. However, the output at these frequencies is substantially below what it is at 1000 KHz.

Engineers have arbitrarily set a standard by which they measure the bandwidth of a resonant circuit. To

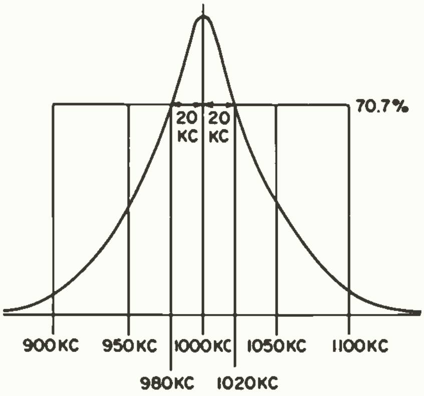

Fig. 4. A response curve showing the two 70.7% points. The bandwidth extends 20 kc on each side of this resonant frequency.

determine the bandwidth of a circuit you find the points at which the output voltage falls to 70.7% of what it is at the resonant frequency. As shown in Fig. 4 these points are at 980 KHz and 1020 KHz. The difference in frequency between these two frequencies is called the bandwidth of the amplifier. In other words, the bandwidth of this amplifier is 40 KHz. It will pass frequencies up to 20 KHz above and down to 20 KHz below the resonant frequency, with at least 70.7% of the output that will be obtained at the resonant frequency.

As in low-frequency amplifiers, the points at which the voltage falls to 70.7% are called the half-power points.

Now the question might come up, do all resonant circuits have the same bandwidth? The answer is no; the bandwidth depends upon the L-C ratio of the resonant circuit and on the Q of the resonant circuit. You will remember that there are many different combinations of L and C that will resonate at a given frequency. Different combinations will have different bandwidths. Furthermore, the Q of the resonant circuit, which is determined chiefly by the inductive reactance of the coil and the resistance in the resonant circuit, will have an effect on the bandwidth of the circuit.

In actual practice the bandwidth of the circuit is sometimes altered by loading the circuit with resistance. In Fig. 5A we have shown a typical parallel resonant circuit. In Fig. 5B we have shown the circuit loaded with a resistor. In Fig. 5C curve 1 shows the bandwidth of the resonant circuit alone and curve 2 shows how the bandwidth is altered by connecting the resistance in parallel with the coil and the capacitor. Notice that curve 2 does not come to as high a peak at the resonant frequency. This indicates that the output from the resonant circuit has been reduced by loading the circuit. However, the bandwidth of the circuit has been increased. Often, it is desirable to sacrifice output in order to obtain a wide bandwidth; this is frequently accomplished by loading the circuit with a resistance. The lower the value of resistance, the lower the output and the wider the bandwidth of the resonant circuit.

Loading resonant circuits by connecting resistors across them reduces the Q of the circuit. It is seldom necessary to do this in radio receivers because the required bandwidth can be obtained by the correct design of the tuned circuit. In fact you do not want too wide a bandwidth because you must have sufficient selectivity to be able to select the one signal you want from among many signals picked up by the receiver. The ideal arrangement is a circuit with a wide enough bandwidth to pass all the sidebands being transmitted by the station and enough selectivity to reject all signals beyond the sideband frequencies. However, you will find that in TV receivers the resonant circuits are frequently loaded by connecting resistors across them in order to get the wide bandwidth needed to pass all the sidebands that carry the picture and color detail.

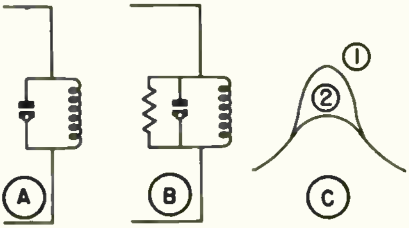

Fig. 5. The response curves at C show the effect of loading a parallel resonant circuit as at B.

COUPLING RESONANT CIRCUITS

RF stages are frequently coupled together by means of rf transformers. A typical example of this type of transformer is an i-f transformer. An i-f transformer consists of two resonant circuits as shown in Fig. 6A. One resonant circuit is used as the load in the output circuit of one stage and the other resonant circuit is used as the input in the following stage. This double resonant circuit helps to improve the selectivity of the receiver. Selectivity is the ability of the receiver to receive the desired signal and reject undesired signals. As we pointed out, the receiver must have enough selectivity to reject undesired signals from stations operating near the frequency of the desired signal.

A photograph showing construction of an i-f transformer is shown in Fig. 6B. Notice that the two coils are wound on a round cardboard form. The coils are not wound on top of each other nor are they placed exactly side by side; you can see that there is some spacing between the two coils. However, in spite of this spacing, the coils are close enough so that they are inductively coupled together.

The exact spacing between the two coils affects the degree of coupling between the two coils. In other words, if the spacing is great, not all the lines of force produced by the primary will cut through the secondary. There is some maximum spacing beyond which some of the lines of force produced by the primary will be lost and will not cut the secondary.

An example of the effect of varying the spacing between the two coils is shown in Fig. 7. If we apply a signal from a variable frequency generator to the primary and measure the output voltage across the secondary as the frequency is varied, we would obtain data from which we could plot curves like those shown. Curve 1 shown in Fig. 7A represents a certain spacing between the two coils, where the coils are pushed quite far apart. As the coils are pushed closer together the output across the secondary will increase until eventually a point is reached where maximum output is obtained as shown in curve 2 at B. If the coils are pushed still closer together we find that the output at the resonant frequency drops somewhat, as shown in curve 3 in Fig. 7C, but rises slightly above and slightly below the resonant frequency, producing two humps in the response curve with a valley in between them. This is often called a double-hump curve. If we push the coils still closer together, the response curve will be still broader. The two peaks have a tendency to move somewhat farther apart and drop in height, and the valley in the center becomes more pronounced.

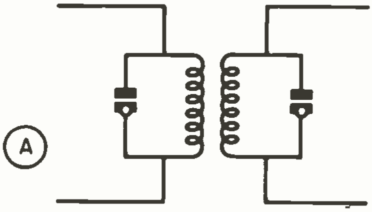

Fig. 6. A schematic diagram of an i-f transformer is shown at A; a photo at B.

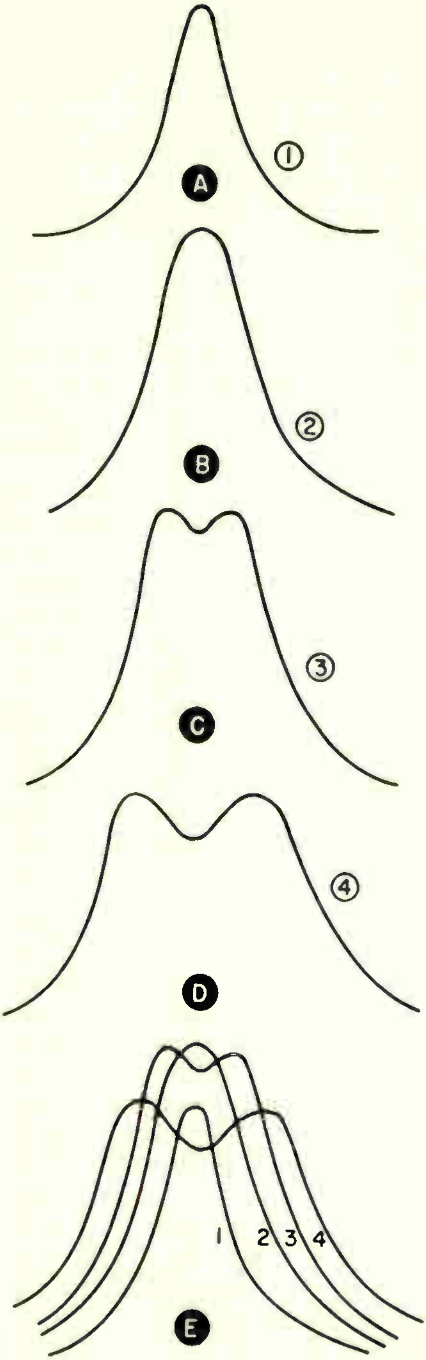

Fig. 7. Response curves showing how coupling affects bandwidth and response.

The four curves shown in A, B, C, and D have been superimposed on a single drawing at E so you can see the effect of changing the spacing between the coils.

As the coils are pushed closer together some point is reached where the output from the secondary is at a maximum value. Reducing the spacing beyond this point results in the two humps in the curve appearing. At the point where the output is maximum and just before the humps in the curve begin to appear, we have what is called critical coupling. If the coils are spaced farther apart than this particular spacing we say that they are under-coupled, in other words the coupling is less than critical coupling. If the coils are pushed closer together than this spacing, we say that the circuits are over-coupled, in other words the coupling is tighter or closer than critical coupling.

As a technician you will not have to adjust the spacing between the primary and secondary coils on an i-f transformer. They will already be adjusted for you by the manufacturer. The i-f transformers in a broadcast-band radio receiver are usually adjusted at, or slightly beyond, the critical coupling point. The i-f transformers in a communications receiver are usually adjusted below the critical coupling point. The i-f transformers in an FM receiver or in the FM sound section of a television receiver are adjusted somewhat beyond the critical coupling point.

In the early days of television, double-tuned i-f transformers were used in the video (picture) i-f amplifier stages. These transformers were very heavily overcoupled, and in addition, they were usually loaded by resistors in order to reduce the Q of the primary and secondary circuits and obtain a very wide bandwidth.

However, modern TV receivers usually employ what is called bifilar wound transformers. A transformer of this type is shown in Fig. 8A. Notice that the secondary winding is wound directly over top of the primary winding in order to obtain as tight coupling as possible between the two windings. Bifilar windings are usually represented schematically by the symbol shown in Fig. 8B. The fact that the coils are interwound so that the primary turns are mixed directly with the secondary turns is schematically represented. The advantage of the bifilar wound transformer is that the coupling between the two coils is very tight. A single slug is used to adjust the resonant frequency of the circuit. The two coils are so tightly coupled that they act like one coil. The output capacity of the stage driving the primary circuit is in effect directly in parallel with the input of the second stage. The net result is that the single slug can be used to adjust the two circuits to resonance at the same frequency. Bifilar wound coils are excellent where a wide frequency band is needed. This situation is encountered in the video i-f amplifier of a television receiver as you will see later.

There are reasons for using the various types of coupling in each of the particular applications mentioned. In a radio receiver designed to receive radio signals on the standard broadcast band the receiver must be able to pass the carrier wave of the broadcast station plus its sidebands. In the standard broadcast band the sidebands do not extend too far above and below the carrier frequency and therefore an extremely wide bandpass is not required.

In communications receivers the primary purpose of the receiver is to be able to receive information. Often the station that you are listening to may be operating very close to other more powerful stations. Here you want as much selectivity as you can get. Therefore the i-f coils are set either at or below critical coupling in order to get as much selectivity as possible from the transformer. If some of the sidebands of the signal are missing this will not be too important. In communications circuits where communications receivers are used, you are usually interested in receiving voice transmission, and the frequency range of the human voice is comparatively limited.

A much wider bandwidth is used in FM transmitters than in AM transmitters. In FM transmissions, the amplitude of the signal transmitted by the FM station does not vary. Instead, the frequency of the signal is varied. It can be varied in the standard FM broadcast station as much as 75 kilohertz above or 75

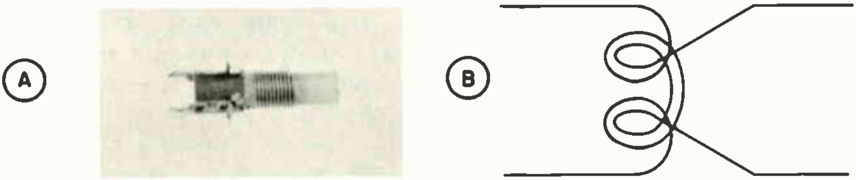

Fig. 8. Bifilar wound transformers are used in modern T.V. A is a photo; B is the schematic symbol.

kilohertz below the center frequency or resting frequency as the carrier frequency of the FM station is called. The rate at which the signal varies above and below the resting frequency is determined by the frequency of the audio signal being transmitted. How far above and below the resting frequency the signal varies is determined by the amplitude of the audio signal. A loud signal can produce sidebands two hundred KHz wide. Therefore the FM broadcast receiver must be capable of passing all these sideband frequencies, particularly if the FM station is a high-fidelity station.

The FM sound system in a television receiver is called narrow band FM. Here the maximum deviation above and below the sound carrier frequency is limited to 25 kilohertz. The rate at which the carrier resting signal is varied above and below the carrier frequency is again determined by the frequency of the signal being transmitted and the amount varied with the amplitude. Even with the deviation limited to 25 KHz, sideband frequencies considerably in excess of 25 KHz are easily produced. The sound i-f transformer must pass this band of frequencies in a TV receiver or the sound signals will be distorted.

In a TV receiver the picture signal consists of a carrier plus the modulation information on it. The modulation signal may produce sidebands up to 4 megahertz wide. Therefore in order to reproduce the sidebands the i-f bandwidth on the TV receiver must be comparatively wide. In color TV, a subcarrier having a frequency of about 3.5 MHz is used. This produces a video i-f signal that is 3.58 megahertz lower in frequency than the video i-f carrier. If the i-f bandwidth of the receiver is not wide enough to pass the video carrier signal, sidebands and the color subcarrier, then the set could not reproduce a color picture. Later in your course when you study television in detail you will understand why it is important that the video i-f amplifier of a television receiver have such a wide bandwidth.

SERVICING NOTES

We have already pointed out that a high Q resonant circuit not only has better selectivity than a low Q circuit, but also for a given input has a higher output. Thus if a piece of electronic equipment is designed with high Q resonant circuits, anything that lowers the Q of the circuits will reduce the gain and the selectivity of the equipment. The chances are that you may not notice a change in selectivity, but it is quite likely that you will notice that the gain of the equipment has fallen off appreciably.

There are several things that might reduce the Q of a resonant circuit. Coils can absorb moisture. Often in damp weather dust or other particles will settle on the coil and adhere to it. Both of these effects will introduce resistance in the circuit, lowering the Q of the circuit and changing both the output and the selectivity.

Sometimes the low Q is due to a poorly soldered connection in a resonant circuit. If the connection is not properly soldered, it may work well for a while and then develop trouble. Poor connections of this type often get through the factory inspection. Holding a hot soldering iron on suspected connections until the solder flows freely over the leads will usually clear up this type of trouble.

You will frequently find in servicing radio receivers that have been in use for many years, that even though you replace defective tubes so that you have all good tubes in the set and all operating voltages throughout the set are normal, the gain of the receiver is not all it should be. When realigning the set does not clear up the trouble, the difficulty is often due to the fact that the Q of one or more of the resonant circuits has fallen off because of moisture or dirt absorption. In a situation like this you must find the resonant circuit causing the trouble and replace it to restore the equipment to its original gain and selectivity.

Trouble of this type is not often found in transistor radios or in TV receivers. As we pointed out, this is something that occurs after a receiver has been used for many years. Most transistor radios are too new to have developed this kind of trouble. The trouble is not found in TV receivers, because usually the resonant circuits in the television receiver are very heavily loaded in order to give the wide bandwidth needed to pass the picture signal.

Resonant circuits are tuned to resonance by adjusting the capacity or the inductance in the circuit so that the inductive reactance of the coil is exactly equal to and cancels out the capacitive reactance of the capacitor at the resonant frequency. Any further change of either the inductance or the capacitance in the circuit will shift the resonant frequency of the circuit.

Both tubes and transistors have a certain amount of internal capacitance. For example, in an i-f tube there is capacity between the grid and the cathode and between the grid and the screen. The screen is grounded insofar as rf is concerned so that the grid-to-screen capacity is effectively placed between the grid and ground. The cathode of the tube is usually operated at rf ground potential so that the grid-to-cathode capacity is placed directly between grid and ground. Thus if the input of the tube is connected across a resonant circuit, the tube capacities affect the resonant circuit. If an i-f amplifier is aligned with one tube in a circuit and then a different tube is installed, it is likely that the new tube will not have exactly the same input capacity as the old one. As a result, installing the new tube in the circuit will slightly detune the resonant circuit. Radio receivers designed for broadcast band reception are usually fairly broad, so the change in capacity will not be enough to cause trouble. However, if you change two or three tubes in an i-f amplifier of a TV receiver the resonant frequency of the various circuits in the i-f amplifier may be altered enough to appreciably alter the bandwidth of the i-f amplifier so that it can no longer pass all the sideband frequencies and there will be some loss in picture detail. In transistor equipment you have capacity between the emitter and the base and between the base and collector which can have the same effect on resonant circuits.

In communications receivers designed to provide good selectivity in order to separate stations operating very close together, changing one or more tubes or transistors in one of the tuned circuits such as the rf amplifier, mixer, or i-f stages will usually alter the resonant frequency of the particular circuit involved to such an extent that the selectivity of the receiver will suffer. This is particularly true of stages designed to operate at high frequencies.

Disturbing the wiring in a resonant circuit designed for operation at a high frequency may change both the inductance and capacity in the circuit. Even a straight short piece of wire has a certain amount of inductance. At the comparatively low frequencies used for standard radio broadcasting a straight short piece of wire has so little inductance that it can be ignored. However when you get up into the higher frequencies such as those used for TV and FM broadcasting, even the smallest inductance becomes important. Changing the length of a wire in a critical circuit may have some effect on the resonant frequency because the inductance in the circuit is changed. Also moving the position of a wire in a resonant circuit operating at a high frequency and pushing it closer to a metal chassis or moving it further away from the metal chassis may change the capacity of the circuit. There is always capacity between the wires in a resonant circuit and the chassis or ground. Moving the wires around in a broadcast-band receiver is not likely to cause any trouble, but changing the position of a wire in a high-frequency circuit will frequently have an appreciable effect on the circuit.

These points are very important and are worth remembering when working on resonant circuits found in TV receivers or any other equipment designed for high-frequency operation. When it is necessary to make repairs on components in or near resonant circuits, it is a good idea to avoid disturbing the parts and leads as much as possible. If you have to move a lead to get at another part in order to replace it, try to put the lead back in as close as possible to the original position. Often this is an unnecessary precaution, but it is a precaution that can keep you out of difficulty in some critical circuits.

Much of the material covered in this section has been a review for you, but now that you have the important points about resonant circuits fresh in your mind you are ready to go ahead with your study of rf amplifiers.

SELF TEST QUESTIONS

(a) What is the basic difference between the circuit used in an rf amplifier and the circuit used in an audio amplifier?

(b) What is the basic difference between a series-resonant and a parallel-resonant circuit?

(c) What are sideband frequencies?

(d) What do we mean by the bandwidth of a resonant circuit?

(e) On what factors does the bandwidth of a resonant circuit depend?

(f) How can the bandwidth of a given parallel-resonant circuit be increased?

(g) What do we mean by critical coupling between two coils?

(h) What do we mean by overcoupling?

(i) What happens to a resonant circuit that absorbs moisture, and dust and particles settle on the coil and adhere to it?

(j) Why should you avoid moving any of the wires in the rf section of a TV receiver?

Resonant circuits are extremely important in rf amplifiers. If you think you may have forgotten some of the details you learned about resonant circuits it would be a good idea to spend some time reviewing to be sure you understand and remember the important characteristics of both series and parallel-resonant circuits. This will help you in these sections of the lesson to follow where we'll go into detail about both vacuum tube and transistor radio-frequency amplifiers.

Radio-Frequency Voltage Amplifiers

A block diagram of a superheterodyne receiver is shown in Fig. 9. You have seen this block diagram before. The rf amplifier is the stage connected to the antenna. The weak signal from the antenna is fed to the rf stage where it is amplified and then fed to the mixer. The rf stage also has tuned circuits so that it provides a certain amount of selectivity. In other words, it helps select the desired signal and reject undesired signals.

The signal from the rf amplifier is fed to a mixer-oscillator stage. In this stage the incoming signal is mixed with a locally generated signal and a new signal is produced. This signal that we are interested in is called the intermediate-frequency signal. It is equal in frequency to the difference between the incoming signal and the oscillator signal. This intermediate-frequency signal, or i-f signal as it is called, is fed to an i-f amplifier where it receives further amplification. The signal is still a radio-frequency signal so strictly speaking the i-f amplifier is a radio-frequency amplifier. However, it operates at much lower frequencies than the rf amplifier that precedes the mixer. From the i-f amplifier the signal is then fed to a second detector where the intelligence on the carrier wave is removed and then it is fed to a low-frequency amplifier. In the case of a radio receiver the signal is then fed to a speaker; in the case of a television receiver the sound signal is fed to a speaker and the picture signal is fed to the picture tube and to various other circuits you will study later.

The circuit we are going to be concerned about in this part of this lesson is the rf amplifier used between the antenna and the mixer. This stage is omitted in some of the small low-cost radio receivers, but it is invariably found in the better receivers and television receivers.

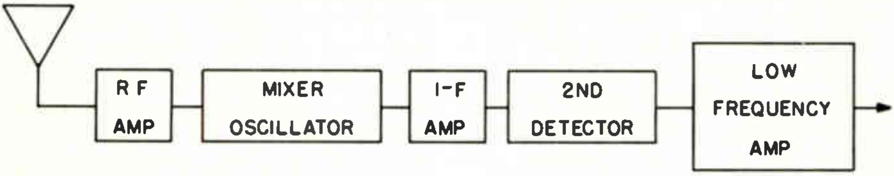

Fig. 9. A block diagram of a typical superheterodyne receiver.

The stage is a voltage-amplifier stage. In later sections of the lesson you will study i-f amplifiers and in another section rf power-amplifier stages.

The rf voltage amplifiers used in radio and television receivers are all Class A amplifiers. Some use pentode tubes, some use triode tubes, and some use transistors. You will study all three types in this section of the lesson.

PENTODE RF AMPLIFIERS

A typical rf amplifier using a pentode tube is shown in Fig. 10. This is the type of amplifier that is used between the antenna and the mixer in a communications-type superheterodyne receiver, in a few of the better broadcast-band receivers, and in many FM receivers.

In the circuit shown in Fig. 10, the signal picked up by the antenna causes a current to flow through L_1 which is the primary of the antenna transformer T_1. L_1 and L_2 are wound on the same form and are inductively coupled together. Thus the magnetic field produced by the current flowing through L_1 cuts the turns of L_2 and induces a voltage in series with it. L_2 is tuned to resonance by the capacitor C_1. Since the voltage induced in L_2 is induced in series with it, the combination of L_2 and C_1 forms a series-resonant circuit. The frequency to which this circuit is tuned can be altered by changing the capacity of C_1. This is done by rotating the dial on the receiver, which causes the rotor or moving plates of the tuning capacitor to move in and out between the stator (stationary) plates of the capacitor.

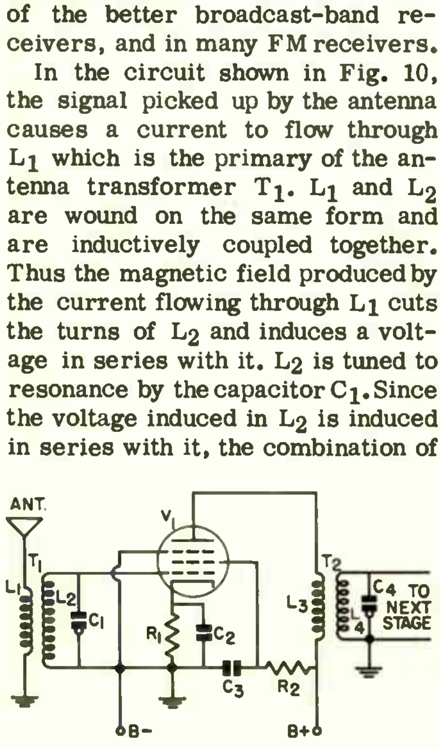

Fig. 10. A typical rf amplifier using a pentode tube.

In some receivers instead of using a variable capacitor such as shown in Fig. 10, a trimmer capacitor is used and a powdered iron slug is used that can be moved in and out of L_2. A trimmer capacitor is a capacitor that is adjusted by means of a screwdriver to adjust the stage at the high-frequency end of the band to be covered. The actual change in the resonant frequency of the tuned circuit required to tune the receiver across the band is then accomplished by moving the slug in and out of the coil L_2. This type of tuning, which is often called permeability tuning, is found more frequently in FM receivers than in broadcast and communications-type receivers.

It makes comparatively little difference whether the frequency of the tuned circuit is varied by varying the inductance of the coil or capacity of the capacitor. Either will change the resonant frequency so that the rf stage can be tuned to the frequency of the signal to be amplified.

We mentioned that L_2 and C_1 form a series-resonant circuit. We have mentioned before that when the voltage is induced in the secondary winding of a transformer, in a circuit of this type, that the circuit is a series-resonant circuit. Fig. 11 is an example of what happens. A small voltage is induced in each turn of the coil. These voltages add up to give you the total voltage induced in L_2. It is more or less like a series of

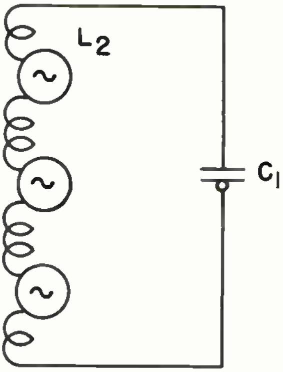

Fig. 11. Voltage induced in L_2 is induced in series with the turns of L_2.

small generators placed in the coil in series with the various turns as shown in Fig. 11. It is important to realize that this type of circuit is always a series-resonant circuit and never a parallel-resonant circuit; it will help you understand better what is happening in the circuit.

You will remember that one of the characteristics of a series-resonant circuit is that there is a high circulating current in the circuit and that there will be a resonant voltage step-up across the coil and across the capacitor. Thus we have the weak signal voltage picked up by the antenna being stepped-up by the resonant circuit. The voltage across the coil and across the capacitor in the resonant circuit is then applied between the grid and cathode of V_1. It is applied directly to the grid of the tube and to the cathode through the cathode-bypass capacitor C_2.

The radio-frequency signal applied between the grid and cathode of V_1 will cause the plate current flowing through V_1 to vary at the same rate as the incoming signal. Remember that L_2 and C_1 will resonate at only one frequency and signals at this particular frequency will normally be stepped up and be much stronger than any other signal.

The varying current flowing through the tube will flow through L_3, which is the primary winding of T_2. L_3 is inductively coupled to L_4 and hence a voltage will be induced in L_4. Again L_4 and C_4 make up a series-resonant circuit. The combination of L_4 and C_4 will be tuned to the same frequency as L_2 and C_1 and hence this resonant circuit will give the signal a still further build up, and at the same time help to reject any signals of a frequency other than the resonant frequency that happened to get by L_2 and C_1 to the grid of V_1.

Thus we have three things increasing the signal voltage. We have the resonant voltage step-up in the L_2 C_1 series-resonant combination, we have the voltage gain that can be obtained from the tube V_1 and a still further voltage step-up in the resonant circuit consisting of L_4 and C_4.

Notice that screen grid of the pentode tube is connected to ground through the capacitor C_3. C_3 is chosen so that at radio frequencies it has a very low reactance, or in other words it acts like a short circuit insofar as radio frequencies are concerned. Thus the screen is said to be at rf ground potential. This simply means that as far as the rf signal is concerned, the screen grid might just as well be connected directly to ground.

The screen grid shields the grid of the tube from the plate so that little or no energy can be fed from the plate of the tube back to the grid of the tube. It is important that we avoid feeding any energy from the plate of the tube back to the grid, otherwise we may have trouble with the stage going into oscillation.

We mentioned that this type of rf amplifier may be found in broadcast band receivers, communication receivers and FM receivers. The main difference between the rf amplifiers found in these different pieces of equipment will be in the number of turns on the coils. In an FM receiver that operates in the vicinity of 100 MHz, the coils L_1, L_2, L_3 and L_4 will usually consist of only one or two turns of a rather large diameter wire. In the broadcast band, the coils will consist of 100 or more turns of a comparatively fine wire. In communications receivers you will find coils all the way between the coils with 100 or more turns used in broadcast receivers to the coils with even fewer turns than those found in FM receivers. The exact number of turns on the coil will depend upon the frequency band the receiver is to cover.

Another pentode rf amplifier is shown in Fig. 12. This is identical to the amplifier shown in Fig. 10 except the capacitor C_5 and resistor R_3 have been added. C_5 is a comparatively large capacitor so that at the signal frequency its reactance is almost zero. Therefore as far as L_2 is concerned it is connected directly to B- and to the rotor of C_1. The signal sees no opposition because the reactance of C_5 is so low. R_3 is a comparatively large resistor so there is no signal fed from R_3 into the circuit we have marked avc.

The purpose of this circuit is to enable us to apply a variable negative voltage to the grid of V_1. The negative voltage applied to the grid of V_1 will control the gain of the tube. The higher the negative voltage, the lower the gain of the tube. The voltage is usually obtained from the detector circuit and the strength of this voltage will depend upon the strength of the signal. This voltage is referred to as the automatic volume control voltage and is used to vary the gain of the stage. If the input signal is very strong, the avc voltage developed will be high and will tend to reduce the gain of the stage. On the other hand, if the signal received is weak, very little avc voltage will be developed and the stage will operate at close to its maximum gain. You will see in a later lesson how this avc or automatic volume control voltage is developed.

As a point of interest, avc is the term used in radio receivers. Actu-

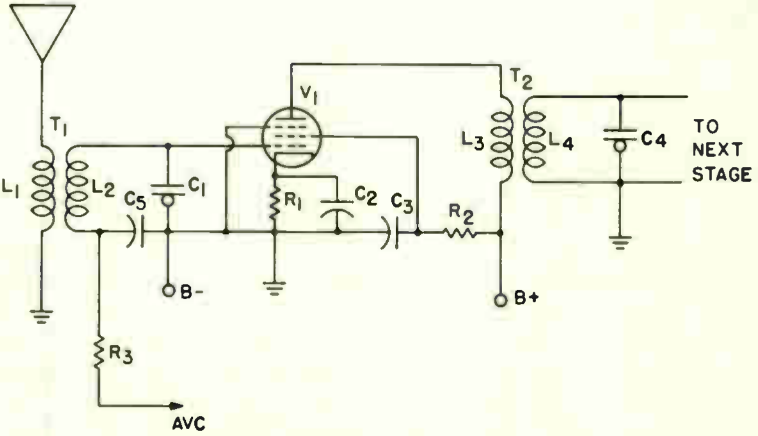

Fig. 12. A pentode rf amplifier modified for automatic gain control.

ally, this is not an automatic volume control, but rather it is an automatic gain control. In television, we use the term automatic gain control, abbreviated agc rather than avc. In television agc is much more suitable because varying the gain of the rf amplifier affects both the picture and sound signals.

TRIODE RF AMPLIFIERS

One of the disadvantages of pentode rf amplifiers is that they generate considerable noise within the tube itself. Part of this noise is often caused by changes in the division of the cathode current between the plate and screen of the tube. Small changes occur at random. These changes are too small to be detected in most cases, but they result in noise being generated within the tube. In the case of radio stations operating in the broadcast band and FM stations, usually the signals are so strong that they simply override this noise and it does not cause any trouble. However, in TV receivers the noise may become objectionable and may appear in the picture, particularly on weak signals. This problem can be overcome by using a triode rf amplifier.

Triode tubes have been especially designed for use as rf amplifiers in vhf tuners of television receivers. The vhf tuner in a television receiver covers channels 2 to 13. A typical triode rf amplifier such as might be found in a television receiver is shown in Fig. 13.

In TV receivers the lead-in or wire used to connect the antenna to the receiver is usually what is called a balanced wire or cable. This cable has two conductors and neither is at ground potential. Each is operated above ground. The resistance or impedance from either wire to ground is the same. We call this type of line a balanced transmission line.

The balanced transmission line is connected to the antenna terminals of the receiver. In the circuit shown in Fig. 13 it is fed to T_1. T_1 is what is called a balun. The purpose of the balun is to match the balanced transmission line to the unbalanced input circuit. An unbalanced input circuit is a circuit in which one side of the circuit is grounded. T_1 serves the

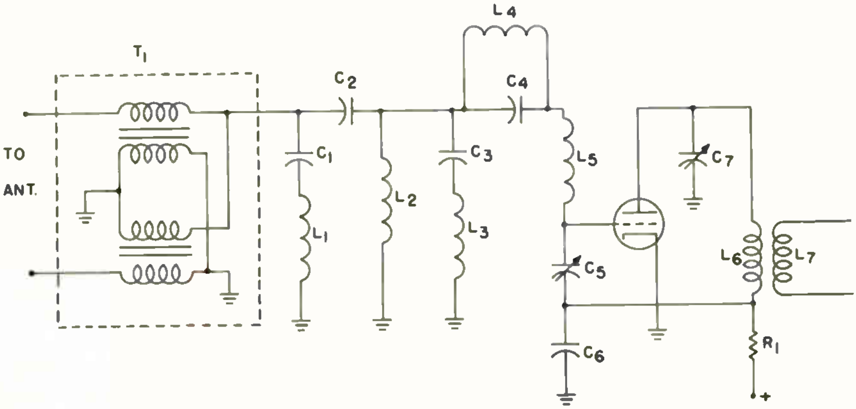

Fig. 13. A triode rf amplifier.

purpose of matching the balanced line to the unbalanced input of the receiver.

The capacitors C_1, C_2 and C_3 along with coils L_1, L_2 and L_3 form what is called a high-pass filter. A high-pass filter is a filter that passes signals above a certain frequency and rejects signals below this frequency. The lowest vhf TV channel is channel 2. The frequency of this TV channel is 54 to 60 megahertz. The high-pass filter is designed to cut out all signals below 54 megahertz and pass signals above 54 megahertz. Thus strong signals from nearby broadcast stations operating the standard broadcast band are prevented from reaching the rf amplifier and causing interference.

The combination of L_4 and C_4 form a parallel-resonant circuit. This circuit is usually a uhf trap and is designed to prevent interference from uhf television signals from reaching the grid of the rf circuit.

L_5 and C_5 form a series-resonant circuit that is resonant to the frequency of the channel received. C_6 is a very large capacitor and insofar as the resonant circuit is concerned has no effect on the circuit.

The signal applied to the grid of the tube is amplified and fed to L_6. The combination of L_6 and C_7 forms a parallel-resonant circuit which is resonant to the frequency of the TV channel.

B+ is applied to the plate of the tube through R_1. The lower end of L_6 is not at ground potential. It is bypassed through C_6. However, C_6 does not bypass all of the signal, but part of it is fed back through C_5 to the grid of the tube. The purpose of feeding this signal back to the grid of the tube is to make up for any signal fed from the plate of the tube back to the grid of the tube through the tube itself. The signal fed from the plate of the tube back to the grid through the tube could cause the stage to go into oscillation. The signal fed from the lower end of L_6 through C_5 to the grid of the tube is 180° out-of-phase with the signal fed through the tube and cancels this signal thereby preventing oscillation. You will remember that when you studied triode tubes before, we pointed out that they would oscillate in rf circuits unless they were neutralized. This is a neutralizing circuit.

In the early days of radio, triode amplifiers were used in broadcast-band receivers, but since the pentode tube was invented, triode tubes have not been used for this purpose. However, you will find triodes in the rf amplifier of TV receivers where the low-noise characteristic of the triode is an advantage over a pentode. The circuit in Fig. 13 is typical. You do not have to memorize this circuit. We will go into it in more detail later when you study TV, but at least you should have an idea of the general circuit configuration and notice that except for the balun and trap in the input circuit, the circuit is not too different from the pentode rf amplifier circuit. Of course, as far as the triode amplifier itself is concerned, the balun, the high-pass filter and the uhf trap could be eliminated and a signal fed directly to the resonant circuit and to the grid of the tube. These other components are needed because of the circumstances under which the amplifier is used.

TRANSISTOR RF AMPLIFIERS

A typical transistor rf amplifier such as might be found in a radio receiver is shown in Fig. 14. The circuits use an NPN transistor in a common-emitter circuit.

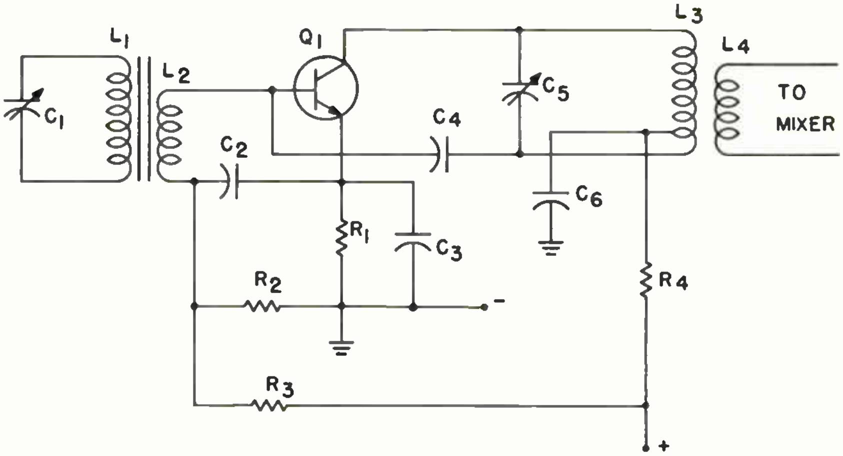

Fig. 14. A transistor rf amplifier.

L_1 is a coil wound on a ferrite rod. A ferrite rod is a rod made of a powdered iron-type material held together by a suitable binder. The coil is wound on this rod to get a very high Q. It is tuned to resonance by C_1 so that the combination of L_1 and C_1 form a series-resonant circuit. The circuit can be tuned to the frequency of the desired station. L_2 is inductively coupled to L_1. Since L_2 has fewer turns than L_1, there will be a current step-up, in other words the current flowing in L_2 will be higher than the current flowing in L_1. This serves two useful purposes; it provides a higher current for the emitter-base circuit of the transistor Q_1, and prevents the transistor from loading the resonant circuit. If it did load the resonant circuit excessively it would lower the Q of the coil and in so doing reduce the selectivity of the circuit.

The signal induced in L_2 is applied to the base of the transistor and to the emitter through C_2. C_2 is selected to have a low reactance at the signal frequency.

The forward bias for the emitter-base junction is provided by the voltage divider consisting of R_2 and R_3. R_3 is much larger than R_2 so that the base is made only slightly positive with respect to the emitter. R_1 is placed in the emitter circuit between the emitter and ground in order to stabilize the bias with temperature increases.

The signal applied between the emitter and base of the transistor varies the forward bias across the emitter-base junction which causes the number of electrons crossing the junction and reaching the collector to vary. The varying current flowing through the transistor reaches the parallel-resonant circuit consisting of L_3 and C_5. The current flows through L_3 to the tap on the coil and then through R_4 back to the positive terminal of the power supply.

Notice that the coil L_3 is tapped. The tap on L_3 is essentially at signal-ground potential. A voltage is induced in the lower end of L_3 which will be 180° out-of-phase with the voltage at the upper end of L_3. The voltage from the lower end of L_3 is fed through C_4 back to the base of the transistor. This voltage is fed back to neutralize or cancel any voltage that is fed from the collector of the transistor to the base through the collector-base capacity. This will prevent the stage from oscillating.

L_4 is inductively coupled to L_3, and since it has fewer turns than L_3 we have in effect a step-down transformer. Thus the input of the mixer transistor does not load the resonant circuit in the collector circuit of the rf amplifier.

In many ways the transistor rf amplifier is similar to the triode tube rf amplifier. Both may go into oscillation unless steps are taken to neutralize the feedback voltage through the device.

Transistors are also used as vhf rf amplifiers in TV receivers. A typical transistor vhf amplifier for a television receiver is shown in Fig. 15. Here you can perhaps see more closely the similarity between the transistor circuit and the triode tube circuit.

In Fig. 15, T_1 is a balun and its purpose once again is to match the balanced transmission line from the antenna to the unbalanced input of the rf amplifier.

In this circuit the combination of L_1 and C_1 form a parallel-resonant circuit. This circuit is resonant at approximately 41 MHz. The sound i-f frequency in the TV receiver is 41.25 MHz. The purpose of this circuit is to prevent any interference by a nearby station operating on 41 MHz from getting to the rf stage and on through into the sound circuits of the receiver.

The combination of C_2 and L_2 form a series-resonant circuit at 45.75 MHz. The picture i-f frequency in the TV receiver is 45.75 MHz. A series-resonant circuit offers a low resistance to signal frequencies near 45.75 MHz. Therefore this circuit will prevent interference from a nearby station operating on or near the video i-f from getting into the picture and causing interference.

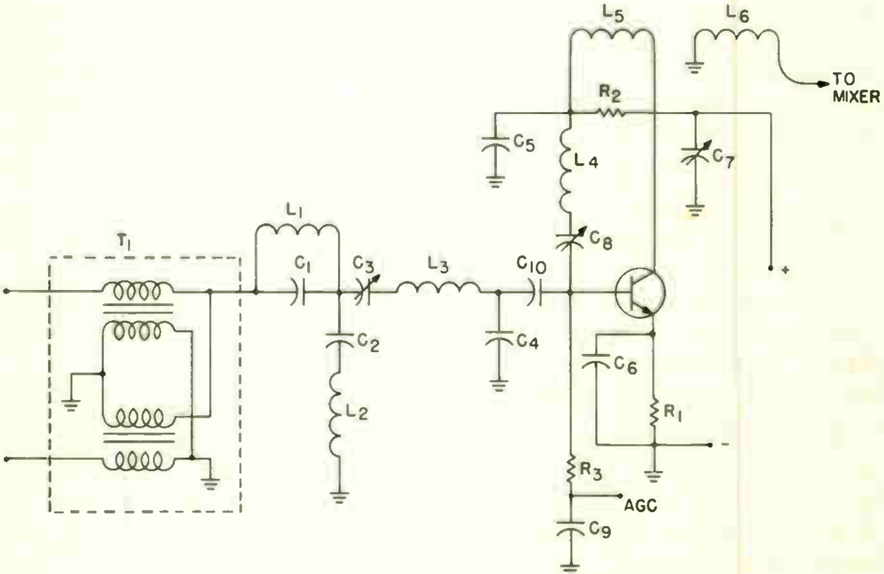

Fig. 15. Transistor vhf amplifier.

C_3 and L_3 form a series-resonant circuit which is tuned to the frequency of the desired TV station. The signal is fed through the capacitor C_{10} to the base of the transistor. The emitter of the transistor is at signal-ground potential, the resistor R_1 in the emitter circuit is bypassed by capacitor C_6.

The signal voltage fed between the base and emitter of the transistor causes the electron current through the transistor to vary and this causes the current flowing from the collector of the transistor and through L_5 to vary. The current from the collector flows through L_5, through R_2 and on to the + terminal of the power supply.

L_5 is inductively coupled to L_6; therefore a voltage will be induced in L_6. This voltage is fed to the mixer stage which follows the rf stage.

The signal at the lower end of L_5, that is the opposite end from the collector, is bypassed to ground through C_5. However, C_5 is not a perfect bypass and part of the signal is fed through L_4 and C_8 back to the base of the transistor. This is the neutralizing voltage which makes up for and cancels the signal fed across the collector-base capacity of the transistor back into the base circuit. Without this neutralizing circuit the rf stage would oscillate.

The forward bias for the transistor is applied through the resistor R_3 to the base. This bias circuit connects back to the automatic gain control circuit in the television receiver. The automatic gain control circuit regulates the gain of the rf stage automatically. In the case of a strong signal, the automatic gain control voltage reduces the gain of the rf stage, and in the case of a weak signal, it allows the stage to operate at maximum gain. You will go into automatic gain control circuits in detail later. Using an automatic gain control circuit to control bias across the emitter-base junction of the transistor will provide much more satisfactory results than applying a fixed forward bias across the junction.

FIELD-EFFECT TRANSISTOR AMPLIFIERS

As you learned earlier, the field-effect transistor combines many of the desirable characteristics of the vacuum tube, along with those of the transistor. Therefore it is reasonable that the field-effect transistor would make an excellent rf amplifier. Both the junction type and the insulated-gate type can be used as rf amplifiers.

Fig. 16 is a diagram showing a junction-type N channel field-effect transistor used as an rf amplifier.

In the circuit shown in Fig. 16, the source is connected to the negative side of the power supply and the drain to the positive side. A negative bias is applied to the gate through L_2 and R_1 from the agc terminal. The negative bias on the gate sets the current flow through the channel from the source to the drain of the transistor.

When a signal is received by the

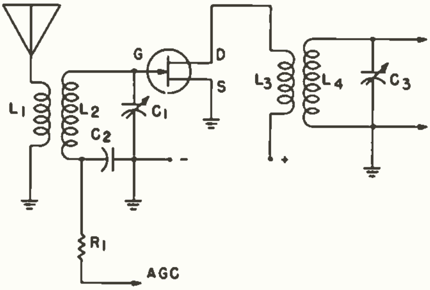

Fig. 16. An rf amplifier using a junction field-effect transistor.

antenna it causes a current to flow through L_1. L_1 is inductively coupled to L_2 and the voltage is induced in series with the turns of L_2. L_2 and C_1 form a series-resonant circuit which is tuned to the frequency of the incoming signal.

The induced voltage across L_2 is applied between the gate and ground in series with the negative bias applied to the gate. This voltage will add to or subtract from the gate bias depending upon the polarity of the signal voltage. The varying rf voltage will modulate the current flowing from the source to the drain, by varying the effective width and hence the resistance of the channel. Thus we have the signal voltage applied to the gate of the transistor causing substantial variations in the current flowing through the transistor.

The varying signal current from the drain of the transistor flows through L_3. L_3 is inductively coupled to L_4 and hence a signal voltage is induced in L_4. L_4 and C_3 form a series-resonant circuit which is tuned to resonance at the same frequency as L_2 and C_1. The output from the resonant circuit consisting of L_4 and C_3 can then be fed to another rf amplifier, to a mixer or to a detector.

The high input resistance of the junction-type field-effect transistor makes this transistor ideally suited for use as an rf amplifier. In operation, it actually resembles very closely a pentode tube. While the transistor we have shown in Fig. 16 is an N-channel transistor, a P-channel transistor can be used just as well. In this case the polarity of the voltages would be reversed and also a positive voltage would be applied to the gate in order to reverse bias the junction and prevent any current flow in the gate circuit.

There will be some reverse current flow across the junction in a junction-type field-effect transistor. This will have the effect of lowering somewhat the input resistance of the transistor. This can be overcome by the use of an insulated-gate field-effect transistor in a circuit such as shown in Fig. 17. The circuit here shows an N channel depletion-type insulated-gate field-effect transistor.

In the circuit shown, current flows from the negative side of the power supply through R_2 to the source of the transistor. It flows through the transistor to the drain and then through L_3 back to the positive side of the voltage source. The gate is connected to the negative automatic gain control voltage through L_2. The negative voltage applied to the gate will limit the width of the channel

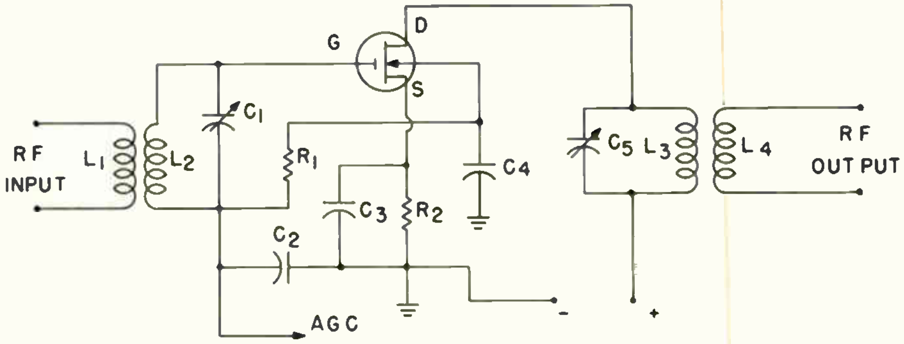

Fig. 17. An rf amplifier using an insulated-gate field-effect transistor.

and hence control the resistance of the channel.

In operation, the rf signal input is applied to L_1. This may be from another rf amplifier or directly from an antenna. The signal current flowing through L_1 induces a voltage in series with L_2. L_2 and C_1 form a series-resonant circuit. The resonant signal voltage is applied to the gate of the transistor and this voltage is applied in series with the negative agc voltage and hence varies the negative voltage on the gate at an rf rate. The varying signal voltage causes the resistance of the channel to vary and this causes the current flowing from the source through the transistor to the drain to vary. L_3 and C_5 form a parallel-resonant circuit. This high-impedance circuit develops a high signal voltage due to the varying current flowing through it. L_3 is inductively coupled to L_4 and the output from L_4 can be fed to another rf amplifier or to a mixer as it would be in the case of a superheterodyne receiver.

As in the case of the preceding circuit, a P-channel transistor could be used as well as an N-channel transistor. Also the enhancement type of insulated-gate transistors could be used. However, it is likely that most rf amplifiers using the insulated-gate field-effect transistors will be of the depletion type N channel transistors.

As mentioned previously, one of the disadvantages of the insulated-gate transistor is that they are easily damaged. Simply removing or inserting the transistor in the circuit when the voltages are applied could destroy the transistor due to high peak voltages built up in the gate circuit due to the very high resistance of the gate. Since the gate is actually insulated from the drain source by means of a layer of insulation the input resistance of the gate is extremely high. Pickup from a nearby power line can induce a high enough voltage in the gate to destroy the transistor if the gate circuit is open.

SELF TEST QUESTIONS

(k) What type of amplifiers are the rf amplifiers found in radio and television receivers?

(l) What type of resonant circuit is C_1 and L_2 in Fig. 10?

(m) What is the purpose of C_3 in the circuit shown in Fig. 10?

(n) What is permeability tuning?

(o) What is T_1 in the circuit shown in Fig. 13, and what purpose does it serve?

(p) Why are triode tubes often used as rf amplifiers in television receivers?

(q) Why does L_2, in Fig. 14, have fewer turns than L_1?

(r) What is the purpose of C_4 in the circuit shown in Fig. 14?

(s) In the circuit shown in Fig. 15 what are the combinations of L_1 and C_1 and L_2 and C_2 used for?

(t) Why must a negative voltage be applied to the gate of the junction field-effect transistor shown in Fig. 16?

(u) What is the primary advantage of the field-effect transistor in an rf amplifier circuit over the typical NPN or PNP transistor?

(v) Which of the two circuits, the one shown in Fig. 16 or the one shown in Fig. 17 has the least loading effect on the input circuit?

I-F Amplifiers

From the block diagram of the superheterodyne receiver which we have shown in Fig. 9, we see that the signal picked up by the antenna is amplified by an rf amplifier and then fed to a combination mixer and oscillator stage. In this stage the rf signal is mixed with a signal from a local oscillator. The local oscillator simply generates an rf signal which we use to mix with the incoming signal. The signal produced by the local oscillator is always a fixed frequency either above or below the frequency of the incoming signal. In most cases the oscillator is operated at a frequency above the frequency of the incoming signal.

Mixing the incoming rf signal with the locally generated signal produces two new signal frequencies in the mixer. It produces a signal equal to the sum of the frequency of the incoming signal plus the frequency of the oscillator and also a signal equal to the difference between the two frequencies. We use the difference signal as the intermediate frequency signal in a superheterodyne receiver. This signal is referred to as the i-f signal.

Since the frequency relationship between the incoming signal and the local oscillator is maintained constant, the i-f signal produced in the mixer will always have the same frequency. In other words, when the receiver is tuned to a signal of one frequency, for example a signal 1000 KHz, the oscillator might be operating at 1455 KHz. The difference between these two signal frequencies is 455 KHz and therefore this will be the i-f signal frequency. If we tune the receiver to a higher frequency, for example 1500 KHz, then the frequency of the local oscillator will also be increased so that when the rf and mixer stages are tuned to 1500 KHz, the local oscillator will be operating at 1955 KHz. Once again the difference frequency is 455 KHz. In other words, as long as we maintain the same difference between the incoming signal and the oscillator signal frequencies, the i-f signal frequency produced will be the same.

The advantage of a constant signal frequency for the intermediate frequency lies in the fact that we can design an amplifier with a higher gain when it is to be operated at a fixed frequency than we can if we have to be able to vary the frequency. Also, using a low frequency i-f gives us some advantages insofar as selectivity is concerned. We will go into this in detail later when you study superheterodyne receivers in more detail.

In this section of the lesson we are going to study some typical i-f amplifiers. Remember, even though we call the amplifiers intermediate frequency amplifiers, they are radio-frequency amplifiers because the signals they amplify are radio-frequency signals. However, they are different from the rf amplifiers you studied in the preceding section because they operate at a lower frequency, and also because once their frequency is set, it normally is not varied.

PENTODE I-F AMPLIFIERS

A typical pentode i-f amplifier is shown in Fig. 18. Notice that we have resonant circuits both in the input and the output of the stage, and that

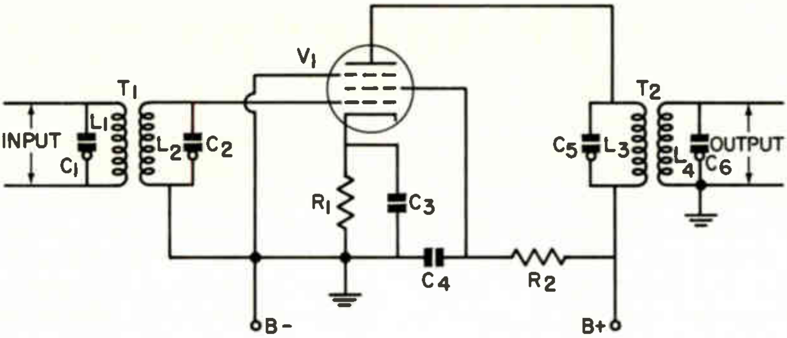

Fig. 18. A typical i-f amplifier using a pentode tube.

in many respects it resembles the pentode rf amplifier shown in Fig. 10.

In the circuit shown in Fig. 18, the input signal is obtained from the mixer output. In the output of the mixer we will have four signals. One signal will be equal to the frequency of the incoming signal, another signal will be equal to the frequency of the local oscillator. In addition, we have the two new signals produced by beating the incoming signal with the local oscillator signal. We have a signal equal to the sum of the two and a signal equal to the difference between the two. C_1 and L_1 form a parallel-resonant circuit which is resonant at a frequency equal to the difference between the local oscillator frequency and the incoming signal frequency. Thus, the parallel-resonant circuit acts as a high impedance at the difference signal frequency and a comparatively high signal voltage of this frequency is developed across it.

L_1 is inductively coupled to L_2. This causes a signal voltage to be induced in L_2. L_2 and C_2 form a series resonant circuit, and they also are tuned to the difference frequency, which from now on we will call the i-f frequency. In the series-resonant circuit we have a resonant voltage step-up, and this voltage is applied to the grid of V_1, and to the cathode through C_3. C_3, the cathode bypass is chosen so that it has a low reactance at the signal frequency.

The i-f signal applied between grid and cathode of V_1 causes the plate current flowing through the tube to vary and this varying plate current is fed to the parallel-resonant circuit consisting of L_3 and C_5. A high signal voltage is developed across the high impedance parallel-resonant circuit. L_3 is inductively coupled to L_4 and the combination of L_4 and C_6 form a series-resonant circuit which is also tuned to the i-f frequency. From the output, the voltage is fed to another i-f amplifier or to the second detector which separates the intelligence signal on the carrier from the carrier.

As in the rf amplifier the screen of the pentode tube is operated at signal ground potential by means of a bypass capacitor C_4 which has a low reactance at signal frequency. A positive dc voltage is applied to the screen of the tube through the resistor R_2. Normally the screen of the tube will be operated at a lower voltage than the plate and R_2 is chosen so that the voltage drop across it, when subtracted from the plate voltage, will provide the correct screen voltage for the tube.

In some circuits the suppressor

grid, the grid nearest the plate, is tied directly to the cathode of the tube. However, tieing the suppressor to ground will often introduce a small amount of degeneration in the stage and improve the stability of the stage. With modern pentode tubes there is such a high voltage gain in the stage, that even though the voltage fed from the plate of the tube through the tube, back to the grid of the tube is very small, it is possible that this voltage might be high enough to cause oscillation unless steps are taken to prevent it.

In some amplifiers you will find that the cathode of the tube is not bypassed. Leaving the cathode unbypassed again introduces some degeneration as it did in the case of audio amplifiers and this will tend to stabilize the stage and further prevent the stage from going into oscillation.

We mentioned earlier that the i-f amplifier is operated at a fixed frequency. Once the receiver is set up, the resonant frequency of the tuned circuits is not changed as you tune from station to station. When the receiver is set up, the various resonant circuits are all adjusted to resonate at the i-f frequency. This is usually accomplished by feeding a signal from an instrument called a signal generator into the i-f amplifier. The signal generator is set to the intermediate frequency and then the various resonant circuits are adjusted for maximum output from the i-f amplifier. The coupling between the coils is adjusted by the manufacturer so that when the various circuits are tuned for maximum output the required bandpass will be obtained. It is possible to do this in radio receivers because the bandwidth required in radio reception is comparatively narrow. In television receivers, however, the i-f amplifier presents special problems and alignment methods other than peaking the transformers or coils at one frequency must be used.

In the early days of radio, triode i-f amplifiers were used, but since the development of the pentode tube, the triode tube has not been used for this purpose. You can get a higher gain with a pentode i-f amplifier than with a triode, and in addition the pentode does not require neutralization.

TRANSISTOR AMPLIFIERS

A typical transistor i-f amplifier is shown in Fig. 19. Notice that this circuit is practically identical to the

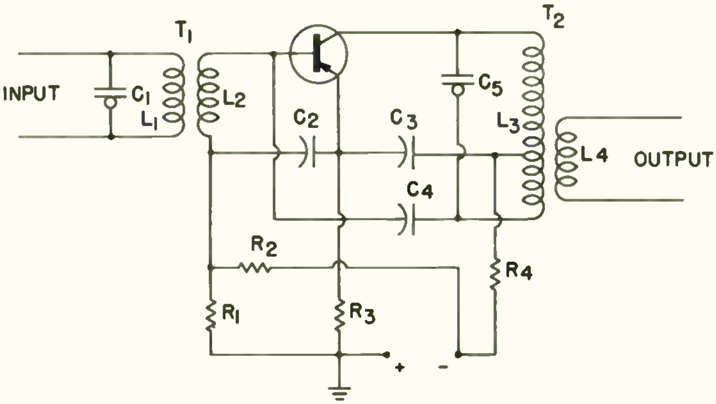

Fig. 19. A typical transistor i-f amplifier using a PNP transistor.

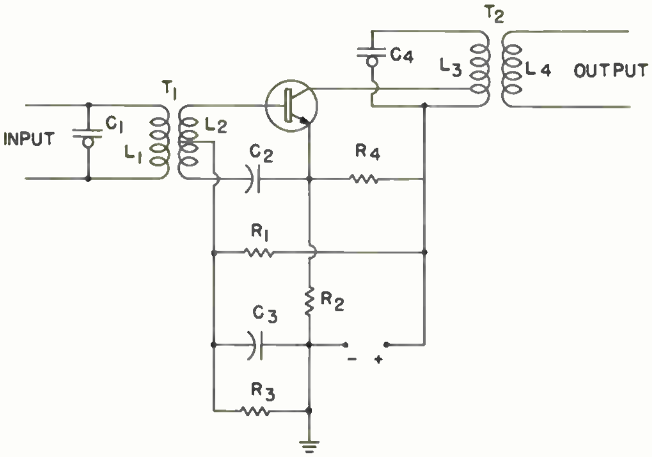

Fig. 20. Transistor i-f amplifier using NPN transistor.

circuit of the rf amplifier shown in Fig. 14.

In Fig. 19, C_1 and L_1 form a parallel-resonant circuit and would be in the collector circuit of the mixer stage. L_1 is inductively coupled to L_2. L_2 has fewer turns than L_1 so that we have a step-down transformer to match the low input resistance of the transistor circuit to the high resistance of the parallel circuit. The signal is applied to the base of the transistor and to the emitter through C_2. The i-f signal current from the collector is fed to the parallel resonant circuit which consists of L_3 and C_5. L_4, which has fewer turns than L_3, is inductively coupled to L_3 so that a signal current will be induced in L_4. The output from L_4 would probably be connected to another transistor i-f amplifier or to a detector stage. As in the rf stage shown earlier, C_4 provides neutralization and feeds a signal back into the base which is 180° out-of-phase with the signal fed from the collector to the base through the transistor.

Forward bias for the transistor is provided by the voltage divider network consisting of R_1 and R_2. As in the previous circuits, R_3 is put in the circuit for bias stabilization, to prevent thermal runaway of the transistor.

Another transistor i-f amplifier is shown in Fig. 20. This amplifier uses an NPN transistor whereas the one shown in Fig. 19 uses the PNP transistor. In addition to the different transistor types, the method of obtaining neutralization is somewhat different. Notice the resistor in the emitter circuit, R_2. This resistor is not bypassed and therefore a signal voltage will be developed across this resistor. This signal voltage is fed through C_2 into the lower end of the coil L_2. The center tap of L_2 is at signal ground potential, because C_3 has a low reactance at the signal frequency. The lower end of L_2 is inductively coupled to the upper end so that a voltage is induced in the upper end of the coil 180° out-of-phase with the signal fed to the lower end through C_2. This voltage is fed to the base and will neutralize any signal voltage fed from the collector back into the base through the transistor itself.

Notice that the collector is connected to a tap on the coil L_3. The output resistance of the transistor is comparatively low and by feeding it to a tap on the coil in this manner we prevent loading of the parallel resonant circuit made up of L_3 and C_4. This prevents loading of the resonant circuit which in turn would cause a reduction in the selectivity in the circuit.

Field-effect transistors can also be used as i-f amplifiers, but since they are considerably more expensive than the PNP and NPN types they have not been widely used in this application.

VIDEO I-F AMPLIFIERS

Television receivers are superheterodyne receivers just like radio receivers. However, the rf, mixer and oscillator stages operate at higher frequencies than regular receivers designed for reception on the standard broadcast band.

The i-f amplifier used to amplify the picture signals is called a video i-f amplifier. A video i-f amplifier differs from a sound i-f amplifier inasmuch as it operates at a much higher frequency and must have a much wider bandwidth. This is due to the fact that a wide range of signals is required in order to reproduce a TV picture. Some large areas may be reproduced by comparatively low frequency signals, but the fine detail in a picture is reproduced by comparatively high-frequency signals. The video i-f amplifier must be able to pass the video i-f carrier and the sidebands which contain the video signal. Also, in color TV receivers they must pass an additional signal called the color subcarrier. This signal carries the color information in the picture. In addition, modern superheterodyne TV receivers must be capable of passing the sound i-f signal through at least part of the video i-f amplifier. The sound i-f signal differs from the picture i-f signal by 4.5 megahertz. Therefore the video i-f amplifier must be capable of at least passing with some amplification the sound i-f signal which will be 4.5 MHz lower in frequency than the video i-f carrier frequency.

You'll study video i-f amplifiers later, but here we want you to get some general idea of what the circuit looks like and the problems involved.

A typical video i-f amplifier using a pentode tube is shown in Fig. 21.

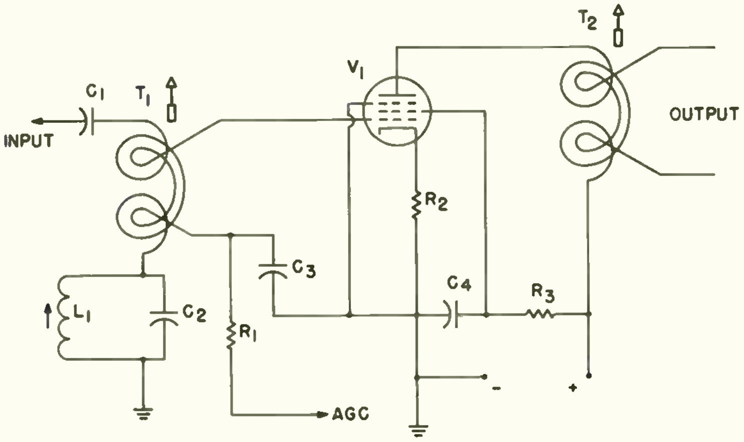

Fig. 21. A pentode video i-f amplifier.

This is typical of the circuits you will find in the first video i-f amplifier of a color TV receiver or of a black and white TV receiver. The input signal is fed to the i-f amplifier from the mixer. It is fed through the capacitor C_1 to the primary of T_1. T_1 is the input i-f transformer and the coils are bifilar wound. This means that the coupling between the coils is extremely tight. The arrow above the two coils indicates that there is an iron slug inside the coils which can be adjusted to tune the two coils to a particular frequency.

An example of how a bifilar wound transformer is constructed was shown in Fig. 8. Notice that the two windings are interlaced to provide very tight coupling between the primary and secondary windings of the transformer.

The combination of L_1 and C_2 form a parallel-resonant circuit. This circuit is resonant at a frequency of 47.25 MHz. This parallel-resonant circuit is referred to as an adjacent channel sound trap. When your TV receiver is tuned to channel 4, for example, if you happen to be near enough to pick up a signal from another station operating on channel 3, the sound signal from the channel 3 station might get through the rf and mixer stages and could cause some interference in the picture. By inserting the parallel-resonant circuit in series with the primary of T_1, if there is any signal current from the channel 3 sound flowing in the circuit, almost all will be dropped across the high impedance of this parallel-resonant circuit. Very little will be fed from the primary to the secondary of T_1.

The grid of the tube is fed to the automatic gain control circuit through R_1. The automatic gain control will provide a negative voltage for the grid of the tube. This voltage will vary in amplitude depending upon the strength of the signal received. If the signal is very strong, a rather high negative voltage will be fed to the grid of V_1. This will reduce the gain of the stage and prevent overloading in following stages. On the other hand, if the signal is weak, the negative voltage fed to the grid of V_1 will be quite low so that the tube will operate at its maximum gain.

T_2 is another bifilar wound i-f transformer. Again, the primary and secondary coils are very tightly coupled.

You might notice that there is no capacitor in the plate circuit of V_1. In spite of this, we have a parallel-resonant circuit in the plate circuit of V_1. You might wonder how this is so, but remember that there is a certain capacity in the tube itself. There is capacity between the plate and cathode and this is in effect electrically across the primary of T_2. This capacity along with the wiring capacity in the circuit is all the capacity we need at the frequencies involved to form a parallel-resonant circuit along with the primary winding of T_2. Video i-f amplifiers usually operate in the 40 MHz region, and at these high frequencies only a small amount of capacity is needed in a resonant circuit.

A typical transistor video i-f amplifier is shown in Fig. 22. This i-f amplifier is the second video i-f amplifier taken from a portable TV receiver. The input signal is received from the first video i-f amplifier and coupled from L_1 to L_2. L_2 has fewer turns than L_1 in order to match the transistor input circuit. C_1 is placed in the circuit to prevent L_2 from shorting out the forward bias across the emitter-base junction of the transistor. The for-

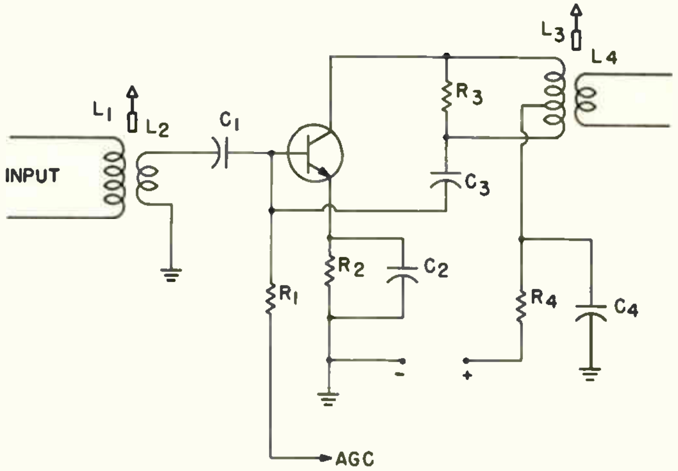

Fig. 22. A transistor video i-f amplifier.

ward bias is applied to the base through R_1. Again, this bias is obtained from the agc system, and is varied to vary the gain of the transistor depending upon the strength of the signal being received.

The coil L_3, which is in the collector circuit of the transistor, along with the transistor capacity and the wiring capacity, form a parallel-resonant circuit. The arrow of the coil indicates that the circuit can be tuned by means of a slug which moves in and out of L_3. Notice that the collector voltage is fed to a center tap on the coil. The center tap is held essentially at ground potential by the capacitor C_4. A voltage is induced in the lower half of L_3 which is 180° out-of-phase with the voltage in the upper half. The voltage from the lower half is fed through C_3 back into the base circuit in order to provide neutralization and to cancel out any signal fed through the transistor from the collector to the base.

The resistor R_3, which is connected across L_3, is a loading resistor. The purpose of this resistor is to load the resonant circuit in order to help get the broad frequency response required of a video i-f amplifier.

L_4 is inductively coupled to L_3 and feeds the next video i-f amplifier.

In aligning a video i-f amplifier such as shown in Fig. 22, L_1 is not tuned to the same frequency as L_3. By tuning the resonant circuits to different frequencies we broaden the response of the amplifier. For example, the resonant circuit in which L_1 is located may be tuned as shown by curve A in Fig. 23. At the same time L_3 and its circuit might be tuned as shown in curve B. The overall response produced by the two amplifiers may then look like curve

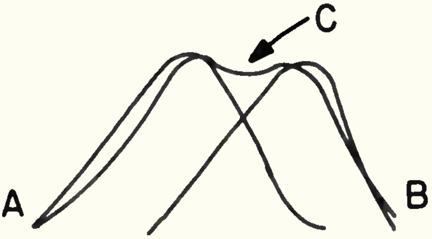

Fig. 23 Response of curves A and B together may give overall response like C.

C which has a wider bandwidth than either curve A or curve B. You will study video i-f amplifiers in detail later and learn more about how the various resonant circuits are adjusted for resonance.

SELF TEST QUESTIONS

(w) What determines the i-f frequency in a receiver?

(x) Why can we usually operate an i-f amplifier at higher gain than an rf amplifier?

(y) Why is the cathode resistor in some pentode i-f amplifiers left unbypassed?

(z) In the circuit shown in Fig. 20, why is the collector connected to a tap on L_3?

(aa) Where is the neutralization for the transistor in the circuit shown in Fig. 20 obtained?

(ab) What is the chief difference between the video i-f amplifier in a television receiver and the sound i-f amplifier in a radio receiver?

(ac) Why is there no capacitor across the primary winding of T_2 in the circuit shown in Fig. 21?

(ad) What purpose does R_3 in Fig. 22 serve?

(ae) What purpose does C_3 in Fig. 22 serve?

Radio-Frequency Power Amplifiers

So far the rf amplifiers we have been discussing are the types found in radio and television receiving equipment. They are voltage amplifiers. They are used to build the weak signal voltage to a reasonably high value before the signal is fed to a detector to extract the intelligence that has been used to modulate the carrier. In radio and television transmitters and in other industrial applications rf power amplifiers are used. RF power amplifiers differ from voltage amplifiers in a number of respects. Not only are the tubes generally much larger than those used in voltage amplifiers, but also the circuit configurations differ in several respects from those used in voltage amplifiers.

A TRIODE POWER AMPLIFIER

Although triode tubes are not very frequently used as rf voltage amplifiers except in the vhf region, they are quite widely used as power amplifiers. Many high-power transmitters today use triode rf power amplifiers.

Schematic diagrams of two triode rf power amplifiers are shown in Fig. 24. Since there are several differences between these two circuits we'll look at the circuits one at a time.

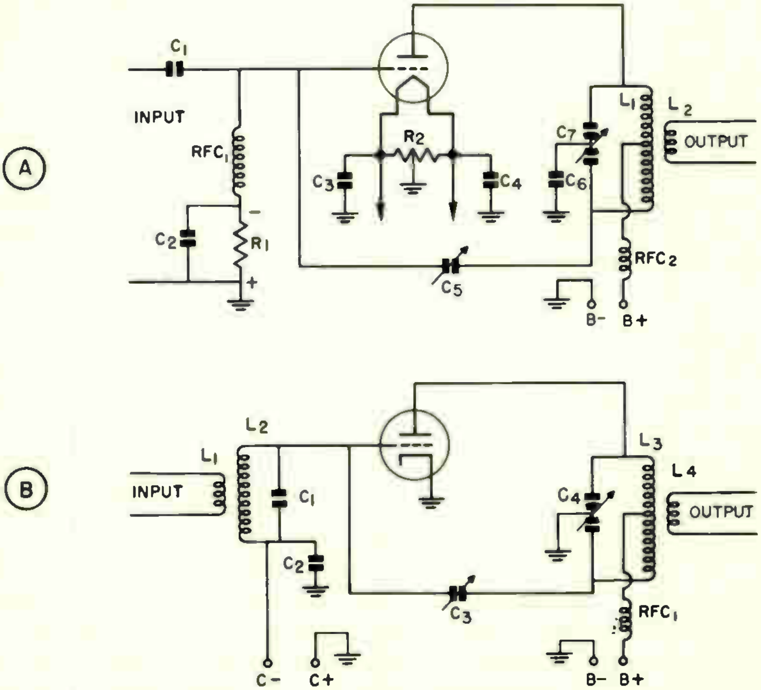

Fig. 24. Schematic of two triode power amplifiers.

In the circuit shown in Fig. 24A we have shown a filament-type tube. This type of tube is frequently found in transmitting applications because a solid tungsten filament or a thoriated tungsten filament will stand up better than an oxide-coated cathode at the high voltages usually used in transmitting tubes. In the circuit shown in Fig. 24B we have shown a cathode-type triode tube so that you will see the difference between the two types.

Examining the grid circuit of the diagram shown in Fig. 24A, you'll see that connected between the grid of the tube and ground we have a coil called a radio-frequency choke. This is abbreviated RFC on the diagram. Also connected between this choke and ground we have a resistor R_1. Power amplifiers are normally operated as class C amplifiers. This means that the input signal drives the grid of the tube positive so that electrons flow from the filament of the tube to the grid. These electrons will strike the grid and then flow from the grid through the rf choke to the parallel combination of R_1 and C_2. Some of the electrons will flow through R_1 to ground, but most of them will charge C_2. During the portion of the cycle when the grid is not drawing current, C_2 will discharge through R_1. The time constant of R_1 and C_2 is selected so that C_2 does not appreciably discharge between cycles of grid current. R_1 is selected so that the average grid current provides the bias required for the tube. Usually for class C operation, this is somewhere between two and four times cut-off bias voltage.

Notice the bypass capacitors and the tapped resistor in the filament circuit. Each side of the filament is bypassed to ground, and a tapped resistor is connected across the filament, and the center tap of this resistor is grounded. Sometimes instead of using a tapped resistor of this type, the filament winding of the transformer used to supply the voltage to heat the tube is center-tapped and the center tap is grounded.

The filament of a transmitting tube is rather heavy, and as a result can be operated from ac. The temperature of the filament changes so slowly that there is no heating and cooling of the filament as the ac voltage goes through its cycle.

With the high bias on the tube, plate current will flow through the tube in a series of pulses. There will be a pulse of plate current each time the input signal drives the grid sufficiently in a positive direction to overcome the bias. Because the grid is driven positive, the peak current reached during each pulse will be high, but because the operating bias on the tube will be substantially beyond cutoff bias, plate current will flow for less than one half of each cycle.

In the plate circuit of this stage, we have a parallel resonant circuit. Notice that the coil L_1 is tapped, and the center tap is connected through another radio-frequency choke (usually called an rf choke) to B+. The B+ voltage applied to the plate of the tube is thus applied through the choke and half of L_1. Capacitor C_7 is a variable capacitor called a split stator capacitor. You will remember that a variable capacitor has two separate plates, one set that is stationary, called the stator, and the other set that rotates, called the rotor. In a split-stator type capacitor there are two sets of stator plates, which are insulated from each other. The rotor consists of two separate sets of plates, one for each set of stator plates, but the rotor plates are electrically connected together. The rotor is operated at signal ground potential by grounding it through C_6 and the stators are connected to the ends of L_1.

The parallel resonant circuit in the plate circuit of the tube is more or less shock-excited by the pulses of plate current received from the tube. The pulse of the plate current sets up circulating currents in the tank circuit. These pulses from the tube are more or less smoothed out by the tank circuit so that the current circulating back and forth in the resonant circuit is a sine wave.

Since the tube used in this circuit is a triode tube, there will be energy fed from the plate of the tube back to the grid circuit. Because a power amplifier develops considerable power in the plate circuit, there will be enough energy fed back into the grid circuit to result in oscillation. This oscillation is overcome by feeding a signal from the tank circuit through C_5 back into the grid circuit of the tube. Notice that the plate of the tube connects to one end of the tank circuit and C_5 connects to the other end. The voltage at the two ends of the tank circuit will be of opposite polarity. Therefore, the signal fed through C_5 back into the grid circuit is of opposite polarity to the signal fed from the plate to the grid circuit through the tube capacity. C_5 is usually an adjustable capacitor that can be adjusted to feed exactly the same amount of signal into the grid circuit as is fed through the tube capacity. C_5 is called a neutralizing capacitor. It is used to feed back energy into the grid circuit to neutralize or cancel the energy fed back into the grid circuit through the tube.

The output signal is taken from the tank circuit by inductively coupling another coil, marked L_2 on the diagram, to L_1.

When a tube is used in a circuit of this type where its bias is developed by the grid current flowing through the grid resistor, we say the tube is self-biased. This type of bias is entirely satisfactory when the stage is operating properly and when the normal signal drive is applied to the input. However, if a defect develops in a preceding stage so that no signal is applied to the input, the grid of the tube will not be driven positive and there will be no current flow. Capacitor C_2 will discharge through R_1 so that the bias applied to the tube will disappear. Once the bias disappears there will be a very high current flow from the filament to the plate of the tube and unless there is some safety measure incorporated in the circuit so that the circuit will be opened when the current goes beyond a certain level, the current will rise to such a high value that the tube will be destroyed.

In the circuit shown in Fig. 24B we have tuned circuits in the input and output circuits. Coil L_1 is inductively coupled to L_2 and its energy fed into L_2. L_2 and C_1 form a series resonant circuit. Here, instead of using self-bias, a fixed bias voltage is applied to the grid circuit of the tube. Notice that the negative terminal of the C battery or C bias supply connects to the coil, and through the coil to the grid. The positive terminal of the C supply is grounded. Sometimes you'll find the bias connections on the diagram labeled C- and C+ as in Fig. 24B and on other occasions you'll find them labeled bias.

The resonant circuit in the plate circuit of this stage is the same as the circuit shown in Fig. 24A. Again, the stage is neutralized by feeding energy from the tank circuit through a capacitor (C_3) back into the grid circuit of the tube.

In some triode power amplifiers you'll find a combination of fixed bias and self bias. In this type of circuit the two types of bias shown in Fig. 24 are incorporated into a single circuit. This is done by selecting a value of resistor in the grid circuit somewhat smaller than what is needed to develop the full bias required by the tube. The remainder of the bias is supplied by a separate bias power supply. For example, if a tube requires a bias of 100 volts for class C operation, a resistor might be put in the grid circuit that would develop 50 volts bias and then a fixed power supply used to provide the other 50 volts. The advantage of this arrangement is that the bias is somewhat self-regulating. In other words if the grid current increases, the bias will increase and tend to prevent overdriving the tube. At the same time, the fixed bias would also protect the tube if the preceding stage develops a defect so that the signal drive is not supplied to the grid of the tube.

TETRODE POWER AMPLIFIERS

Tetrode power amplifiers have two big advantages over the rf triode power amplifiers. Perhaps the greater advantage lies in the fact that a tetrode has a very high power sensitivity. This means that you need only a small input signal to drive the tube hard enough to produce a rather large signal in the output. Thus the power gain in a tetrode rf power amplifier is much greater than in a triode power amplifier, because a substantial amount of driving power is usually required to drive a triode.

The second big advantage of a tetrode power amplifier is the fact that the screen grid effectively shields the grid of the tube from the plate. With careful circuit design it is usually possible to design a circuit that does not require neutralization. This is a big advantage if a power amplifier is to be used over a wide frequency range. In a triode power amplifier, if you have occasion to change the frequency at which the amplifier is operating, you often have to readjust the setting of the neutralizing capacitor. However if a tetrode stage can be operated without neutralization, this problem is not encountered. Of course, in a radio broadcast transmitter that is designed to operate on one specific frequency, neutralizing the triode doesn't present any great problem, and once it is neutralized you do not have to re-neutralize it unless you change the tube. However, in many communications applications, it is necessary to have transmitters that can be operated on a number of different frequencies. In such a case, a tetrode tube that does not need neutralization is quite advantageous.

The tetrode tubes used in modern power amplifiers are beam power tubes. You will remember that a beam power tube is a tube made so that the cathode emits electrons in two streams or beams from opposite sides of the cathode. The electrons are further focused into a beam by means of beam-forming plates which are connected inside the tube to the cathode of the tube. Although you might actually consider the beam-forming plates as separate elements, the general practice is to ignore them when counting the tube elements so the tube is considered to be a tetrode or four-element tube.

A schematic diagram of a tetrode rf power amplifier is shown in Fig. 25. Notice that we have a resonant circuit in the input. Again, this tube circuit uses self bias; the bias needed to operate the tube in the Class C amplifier is developed

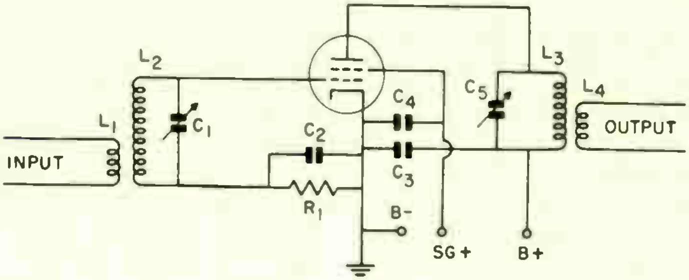

Fig. 25. A tetrode rf power amplifier.

across the parallel combination of R_1 and C_2 by the grid current. Again, grid current flows because on the positive half cycle the signal drives the grid positive and electrons are attracted to the grid.

A parallel resonant circuit is used in the plate circuit, and the output is taken by inductively coupling L_4 to L_3.

The screen grid of the tube is operated with a positive voltage applied to it. Sometimes this voltage is obtained from a separate power supply or from a tap on the main power supply. Sometimes a dropping resistor is connected between the plate supply and the screen grid of the tube in order to drop the screen voltage to a value lower than the plate voltage.

A push-pull tetrode power amplifier is shown in Fig. 26. Here notice that the circuit configuration is quite similar to the push-pull circuits used in audio work with the exception of the resonant circuits used in the grid and plate circuits of the tube. Notice that split stator tuning capacitors have been used in both the input and the output circuits. Again, because the feedback from the plate of the tube to the grid of the tube is low due to the shielding effect of the screen, neutralization is not required. However, sometimes you will find tetrode power amplifiers using neutralization.

Pentode rf power amplifiers are sometimes used, but they are not nearly as common as tetrode power amplifiers. The circuits used for

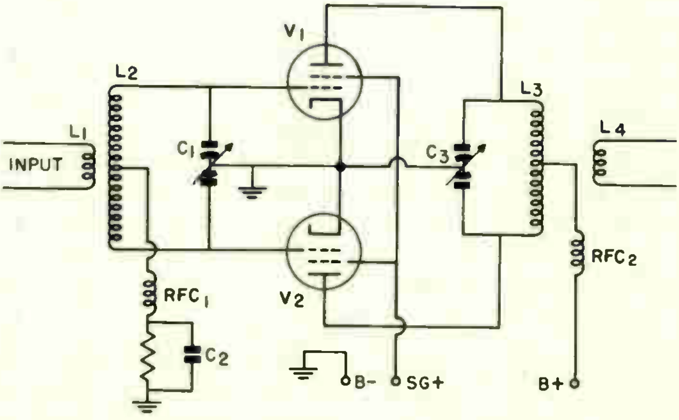

Fig. 26. A push-pull tetrode rf power amplifier.

pentode tubes are similar to those used for tetrodes. The suppressor grid of the pentode tube is usually connected to B-.

TRANSISTOR POWER AMPLIFIERS

A few years ago there were relatively few transistor rf power amplifiers because the rf power that could be generated by transistors was quite limited. However, a great deal of progress has been made in transistor design and manufacture and now there are many transistor rf power amplifiers in use. Of course, there are no transistors available that can develop the very high rf powers that vacuum tubes can develop, but low and medium power rf transistors are available.

Transistor power amplifiers may be used in either the common-emitter or common-base circuits. The common-emitter circuit is more stable, but at very high frequencies the emitter lead inductance may restrict the power capability of the transistor. In this case the common-base circuit may provide a higher power gain, but it will be more unstable than the common-emitter circuit.

Transistor rf power amplifiers may be operated as Class A, Class B or Class C amplifiers. Class A amplifiers provide extremely good linearity but the efficiency is low. This type of power amplifier is used only when the power requirements are quite low. A Class B power amplifier will provide a higher power gain and better efficiency. Of course, a Class C power amplifier will provide the best efficiency, but the harmonic output from a Class C power amplifier will be quite high. The tank circuits used with Class C power amplifiers are designed to offer a high impedance to the harmonics and a low impedance to the fundamental frequency.

Biasing Methods.

For Class A bias on a transistor power amplifier, we must have a forward bias across the emitter-base junction as in the case of transistor voltage amplifiers. For Class B bias, the bias across the emitter-base junction of the transistor is zero. For Class C bias, we must have a reverse bias across the emitter-base junction so that current will flow through the transistor only on the peak of the rf cycle. That overcomes the reverse bias and drives the emitter-base junction into the conduction region. As in the case of vacuum-tube Class C amplifiers, current will flow through the transistor for less than half a cycle.

Two typical circuits for developing Class C bias for a transistor power amplifier are shown in Fig. 27. In the circuit shown in Fig. 27A, the incoming rf signal drives the

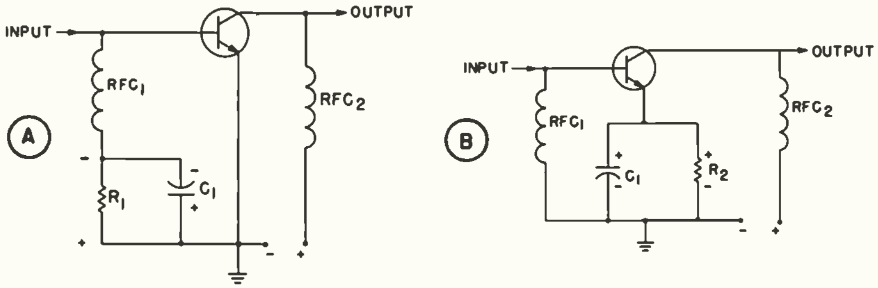

Fig. 27. Two methods of producing bias for Class C power amplifiers.

base of the transistor positive and electrons leave the base and flow through the rf choke and charge the capacitor C_1 with the polarity shown. Some of the electrons flow through R_1 to ground developing a voltage drop across this resistor having the polarity shown.

During the portion of the rf cycle when the transistor is not conducting, C_1 discharges through R_1 maintaining the reverse bias across the emitter-base junction essentially constant.

Another method of obtaining Class C bias is shown in Fig. 27B. In this circuit, when the input signal drives the base positive, current flows through the resistor R_2 to the emitter, across the emitter-base junction of the transistor, across the base and the base-collector junction and then through the rf choke RFC_2 back to B+. The electrons flowing through R_2 will charge capacitor C_1 with the polarity shown. During the portion of the cycle when the base is not driven positive by the rf signal, C_1 will discharge through R_2 maintaining the emitter positive with respect to ground. Thus the emitter will be positive with respect to the base and will have a reverse bias across the emitter-base junction so there will be no current flow through the transistor.

Typical Circuits.

A typical Class C transistor rf power amplifier is shown in Fig. 28. In this circuit the biasing method shown in Fig. 27B is used to provide a reverse bias across the emitter-base junction.

The rf signal is fed into the input and on the positive half of the cycle the rf signal overcomes the reverse bias across the emitter-base junction and electrons flow through the transistor. The choke in the collector circuit completes the dc current path through the transistor. The rf signal is fed to the output network consisting of C_2, C_3, L_1 and L_2. C_2 is adjusted for resonance and C_3 is adjusted to obtain the desired loading.

When more power is required from an rf power amplifier than can be obtained from a single transistor, two or more transistors can be used either in push-pull or in parallel. In push-pull operation transformers must be used for proper input signal phase. This works out quite satisfactorily at lower i-f frequencies, but at very high frequencies it is difficult to build transformers which provide the required impedance

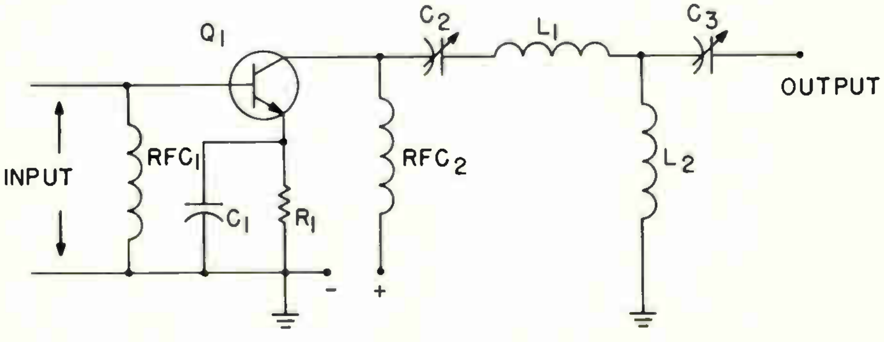

Fig. 28. A Class C transistor power amplifier.

transfer. Therefore parallel operation of transistors is generally preferred at vhf over push-pull operation.

In Fig. 29 we have shown a schematic diagram of two transistors operated in parallel. If additional power is required, a third parallel transistor in an essentially identical circuit could be added.

Previously we mentioned the effect of emitter-lead inductance at vhf. The effect of this inductance is tuned out by the capacitors C_3 and C_4.

In a circuit of this type, it is desirable to have transistors with matched characteristics in order to insure that each transistor will pick up half of the load.

To check the operation of the transistors to be sure that each is handling half the total current, we measure the voltage across R_1 and the voltage across R_2. The voltages across these two resistors should be equal; this would indicate each transistor is picking up half of the load.

SELF TEST QUESTIONS

(af) What is the purpose of C_5 in Fig. 24A?

(ag) Why is it possible to operate the filament of the triode tube shown in Fig. 24A from ac power?

(ah) How are the pulses of current that flow through a Class C amplifier stage smoothed into a sine wave?

(ai) What are the two big advantages of the tetrode power amplifier over the triode power amplifier?

(aj) What type of bias is placed across the emitter-base junc-

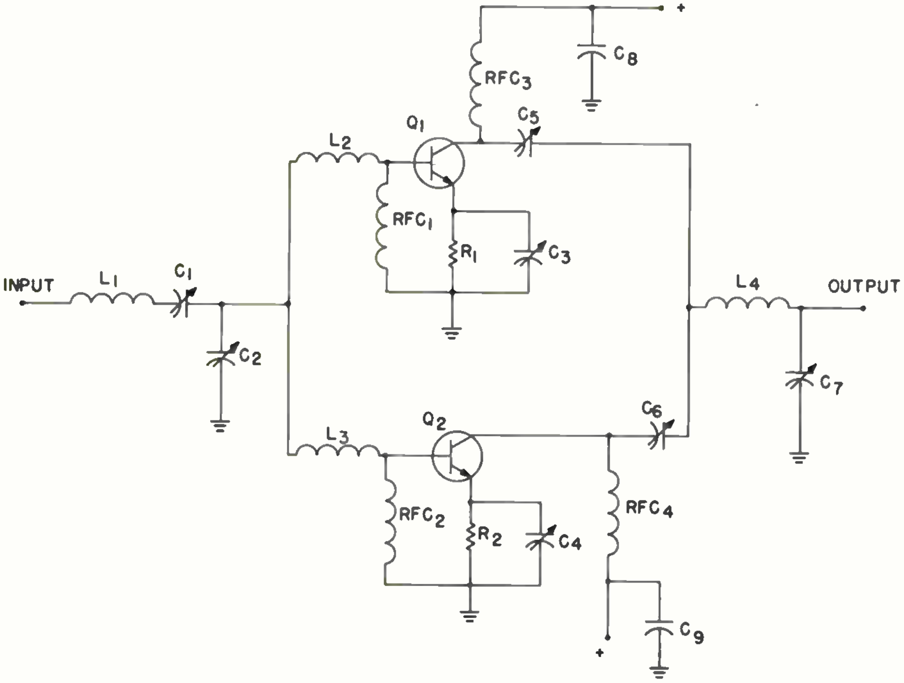

Fig. 29. A high-frequency power amplifier using two transistors in parallel.

tion of a transistor operated as a Class C power amplifier?

(ak) Across what parts is Class C bias developed in the circuit shown in Fig. 27A?

(al) What purpose do the capacitors C_3 and C_4 in the circuit shown in Fig. 29 serve?

ANSWERS TO SELF TEST QUESTIONS

(a) The basic difference is in the load found in the rf amplifier. It is usually some type of resonant circuit.

(b) The basic difference is how the voltage is applied to the coil and capacitor in the resonant circuit. If the voltage is applied to the coil and capacitor in series, it is a series-resonant circuit, but if it is applied to the coil and capacitor in parallel, it is a parallel-resonant circuit.

(c) Sideband frequencies are frequencies above and below the carrier frequency produced when we add the intelligence to be transmitted to the carrier frequency.

(d) The bandwidth of a resonant circuit is the band of frequencies that will be passed or amplified by the circuit with a gain equal to at least 70.7% of the gain obtained at the resonant frequency of the circuit.

(e) On the L-C ratio of the resonant circuit and on the Q of the resonant circuit.

(f) By loading the circuit with a suitable resistance.

(g) Critical coupling is the point at which maximum signal transfer occurs from one coil to another. This will occur when all the flux lines produced by one coil cut the turns of the other coil.

(h) When we speak of over-coupling we mean that the coils are coupled together beyond the critical coupling point. It results in some drop in output and produces a so-called double-hump response curve.

(i) The moisture and dust particles will introduce resistance into the circuit and lower the Q of the circuit. This will tend to reduce the output from the resonant circuit and also reduce the selectivity.

(j) At the high frequencies used in the rf section of a television receiver, moving a wire may change the inductance or capacitance in a resonant circuit sufficiently to upset the performance of that circuit. This is particularly true of the coils and leads used in conjunction with the high vhf channels in a TV tuner. It is even more true of the parts and leads in a uhf tuner.

(k) The rf amplifiers in radio and television receivers are Class A voltage amplifiers.

(l) C_1 and L_2 in Fig. 10 form a series-resonant circuit.

(m) C_3 is a screen bypass capacitor. It is chosen so that it has a low reactance at the signal frequencies amplified by the stage. Therefore as far as the screen is concerned, it is essentially connected to ground at signal frequencies. This permits the screen to act as an effective shield between the plate and grid of the tube, to prevent feedback from the plate to grid that could cause oscillation.

(n) Permeability tuning is a tuning system where the inductance of the coils is varied by moving a powdered iron slug in and out of the coil. The resonant frequency of the circuit is varied by varying the inductance of the coil rather than by changing the capacity of the tuning capacitor.

(o) T_1 is a balun. It is used to match the balanced transmission line, which has an impedance of 300 ohms, to the unbalanced input of the rf stage, which has an input impedance of 75 ohms. Thus the transformer matches a balanced circuit to an unbalanced circuit, at the same time it matches a 300-ohm circuit to a 75-ohm circuit.

(p) Triode tubes generate a lower internal noise than pentode tubes. Low noise level is extremely important in the rf stage of TV receivers, particularly in the reception of the high-band vhf TV channels.

(q) The combination of L_1 and L_2 form a transformer because L_1 is inductively coupled to L_2. L_1 along with C_1 form a series-resonant circuit. A step-down transformer is used to feed the signal to the input of the transistor because the transistor has a comparatively low input resistance. When using a step-down transformer (having fewer turns on L_2 than on L_1), loading of the resonant circuit can be kept to a minimum. Excessive loading of the resonant circuit would reduce the selectivity of the resonant circuit.

(r) C_4 is used to feed a small amount of signal from the output back into the base of the transistor. The energy fed through C_4 is 180° out-of-phase with the signal fed from the collector back to the base through the transistor itself. The signal fed through C_4 cancels the signal fed internally through the transistor. C_4 is a neutralizing capacitor and prevents the stage from going into oscillation.

(s) L_1 and C_1 form a parallel-resonant circuit. They prevent undesired signals in the sound i-f frequency region from getting to the rf amplifier. C_2 and L_2 form a series-resonant circuit. Since they have a low impedance they bypass the signals around 45 MHz. 45.75 MHz is the picture i-f signal frequency. The trap prevents interfering signals from stations operating at or near this frequency from reaching the rf amplifier.

(t) A negative voltage is applied to the gate to prevent electrons from flowing to the gate. This would cause current to flow in the gate circuit and lower the input resistance of the transistor.

(u) The field-effect transistor has a very high input resistance. Therefore the transistor has very little or no loading effect on the resonant circuit which permits a high degree of selectivity. In addition, very high gains are possible with the field-effect transistor.

(v) The circuit shown in Fig. 17. This circuit makes use of an insulated-gate field-effect transistor. There will be no current flow in the circuit. In the circuit shown in Fig. 16 there will be some small reverse current which has some slight effect on the input resistance of the transistor.

(w) The i-f frequency is determined by the difference between the frequency of the incoming signal and the frequency of the local oscillator.

(x) I-F amplifiers operate at a fixed frequency and therefore the circuit is usually somewhat simpler and can be better shielded than an rf amplifier which must be adjustable over a frequency range.

(y) To introduce a small amount of degeneration which may prevent the stage from going into oscillation.

(z) The collector is connected to a tap to prevent the comparatively low output resistance of the transistor from loading the parallel-resonant circuit made up of L_3 and C_4.

(aa) Neutralization is obtained by taking a signal from the emitter and feeding it through C_2 into L_2. L_2 inverts the signal so that the signal fed to the base will be out-of-phase with the signal fed back to the base through the collector-to-base capacity. The emitter is left unbypassed so that a signal voltage for neutralization will be developed across R_2.

(ab) The video i-f amplifier in a television receiver will have a much wider bandwidth than the sound i-f amplifier in a radio receiver. In order to get this wider bandwidth, the video i-f amplifier is operated at a much higher frequency.

(ac) A capacitor is not necessary at the high frequencies used in video i-f amplifiers. There is already enough capacity in the tube and in the circuit wiring to provide the capacity necessary to form a parallel-resonant circuit along with the primary winding of T_2.

(ad) R_3 is used to load the parallel-resonant circuit consisting of L_3 plus the transistor and distributed capacity in the circuit. The resonant circuit is loaded giving wider bandwidth.

(ae) C_3 is the neutralizing capacitor. A signal voltage is fed through it to neutralize the voltage fed through the collector–to–base capacity of the transistor.

(af) C_5 is a neutralizing capacitor. It is used to feed energy from the plate circuit back into the grid circuit to cancel out the energy fed from the plate circuit to the grid circuit through the interelectrode capacity of the tube.

(ag) The filament of the transmitting tube is quite heavy and does very little heating or cooling as the ac current goes through its cycle. Operating the filament on ac does not introduce hum into the circuit.

(ah) The tank circuit consisting of the coil and the capacitor in the plate circuit of the rf power amplifier smooth the current pulses from the tube into a pure sine wave.

(ai) The tetrode tube provides a higher power gain, and a properly designed tetrode amplifier usually does not require neutralization.

(aj) The emitter-base junction of a transistor Class C power amplifier is reverse biased.

(ak) R_1 and C_1.

(al) They are used to tune out the emitter lead inductance.

Lesson Questions

Be sure to number your Answer Sheet B203.

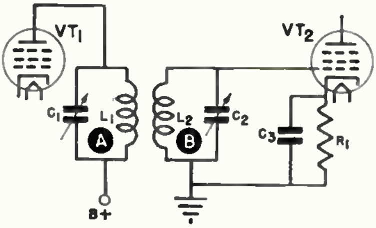
Place your Student Number on every Answer Sheet.

Most students want to know their grade as soon as possible, so they mail their set of answers immediately. Others, knowing they will finish the next lesson within a few days, send in two sets of answers at a time. Either practice is acceptable to us. However, don't hold your answers too long; you may lose them. Don't hold answers to send in more than two sets at a time, or you may run out of lessons before new ones can reach you.

1. What type of load will be found in the plate circuit of most rf amplifiers?

2. If a 1000-KHz signal is modulated by a 3000-cycle audio signal, what will the frequencies of the sidebands be?

3. In the circuit shown to the right what type of resonant circuit is the circuit marked A; what type is the resonant circuit marked B?



4. Which type of rf amplifiers are found in radio and TV receivers, voltage amplifiers or power amplifiers?

5. Why are triode rf amplifiers frequently used in television receivers?

6. What is the purpose of C_4 in the circuit shown in Fig. 14?

7. What purpose do L_1 and C_1 in the circuit shown in Fig. 15 serve?

8. What characteristic of the junction-type field-effect transistor makes it ideally suited for use as an rf amplifier?

9. Why is the suppressor grid of a pentode tube, used as an i-f amplifier, often connected to ground rather than the cathode of the tube?

10. How is bias developed for the Class C transistor power amplifier shown in Fig. 28?

FEAR LEADS TO FAILURE

No matter how hard a person may work for success, there is nothing which can help him if he is always doubting his own ability-if he is always thinking about failure.

To be ambitious for wealth yet always expecting to be poor is like trying to get past a vicious dog when afraid of the dog and uncertain of your ability to make friends with him-in each case, fear of failure is almost certain to result in failure. Success, on the other hand, is won most often by those who believe in winning.

Never doubt for a moment that you are going to succeed. Look forward to that success with just as much assurance as you look forward to the dawn of another day, then work-with all that's in you-for success.

WIDE-BAND AMPLIFIERS

B204

STUDY SCHEDULE

☐ 1. Introduction . . . . **Pages 1 - 2**
A look at what you will study in this lesson.

☐ 2. Logarithms and Decibels . . . . **Pages 3 - 10**
You are introduced to the theory of logarithms, you learn what we mean by a decibel and learn how the decibel is used.

☐ 3. Extending the High-Frequency Response of an Amplifier . . . . **Pages 11 - 24**
You learn what factors limit the high-frequency of an amplifier and what can be done to improve it.

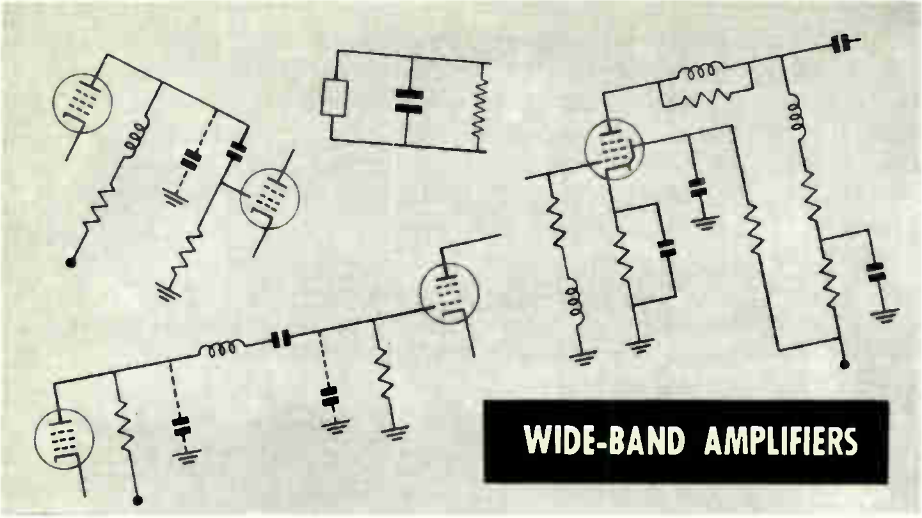
☐ 4. Extending the Low-Frequency Response of an Amplifier . . . . **Pages 24 - 31**
You study the factors affecting the low-frequency response and how they can be compensated for.

☐ 5. Typical Wide-Band Amplifiers . . . . **Pages 32 - 41**
Both typical tube and transistor wide-band amplifiers are discussed.

☐ 6. Answer the Lesson Questions.

☐ 7. Start Studying the Next Lesson.

KL5M1273 1975 EDITION Litho in U.S.A.



WIDE-BAND AMPLIFIERS

A wide-band amplifier is an amplifier designed to amplify a wide range of signal frequencies. The amplifiers you studied in earlier lessons were designed to amplify only a limited range of frequencies. For example, a low-frequency voltage amplifier such as found in a typical radio receiver or in the sound portion of a television receiver, is designed to amplify only frequencies from about 100 Hertz up to about 10,000 Hertz. Even in a high fidelity amplifier or a high fidelity radio receiver, the low-frequency voltage amplifier is designed to amplify only frequencies from about 10 Hertz up to about 30,000 Hertz. Amplifiers of this type are entirely unsatisfactory for use as video amplifiers in a television receiver. Here, we need a special wide-band amplifier that can amplify all the signals in a TV picture from only a few cycles per second (a few Hertz) all the way up to several megacycles per second (several megahertz). Furthermore, the amplifier must be able to amplify all these signals equally well and must not shift the phase of any signal more than or less than the phase of the other signals.

In your earlier lesson on low-frequency amplifiers you learned that the response of a resistance-capacitance coupled amplifier is limited by three things. The low-frequency response is limited by the reactance of the coupling capacitor. In amplifiers that use vacuum tubes, when the coupling capacitor has a reactance that is equal to or greater than the resistance of the grid resistor in the following stage, the gain of the amplifier begins to drop to such a low level that considerable frequency distortion results. You will remember that we have frequency distortion in an amplifier when signals of different frequencies do not receive the same amount of amplification. In transistor amplifiers we have the same problem when the reactance of the coupling capacitor becomes equal to or greater than the input resistance of the following stage. This input resistance is equal to the input resistance of the transistor itself (which is usually quite low) in parallel with any resistance connected between the base and the emitter.

The high-frequency response is limited by the shunt capacities in the circuit. At high frequencies the shunt capacities in the circuit have a low enough reactance to have an appreciable effect on the gain of the amplifier. In a vacuum tube amplifier, the shunt capacities reduce the effective value of the plate load resistance. In a transistor amplifier they reduce the effective collector load resistance. In both cases the gain of the amplifier drops so that it no longer gives satisfactory results.

Both the low-frequency and the high-frequency response are limited by phase shift. You will remember that the current flowing through a capacitor leads the voltage across it by 90 degrees. Thus, as the capacitive reactance in the circuit becomes appreciable, there is an appreciable phase shift. This means that both low-frequency and high-frequency signals are shifted in phase with reference to middle-frequency signals. In TV receivers and in other electronic devices, this phase shift can appreciably affect the performance of the equipment.

In this lesson we are going to learn what steps are taken to improve both the low-frequency response and the high-frequency response of resistance-coupled amplifiers so that they can be used as wide-band amplifiers.

Another thing we are going to investigate in this lesson is the method used to describe the performance of an amplifier. For example, a manufacturer may say that an amplifier is flat from 100 Hertz to 100 KHz. This means that the gain of the amplifier is constant from 100 Hertz to 100 KHz. In other words, if the voltage gain is 100 at 100 Hertz it will be 100 at all frequencies between 100 Hertz and 100 KHz.

An amplifier that is flat from 100 Hertz to 100 KHz is quite a good amplifier. Usually it is impossible to design an amplifier that has exactly the same gain over a wide range of frequencies. The gain may be a little higher or a little lower at some frequencies than it is at others. The exact variation in gain that can be tolerated depends largely on what the amplifier is to be used for. Therefore, manufacturers must have a method of describing how much the gain of the amplifier varies. To do this they use a unit called the decibel (db). Since the decibel is such a useful unit and since you will encounter it in all branches of electronics, we will learn something about it now before going ahead with our study of wide-band amplifiers. We will then be able to use the decibel in describing amplifier performance so you can see how it is used by manufacturers, engineers, and technicians.

Logarithms and Decibels

The decibel is a logarithmic ratio. In other words, it is a ratio that is based on logarithms. Therefore, before we can understand what a decibel is, we must first learn something about logarithms.

There are two important types of logarithms in use today. One is called a "common" logarithm and the other a "natural" logarithm. Common logarithms are based on the number 10. This is the type of logarithm that we will study and use now.

THE THEORY OF LOGARITHMS

The basic idea of logarithms comes from the fact that any number can be expressed as the "power" of another number. The "power" of a number is the product of a number multiplied by itself a given number of times. The first power of a number is the number itself; the second power is that number multiplied by itself; the third power is that number multiplied by itself twice, etc.

This is easiest to understand by taking an example. In the system of common logarithms, we express all numbers as powers of 10; so we will use 10 as our example. The number 10 itself is equal to 10 to the first power. This can be written 10^1. 100 is equal to 10 X 10. This is 10 to the second power, and can be written 10^2. Similarly, 1000 is equal to 10 X 10 X 10, which is 10 to the third power, and can be written 10^3. The number 10,000 is 10 to the fourth power. Since 10 X 10 X 10 X 10 is equal to 10,000 it can be written 10^4.

Now, as we have said, 100 is 10 to the second power; the logarithm of 100 is simply the power to which 10 must be raised to give us 100. Ten must be raised to the second power (10^2) to give us 100. Therefore, the logarithm of 100 is 2. Similarly the logarithm of 1000 is 3, and the logarithm of 10,000 is 4. The logarithm of 10 is 1.

This is not very complicated when a number is an exact power of 10. But let us consider the numbers between 10 and 100. It is a little more difficult to see how a number between 10 and 100 can be expressed as a power of 10. Actually, this is quite difficult to work out mathematically, but it can be done. Fortunately all these values have been worked out and are available in tables called logarithm or "log" tables. If you want to know the logarithm of a number, you must refer to the table. For example, the logarithm of the number 2 is .301. This means that if it were possible to multiply the number 10 by itself .301 times, the product would be 2. This can be written $10^{.301}$. The exponent, or power, .301, is called the logarithm.

Now let's take the number 20. The logarithm of 20 is 1.301. Notice now that the logarithm is divided into two parts - one part to the left of the decimal point, the other to the right of the decimal point. The part to the left is called the "characteristic" and the part to the right is called the "mantissa".

In the logarithm of a number, the "characteristic," is 1 less than the number of figures to the left of the decimal point in the original number. In other words, any number between 10 and 99 would have a logarithm with a characteristic of 1. The important rule to remember here is that the characteristic is always one number smaller than there are whole numbers in the original number. Thus if the logarithm of a number is exactly three, the number itself is exactly 1000 because 1000 has four places to the left of the decimal.

The chart shown in Fig. 1 gives the characteristics of the numbers you are likely to encounter.

For numbers from:			Characteristic
1	to	9	0.
10	to	99	1. (10^1)
100	to	999	2. (10^2)
1,000	to	9,999	3. (10^3)
10,000	to	99,999	4. (10^4)
100,000	to	999,999	5. (10^5)

Fig. 1. The characteristics of numbers from 1 to 999,999.

A table of logarithms is shown on pages 6 and 7. As you can see, it shows only the mantissas. When you are looking up a logarithm, you must supply the characteristic from the information in Fig. 1. Notice that the table does not list an infinite number of mantissas because logarithms repeat themselves. For example, the mantissa of a logarithm will be the same for the number 2 as it is for the number 20, or 200 or 2000. The only difference in the logarithm will be in the characteristic. For example, the logarithm of the number 2 is .301. The logarithm of 20 is 1.301 and the logarithm of 200 is 2.301. The logarithm table would simply give you a value for the number 2. If the number is 20 or 200 or 2000, you must remember to add the correct characteristic in front of the mantissa. Similarly the mantissa of the logarithm of 21 would be the same as the mantissa of the logarithm of 210, the difference would be in the characteristic. The log of 21 is 1.322 and the log of 210 is 2.322.

Let's take the number 39 and see how we would find the logarithm. We know that the characteristic will be 1, because it is always equal to 1 less than the number of figures in the antilog. (The original number is called the antilog.)

Now, to find the mantissa, refer to the log tables. First find the number (39) in the N column. Since the number 39 is the complete number, follow across to the 0 column. There you will find 5911, which is the mantissa. Since you already know that the characteristic is 1, you have the complete logarithm of 39, that is, 1.5911.

If the number for which you wanted the logarithm had 3 places, you would find the first two in the N column, then follow across to the column under the third digit. For example, to find the logarithm of 399, you would find 39 in the N column, and then follow across to the 9 column, where you would find 6010 for the mantissa. Since the number 399 has 3 places, you know the characteristic is 2, so the complete logarithm is 2.6010.

The last column in the log table is labeled P.P.; this is the "Proportional Parts" column. This column is used when the number has more than three digits. For example, the log of 399 is 2.6010. The log of 3990 has the same mantissa, .6010, but the characteristic is 3, so the log is 3.6010. But what about the log of the number 3995? It is greater than the log of 3990, but less than the log of 4000. The proportional parts column is used to get the log of 3995. We look in this column under the heading 5 and get 6. So to the log of 3990, which is 3.6010 we add .0006 and get 3.6016, which is the log of 3995. The proportional parts column only goes up to 5, so if the fourth digit is greater than 5, we add the proportional parts of two numbers that add up to the fourth digit. For example, to express 3998, we take the log of 3990, which is 3.6010 and add the proportional parts under 3 and 5 (3 and 6) and get 3.6019, which is the log of 3998. We could also take the log of 4000, which is 3.6021 and subtract the value under the 2 column and get 3.6019.

THE DECIBEL

Many years ago engineers working on telephone installations introduced a unit of power measurement called the bel. This unit of measurement was named for Alexander Graham Bell, the inventor of the telephone.

The bel was introduced as a unit of measurement because engineers and scientists discovered that the human ear responds to variations in loudness in an approximately logarithmic manner. Therefore, it is convenient to have a unit that can be used to express the ratio between the power of two signals in a logarithmic manner. The bel is simply the logarithm of the ratio of the power of two signals. For example, if we had a signal power of 100 watts and another signal power of 10 watts, and we wished to express the ratio of these two signals in bels, we would use the formula:

$$\text{bels} = \log \frac{P_1}{P_2}$$

and substitute 100 watts for P_1 and 10 watts for P_2, and we would get:

$$\text{bels} = \log \frac{100}{10}$$

$$\text{bels} = \log 10$$

Now the log of 10 is 1, so this power ratio is equal to 1 bel. In other words, a power ratio of 100 watts to 10 watts, which is a ratio of 10 to 1, is equivalent to 1 bel. Thus a power ratio of 10 watts to 1 watt or 1000 watts to 100 watts are both power ratios of 10 to 1 so they also represent a change in power of 1 bel.

The bel proved to be too large a unit to handle easily, so another unit, one-tenth the size of the bel was introduced. This unit is called the decibel (abbreviated db). Thus the commonly used measuring unit is the decibel; the prefix deci means one-tenth. A power ratio in decibels is defined as:

$$\text{db} = 10 \log \frac{P_1}{P_2}$$

which simply means that the ratio of two powers expressed in decibels is equal to ten times the logarithm of the ratio of the two powers.

You will notice that the above relationship refers to power ratios only. It is common in electronics work to refer to voltage ratios, especially when calculating or discussing the gain of amplifiers. When the ratio between two voltages is calculated in decibels, we must modify the decibel equation to take care of the fact that the power ratios are proportional to the squares of voltage ratios since $P = E^2 \div R$. The formula to express voltage ratios in decibels is:

$$\text{db} = 20 \log \frac{E_1}{E_2}$$

It is important to keep in mind that the voltage formula can be used only when the resistances in the two circuits being compared are equal. If we are trying to compare voltages developed across resis-

tors of unequal value, we must convert the voltage to the power developed across the resistors and then use the power formula.

USING THE DECIBEL

It so happens that the smallest amount of change in sound power level that can be distinguished by the average human ear is 1 decibel on a sine wave signal, or 3 db on complex waves such as the average human voice.

Because the decibel is such a convenient unit for expressing changes in sound level, manufacturers of audio equipment have for some time used it in describing the response of their amplifiers. This practice has generally spread into describing the performance of wideband amplifiers.

Let us now see two examples of how the decibel can be used to describe an amplifier response. In an earlier lesson we discussed the so-called half-power points and the .707 voltage points in an amplifier. Remember that when the reactance of the coupling capacitor used between two resistance-capacitance stages becomes equal to the resistance in the input of the following stage, the voltage gain of the amplifier drops to .707 (70.7%) of what it is at medium frequencies. At the same time, since the voltage drops to .707, the current also drops to .707. The power, which is the product of E X I, is therefore .707 X .707, which is approximately .5 times what it is at the middle frequencies.

Thus we called this point the half-power point. Now let's use decibels to see how much of a change this represents.

Considering first the change in output voltage, let's call E_1, the voltage at the middle frequencies, 1; E_2, the voltage at the low frequency, will then be .707. Thus the change in db is:

$$\text{db} = 20 \log \frac{E_1}{E_2}$$

and substituting 1 for E_1 and .707 for E_2 we get:

$$\text{db} = 20 \log \frac{1}{.707}$$

Now when we divide .707 into 1 we get the following:

$$.707\overline{)\ 1\ }$$

We get rid of the decimal in the division by moving the decimal point in each number three places to the right so we have 1000 ÷ 707, which is:

$$\begin{array}{r}
1.414 \\
707\overline{)1000.} \\
\underline{707} \\
2930 \\
\underline{2828} \\
1020 \\
\underline{707} \\
3130 \\
\underline{2828} \\
302
\end{array}$$

Thus we can see that 1 divided by .707 is equal to 1.414, plus a remainder. For our purposes 1.41 is close enough. Thus we have:

$$\text{db} = 20 \log 1.41$$

The log of 1.41 is .1492, which we can call .15, so we have:

$$db = 20 \times .15 = 3$$

Hence the change in db is 3 db. This means that the voltage gain of the amplifier has changed by 3 db. In this case, at the frequency when the reactance of the coupling capacitor is equal to the resistance in the input circuit of the following stage, the voltage output will have dropped 3 db from what it is at the middle-frequency range.

Now let's see what results we get if we use the power formula. Remember that when the voltage drops to .707, the current also drops to .707, and therefore the power drops to .5. Thus, using the formula:

$$db = 10 \log \frac{P_1}{P_2}$$

and substituting 1 for P_1 and .5 for P_2 we get:

$$db = 10 \log \frac{1}{.5}$$

and since 1 ÷ .5 = 2, we have:

$$db = 10 \log 2$$

The log of 2 is .301, and 10 times this is 3.01, or for all practical purposes, 3 db. Thus, whether we use the power formula or the voltage formula we get the same change in db.

Manufacturers frequently use decibels to express the change in power output over a given frequency range in a power amplifier or the change in voltage output in a voltage amplifier. For example, in describing a voltage amplifier, the manufacturer might say that the voltage gain of the amplifier is flat within 3 db from 10 Hertz to 3 megahertz. This means that the voltage gain of the amplifier does not vary by more than 3 db above or below the middle-frequency gain of the amplifier between the frequencies of 10 Hertz and 3 MHz. You know that 3 db represents a voltage change of .707, or in other words, the gain of the amplifier will not vary more than 29.3% (100% - 70.7%) from what it is at the middle frequencies. The gain will be at least 70.7% of the middle-frequency gain within the frequency range of from 10 Hz to 3 MHz.

The manufacturer of a certain power amplifier might claim that the power output from the amplifier is flat within a certain number of db from 50 Hertz to 1000 Hertz. This means that the power output between these frequency limits is within the specified number of db of the specified power output.

One of the advantages of using the decibel in comparing power ratios is that it gives a pretty good picture of how the amplifier will sound. For example, if you have a 5-watt amplifier that is capable of putting out 5 watts of audio power in the middle-frequency range, but only 1 watt at a frequency of 100 Hertz, you would have a power ratio of 5 to 1. This represents a change of 7 db, which would be very noticeable, even though the actual difference in power output is only 4 watts. On the other hand, if you had an amplifier capable of putting out 100 watts of audio power at the middle frequencies, and dropped to 50 watts at 100 Hz, although the change in power is actually 50 watts, the power ratio is 2 and the db change only 3 db. This is a smaller change in db than the change from 5 watts to 1 watt. This is as it should be, because you would notice a greater change in going from 5 watts to 1

Voltage Ratio	DB	Power Ratio	DB
1	0	1	0
2	6.0	2	3.0
3	9.6	3	4.8
4	12.0	4	6.0
5	14.0	5	7.0
6	15.6	6	7.8
7	16.8	7	8.4
8	18.0	8	9.0
9	19.2	9	9.6
10	20.0	10	10.0
20	26.0	20	13.0

90	39.0	90	19.6
100	40.0	100	20.0
1,000	60.0	1,000	30.0
10,000	80.0	10,000	40.0

Fig. 2. Decibel values corresponding to voltage and power ratios.

watt than you would in going from 100 watts to 50 watts.

The chart shown in Fig. 2 is a table of decibel values corresponding to voltage and power gains. This would give you an idea of what the voltage ratio or the power ratio is for certain db values.

The decibel is an important unit in the electronic field. You should be familiar with what it is and how it is used. If you plan on doing radio and TV service work you do not have to be able to calculate either voltage gain or power ratios in decibels. However, you should realize what the decibel is, and become familiar with its use. As a technician you will run into it time and time again. Manufacturers frequently use it in describing the performance of electronic equipment. You'll be called on to interpret the meaning of characteristics of this type. Also an understanding of what a decibel is and how it is used will help you in evaluating the performance of certain types of electronic equipment. By comparing an amplifier with the manufacturer's specifications, you can decide whether or not the amplifier is performing as well as it is supposed to be able to.

If you intend to go into communications or into industry as an electronics technician you should be able to calculate both voltage gain and power ratios in decibels. The Self-Test Questions that follow will give you an opportunity to try to perform these calculations; you can check your answers with those given.

SELF-TEST QUESTIONS

(a) What is a common logarithm?

(b) What is the part of the logarithm to the left of the decimal point called?

(c) What is the part of the logarithm to the right of the decimal point called?

(d) What is the characteristic of numbers from 100 to 999?

(e) Write the logarithm of 7.

(f) Write the logarithm of 700.

(g) Write the logarithm of 41.7.

(h) What is the bel?

(i) What is the decibel?

(j) If the power output of an amplifier changes from 222 watts to 37 watts, how many db does this change represent?

(k) If a defect develops in an amplifier and the output voltage drops from 150 volts to 75 volts, what change in decibels does this represent?

Extending the High-Frequency Response of an Amplifier

A schematic diagram of a typical two-stage R-C coupled amplifier using vacuum tubes is shown in Fig. 3. The first stage, V_1, uses a triode tube, and the second stage, V_2, uses a pentode tube. In your study of low-frequency amplifiers, you learned that the high-frequency response of an R-C coupled amplifier is limited by shunt capacities in the circuit. You will remember that the first tube, V_1, has a certain capacity between the plate and cathode of the tube. This capacity in effect is in parallel with the plate load resistor R_3. You will remember that as far as the signal is concerned, R_3 is connected between the plate of the tube and ground. The end of R_3 that connects to the positive side of the power supply is at signal ground potential because the output filter capacitor in the power supply will be so large that at signal frequencies it acts like a short circuit. The cathode of the tube is adequately bypassed by the bypass capacitor C_1 so that the plate-to-cathode capacity of V_1 is in effect connected directly between the plate of the tube and ground, or in parallel with R_3.

There is also another capacity that must be considered in the input circuit of V_2. This capacity is the grid-to-cathode capacity of the tube. This capacity will depend upon the tube structure and also upon the gain of the stage. At high frequencies, the coupling capacitor C_2 has such a low reactance that it can be ignored so that in effect the output capacity of V_1 is connected directly in parallel with the input capacity of V_2.

In addition to the capacities in the tubes V_1 and V_2, there will be a certain amount of stray capacity in the wiring. For example, the coupling capacitor C_2 will have a certain capacity to ground, the lead connecting C_2 to V_1 and V_2 will also have a certain capacity to ground. All this capacity is added to the capacity in the output circuit of V_1 and the capacity

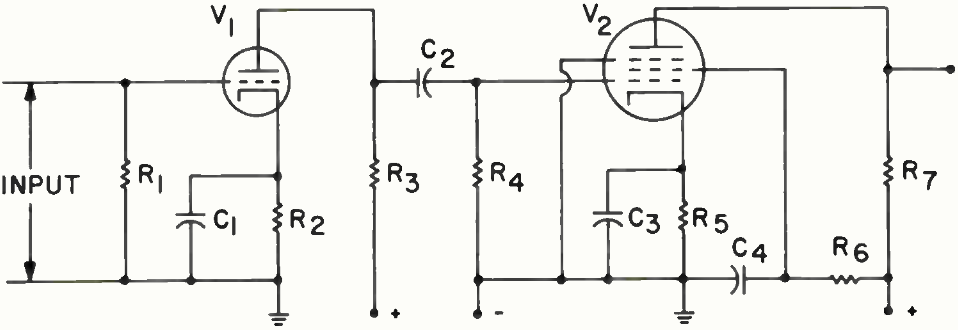

Fig. 3. An R-C coupled amplifier.

in the input circuit of V_2, and tends to limit the high-frequency response of the amplifier.

EFFECT OF SHUNT CAPACITY

In Fig. 4 we have shown the equivalent circuits of the coupling network used between V_1 and V_2 at middle frequencies and at high frequencies. The circuit in A is the equivalent circuit of the coupling network at middle frequencies. The resistor $R_{3\text{-}4}$ represents the resistance of R_3 and R_4 in parallel. As far as the signal is concerned, they are in parallel because the reactance of C_2 is so low that the capacitor acts like a short circuit. The parallel combination of R_3 and R_4 will be almost equal to the resistance of R_3 because R_4, which is the grid resistor of V_2, is many times larger than the plate resistor R_3. Therefore as far as the load in the plate circuit of V_1 is concerned, it is almost entirely controlled by the value of R_3. R_3 will usually have a resistance somewhere between 10,000 and 100,000 ohms. R_4, on the other hand, will be considerably larger than this, usually between .25 and a .5 megohm. The value of R_4 is limited by the type of tube used for V_2. Some tubes will develop a negative bias due to electrons accidentally striking the grid if too large a resistance is used in the grid circuit. Other tubes may have a small amount of gas present inside of the tube; these tubes will develop a positive voltage on the grid if too large a grid resistor is used. However, in any case, even though R_4 is in parallel with R_3 at middle audio frequencies, it has very little effect insofar as reducing the plate load is concerned because its resistance is usually considerably greater than that of R_3.

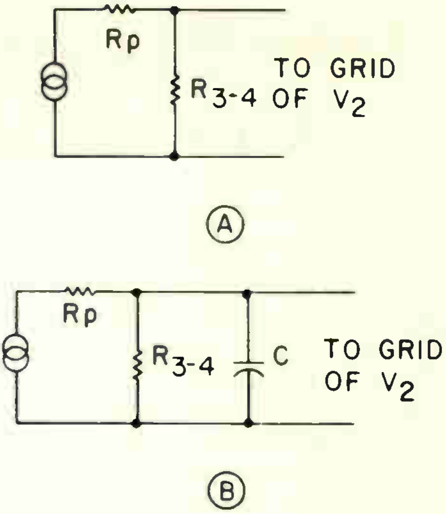

Fig. 4. Equivalent circuits of coupling networks between V_1 and V_2. "A" shows the equivalent circuit at middle frequencies and "B" the equivalent circuit at high frequencies.

In Fig. 4B we have shown the equivalent circuit of the coupling network at high frequencies. The capacity C is used to represent the sum of the output capacity of V_1, the input capacity of V_2, and the distributed capacities in the circuit. Notice that C is connected directly across $R_{3\text{-}4}$.

As the frequency of the signal amplified by the amplifier increases, the capacitive reactance of C decreases. You will remember that the capacitive reactance of the capacitor is given by the formula:

$$X_C = \frac{1}{6.28 \times f \times C}$$

From the formula you can see that if either f or C increases, the value of the capacitive reactance will decrease.

At some frequency the capacitive reactance of C will be equal to the resistance of the parallel combination of $R_{3\text{-}4}$. You will remember that we pointed out previously that when this happens the signal reaching the grid of V_2 will actually be 70.7% of the signal reaching the grid of V_2 at middle audio frequencies. You will remember we called this the half-power point; this is the point at which the signal reaching the grid of V_2 is 3 db lower than the signal reaching the grid of V_2 at middle audio frequencies. Now let us see the steps we can take to increase the frequency at which the signal reaching the grid of V_2 drops 3 db.

REDUCING THE SHUNTING EFFECT

In a practical amplifier that is to be designed to amplify signals of widely different frequencies, we try to keep the response of the amplifier as flat as possible over the required frequency range. This means that we try to design the amplifier so that it will give all the signal frequencies it must amplify the same amount of amplification. If all the signal frequencies receive the same amount of amplification, we say that the amplifier is flat over the range of frequencies it must amplify. However, in actual practice it is impossible to get an amplifier that is exactly flat over a very wide frequency range, so we generally have to be satisfied with an amplifier whose gain is flat within a few db over the frequency range for which the amplifier is designed.

To give a practical example of how the high-frequency response of an amplifier can be extended, let us see what we can do to extend the frequency response of an amplifier like the one shown in Fig. 3. Suppose that we want to be able to amplify signals up to 200 KHz so that the gain of the amplifier at 200 KHz is within 3 db of the gain at the middle frequency. If in checking the amplifier we find that the gain drops 3 db at 100 KHz, we can extend the frequency response of the amplifier by reducing the size of the plate load resistor R_3.

If the gain drops 3 db at 100 KHz, this means that the capacitive reactance of the shunt capacity across the parallel combination of R_3 and R_4 must be equal to the value of the parallel resistors at a frequency of 100 KHz. You will remember that R_4 is much larger than R_3. Therefore, the value of the combination will be almost equal to the value of R_3 alone. If we cut the value of R_3 in half, we will in effect be cutting the value of R_3 and R_4 in parallel, in half. Then the reactance of the capacitance will be equal to $R_{3\text{-}4}$ at twice the original frequency of 100 KHz. Therefore by simply reducing the plate resistor R_3 in the plate circuit of V_1, we can extend the gain of the amplifier at high frequencies. Of course, what we are actually doing is reducing the gain of the amplifier at the low and middle frequencies in order to flatten the response of the amplifier over a wider frequency range. In spite of the fact that this might seem to be somewhat of a disadvantage, it is the method most widely used to extend the high-frequency response of an amplifier. If in reducing the amplifier gain by reducing the plate load resistance, we find that we do not have sufficient gain in the amplifier, then we can overcome this difficulty simply by adding an additional stage.

In video amplifiers found in television receivers, where the frequency response must be reasonably flat up to a frequency of several megahertz, the plate load resistor R_3 may have a resistance of only a few thousand ohms. This makes it possible to obtain a reasonably flat gain over a wide frequency range. Suppose for example, that the value of R_3 is 94,000 ohms and that the gain of the amplifier drops 3 db at 100 KHz. By reducing the size of R_3 to 47,000 ohms, we can extend the 3 db down point to 200 KHz. If we reduce the value of R_3 to 4,700 ohms, then we can extend the 3 db down point to 2 MHz. Of course, the gain of the amplifier will be much lower at low and middle frequencies with a 4700-ohm resistor in the plate circuit of V_1 than it will be with a 47,000-ohm or a 94,000-ohm resistor in the plate circuit. But the gain will be essentially flat from a very low frequency up to approximately 2 MHz with the 4.7K resistor in the plate circuit. Where a flat response over a wide frequency range is required, reducing the size of the plate load resistor in order to reduce the shunting effect of the shunt capacity is the simplest way of obtaining the wide frequency response. When we use a very small value of plate load resistor, it is so small compared to the resistance of the grid resistor in the following stage, that we can forget the shunting effect of the grid resistor and consider the plate load as equal to the value of the plate load resistor. In the next section dealing with high-frequency compensation we will do this.

In the example we have given, we found that by reducing the size of R_3 to 4700 ohms we can extend the 3 db down point to 2 MHz. However, in some applications we may want to keep the gain essentially flat out to 2 MHz or higher. We cannot reduce the value of R_3 much below 4700 ohms or we'll get very little gain from V_1. Therefore, we have to use another method of extending the high-frequency response of the amplifier. We can do this by high-frequency compensation.

HIGH-FREQUENCY COMPENSATION

A method widely used to improve the response of an amplifier at high frequencies is called compensation. By compensation we mean that we add something to the circuit to compensate for other undesirable effects. As you might guess, since the capacity and capacitive reactance are the causes of difficulty at high frequencies, to counteract this, we add inductance that will introduce inductive reactance into the circuit.

The coils that are added to the circuit to improve the high-frequency response are called peaking coils. They are so-called because they will peak the response at some frequency above the maximum frequency that could be amplified by the amplifier without these coils. There are actually three types of circuits that can be used. There is a circuit known as shunt peaking, one known as series peaking and

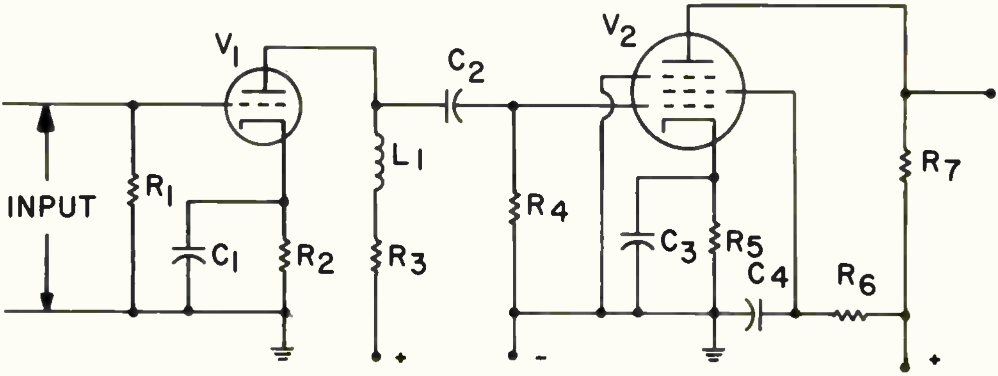

Fig. 5. A wide-band amplifier with shunt-peaking coil.

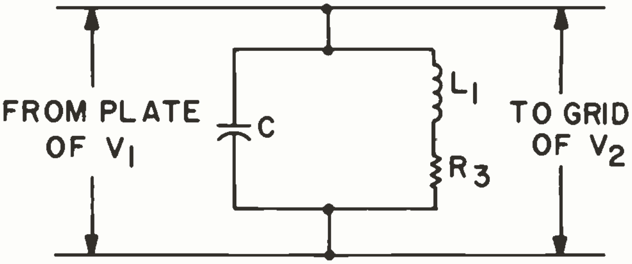

Fig. 6. Equivalent circuit of coupling network between V_1 and V_2.

one that is a combination of shunt and series peaking. The combination of shunt and series peaking is most widely used, but because shunt peaking and series peaking alone are somewhat simpler to understand than the combination, we will look at these two types of peaking-circuits first.

Shunt Peaking. Fig. 5 is a schematic diagram showing how shunt peaking can be added to the R-C coupled amplifier circuit shown in Fig. 3. Notice that the two circuits are identical except that L_1 has been added in series with R_3 in the plate circuit of V_1. The equivalent circuit of the coupling network between V_1 and V_2 with this peaking coil added is shown in Fig. 6.

Notice that in Fig. 6 we see that the peaking coil and load resistor are in parallel with the capacity C which represents the output capacity of V_1, the input capacity of V_2, and the distributed capacity in the circuit. The idea in back of the peaking coil is to select a value of inductance so that a parallel-resonant circuit is formed at a frequency above the frequency at which the gain would drop 3 db without the peaking coil in the circuit. Then, as the frequency of the signal to be amplified approaches the 3 db down point, without the peaking coil, the parallel-resonant circuit begins to take over. You will remember that one of the characteristics of the parallel-resonant circuit is that it acts like a high resistance at resonance. Therefore instead of the load impedance of V_1 dropping because of the shunting effect of the capacity, the load impedance actually begins to increase because of the high resistance of the parallel-resonant circuit. This will cause the gain of the amplifier to increase slightly so that higher frequency signals can be amplified with the same gain as signals at middle frequencies.

At first you might think that the resistance R_3 that is in series with the peaking coil, would lower the Q of the parallel-resonant circuit so that the circuit would not be particularly affected. The resistance does in fact lower the Q of the resonant circuit, but this is desirable. The purpose of L_1 is to keep the gain of the amplifier flat at higher frequencies. R_3 reduces the resistance of the parallel-resonant circuit and tends to keep the load in the plate circuit of V_1 more or less constant. If R_3 does not lower the Q of the resonant circuit sufficiently, then we have a situation where the gain rises as the combination of L_1 and C approach resonance. We'll actually have a peak in the response at resonance, if the coil is not loaded sufficiently, so that the gain in the circuit is much higher at this fre-

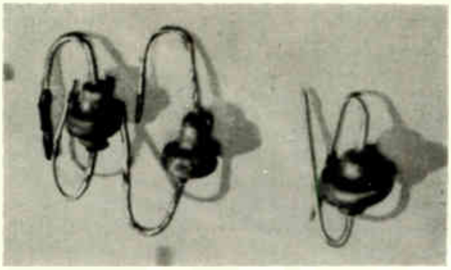

Fig. 7. Peaking coils are wound on ½ watt resistors.

quency than it is at lower frequencies. This is called over compensation, and in most cases it is undesirable. A small amount of over compensation, however, is sometimes used in order to produce some desirable effects. For example, a small amount of over compensation in the video amplifier of a television receiver may tend to make the fine detail in the picture somewhat sharper. However, extensive over compensation will cause ringing where oscillation will occur in the resonant circuit. In a television picture, this would result in fine details being repeated. In other words, if there was a vertical pole appearing in a certain scene, a second or third pole might appear in the picture displaced slightly to the right of the original pole.

Peaking coils are often wound on 1/2 watt resistors If there is not sufficient loading of the resonant circuit to prevent ringing or over peaking, a comparatively low-resistance resistor is used. This provides additional loading on a resonant circuit. Where the circuit already has sufficient loading, the coil can be wound on a dummy form which looks like a 1/2 watt resistor but actually has no electrical connection through it. In some cases, rather than go to the trouble of getting dummy forms on which to wind a coil of this type, manufacturers will simply wind the coil on a very high value resistance. The resistance of the resistor is so high that it has no appreciable loading effect on the circuit. A number of typical peaking coils are shown in Fig. 7.

Series Peaking. Two circuits using series peaking are shown in Fig. 8. The series-peaking coil is labeled L_1 in both circuits. Although L_1 is placed in a slightly different position in the two circuits, the net electrical effect is the same. Coil L_1 isolates the output capacity of V_1 from the input capacity of V_2. At the same time, the value of L_1 is selected so that it will resonate with the input capacity of V_2 at a frequency near or slightly above the frequency at which the gain of the amplifier would drop to 70.7% of the mid-frequency gain without compensation.

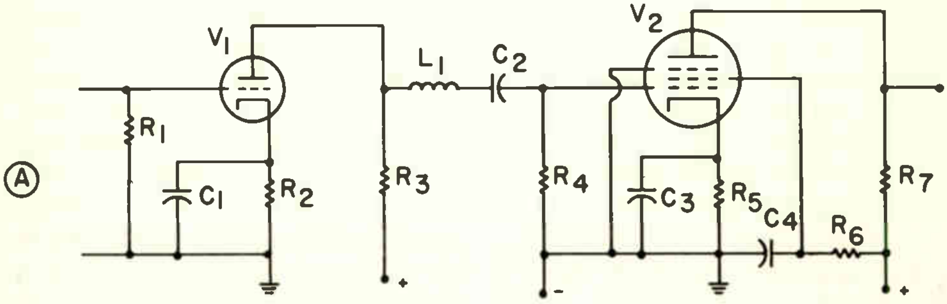

Fig. 8A. Series-peaked wide-band amplifier.

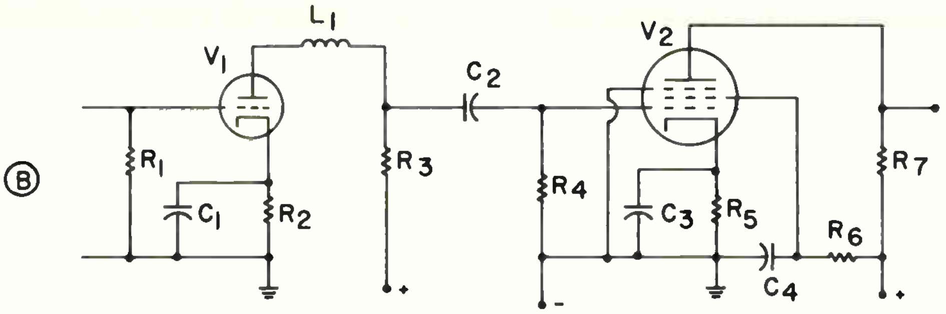

Fig. 8B. Series-peaked wide-band amplifier similar to that shown in Fig. 8A.

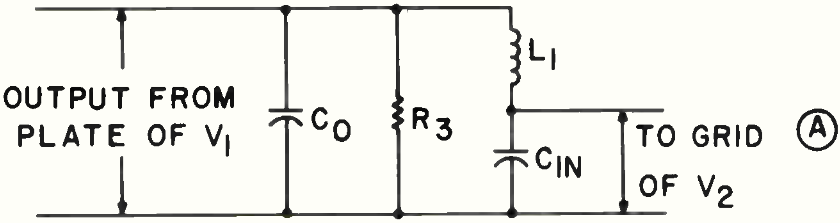
In Fig. 9 we have shown the equivalent circuit of the coupling network. Fig. 9A shows the equivalent of the circuit shown in Fig. 8A. Notice that here we have the capacitor labeled C_O. This represents the output capacity of V_1. This capacity is in parallel with the plate load resistor R_3. Since the output capacity of V_1 represents only a fraction of the total capacity made up of the output capacity, plus the input capacity of V_2, plus the wiring capacity in the amplifier, the gain of the amplifier will not fall off so rapidly. In other words, we have effectively reduced the capacity that is shunting R_3. At the same time, by connecting L_1 into the



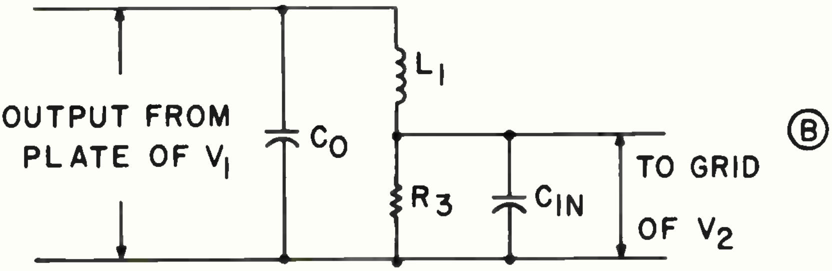


Fig. 9. Equivalent circuits of coupling network in Fig. 8.

circuit (selecting it so that we will resonate it with the input capacity of V_2), we have formed a series-resonant circuit consisting of L_1 and the input capacity of V_2. You know that in a series-resonant circuit there will be a resonant voltage step-up at the resonant frequency. Therefore we will have a resonant voltage step-up across C_{in} at the resonant frequency. This means that although there may be some tendency for the voltage across R_3 to drop at this frequency (because of the shunting effect of the output capacity of V_1), the resonant circuit is able to more than compensate for this drop-off in output from V_1, so that the input voltage of V_2 may actually be higher at high frequencies than the input voltage to V_2 at middle frequencies.

It is usually possible to obtain better peaking with a series-peaking coil than with a shunt-peaking coil. The input capacity of V_2 is usually much larger than the output capacity of V_1, so that splitting the two capacities by means of the peaking coil results in increased output from V_1. At the same time, by using the coil with a high Q, a high resonant voltage step-up can be obtained so that the input signal to V_2 will be substantially boosted. The resistor R_3, which is across the resonant circuit, loads the circuit to prevent over compensation. In some circuits the peaking coil may be loaded by winding it on a resistor to reduce the Q of the circuit still further when the value of the plate load resistor is too high to prevent excessive over compensation. As you will remember, over compensation results in excessive increase in amplification at the high frequency to which the circuit is peaked, and in most cases this is to be avoided.

In Fig. 9B we have shown the equivalent circuit for the circuit shown in Fig. 8B. Here the circuit is somewhat different from the circuit shown at A. In this circuit the load resistor R_3 is across C_{in} at the high frequencies instead of across the entire series circuit. Again at high frequencies the peaking coil L_1 forms a series resonant circuit with the input capacity in the grid circuit of V_2. The resonant voltage step-up in the series circuit tends to compensate for the drop in gain from V_1 due to the reduced size of the plate load.

In servicing amplifiers where peaking coils are used, sometimes you may suspect that a peaking coil is open. If you check across the peaking coil with an ohmmeter, you should get a resistance reading of only a few ohms. If you get a resistance reading of several thousand ohms it indicates that the coil is open and that you are reading through the resistor on which the peaking coil is wound. Usually when a peaking coil is open, it is open right at the end of the coil where the coil is connected to the resistor lead. If you can find the place where the coil connects to the resistor lead, resolder it and if the connection is poor this should clear up the trouble. If on the other hand, it doesn't clear up the trouble, sometimes you can find the wire going from the resistor lead to the coil and see where it is broken. If there isn't enough wire to stretch over to make a connection to the resistor lead, unwinding one turn of the coil will usually enable you to make the connection. Taking a single turn off the coil will not affect its inductance enough to upset its performance in the circuit.

Shunt-Series Peaking. The most satisfactory peaking arrangement is a combination of both shunt and series peaking. You'll find this type of peaking is widely used in the video amplifiers of television

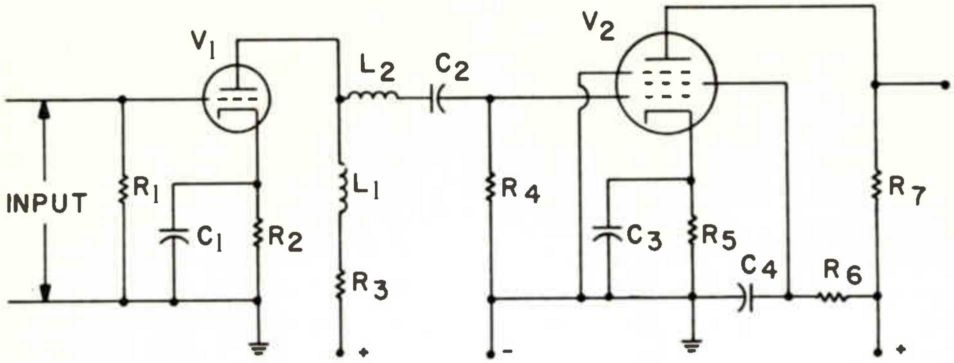

Fig. 10. A shunt-series compensated amplifier.

receivers and in other amplifiers where a wide frequency response is required. The schematic diagram of an amplifier using series-shunt peaking is shown in Fig. 10. This is the same basic amplifier circuit that we started with in Fig. 3, but the shunt-peaking coil, L_1, and the series-peaking coil, L_2, have been added.

An equivalent circuit of the coupling network is shown in Fig. 11. Notice that in the previous case where we used shunt peaking alone, the coil L_1 forms a parallel resonant circuit. However, this time instead of forming a parallel-resonant circuit with the entire capacity in the circuit, it forms a parallel-resonant circuit with the output capacity of V_1. The peaking coil L_2 effectively separates the output capacity of V_1 from the input capacity of V_2. L_2 forms a series-resonant circuit with the input capacity of V_2.

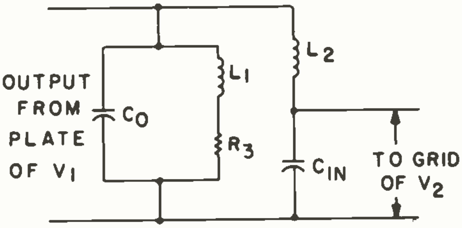

Fig. 11. Equivalent circuit of coupling network in Fig. 10.

By using the series-peaking coil L_2 in this way, we have less capacity in the plate circuit of V_1. This often enables us to increase the size of R_3 which will increase the gain at low and middle frequencies. At the same time, by using the shunt-peaking coil L_1, we can increase the gain of the amplifier at the higher frequencies where it would normally start to fall off. Thus we can maintain a constant output voltage from V_1 over a wider frequency range.

The series-peaking coil, L_2, in addition to separating the output capacity of V_1 from the input capacity of V_2, also forms a series-resonant circuit with the input capacity of V_2. Therefore, as the output signal starts to fall off from V_1, the resonant circuit made up of L_2 and the input capacity of V_2 takes over, and by means of the resonant voltage step-up can keep the signal fed to the grid of V_2 essentially constant.

In circuits using both series and shunt peaking we can select the values of the

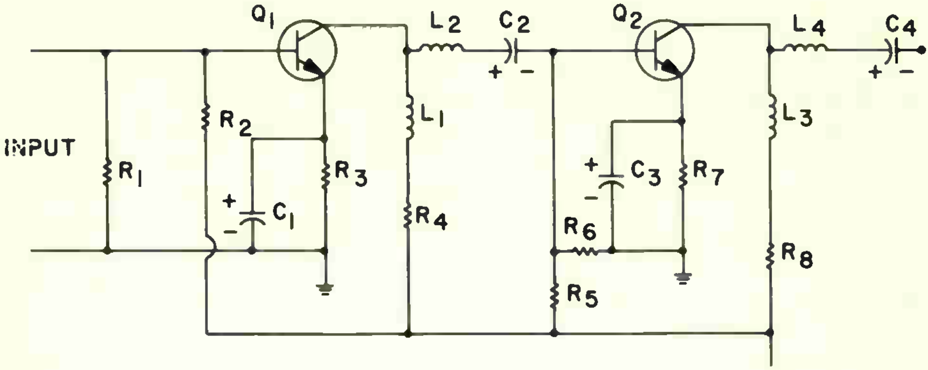

Fig. 12. A series-shunt compensated transistor amplifier.

peaking coils so the resonant circuits resonate at slightly different frequencies. Thus it is possible to make one resonant circuit take over (usually the parallel-resonant circuit) when the gain of the amplifier first starts to fall off. At a frequency above the resonant frequency of the parallel-resonant, the series circuit becomes resonant and compensates for the drop in impedance in the plate circuit of V_1 above the resonant frequency of the shunt-peaking circuit. Thus by using a combination of shunt and series peaking it is usually possible to get more gain from the amplifier over this entire bandwidth because we can use a larger value of load resistor, and also it is easier to extend the high-frequency response of the amplifier and maintain the response essentially flat over a wider frequency range.

TRANSISTOR AMPLIFIERS

So far in our discussion we have been talking about extending the high-frequency response of tube amplifiers. Essentially the same problems exist in transistor amplifiers as exist in tube amplifiers. The output capacity of one transistor, the input capacity of the second transistor, and the stray capacity in the coupling network coupling the two transistors together, limits the high frequency response of the amplifier.

A typical two-stage series-shunt compensated transistor amplifier is shown in Fig. 12. Notice that we have a shunt-peaking coil, L_1, in the collector circuit of Q_1. We have a series-peaking coil connected between the collector of Q_1 and the coupling capacitor C_2. The equivalent circuit of the coupling network used between Q_1 and Q_2 at high frequencies, where the capacity of C_2 can be ignored, is shown in Fig. 13. Notice that we have essentially the same circuit

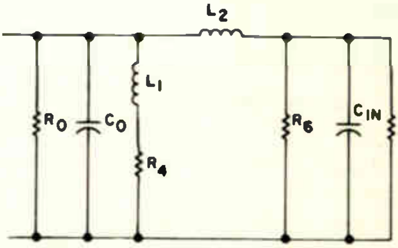

Fig. 13. The high-frequency equivalent of the coupling network used in Fig. 12.

as we had in the series-shunt compensated vacuum-tube coupling circuit except for the resistors R_O and R_{in}. R_O represents the output resistance of Q_1 and R_{in}, the input resistance of Q_2. In the tube circuit, these resistances were so high they could be ignored. However, in transistors, these resistances are low and must be considered.

The peaking coil L_2 separates the output capacity of Q_1 and the associated capacity of the circuit from the input capacity of Q_2 and its associated stray capacity. L_2 is selected to resonate with the capacity in the input circuit of Q_2 and form a series-resonant circuit in order to peak the input to Q_2 at the frequency desired. At the same time, L_1 forms a parallel-resonant circuit in the collector circuit of Q_1 and helps keep the output from Q_1 up at higher frequencies.

We mentioned earlier that the collector load resistor, R_4, is in parallel with the input resistance of Q_2. You will remember from your study of low-frequency voltage amplifiers, that in a transistor circuit Q_2 has a certain base current. This lowers the effective input resistance of the second transistor amplifier, and since this is in effect in parallel with R_4, it has the effect of lowering the value of the collector load resistor in the collector circuit of Q_1. Therefore we already have a comparatively low collector load resistor and there is a limit to how far we can reduce this resistor in order to level out the response of the coupling network over a wide frequency range. You will remember that in the vacuum-tube coupling network we were able to drop the value of the plate load resistor in the first stage and in so doing bring down the low and middle-frequency gain of the amplifier. At the same time, we extended the frequency at which the gain of the amplifier begins to drop off appreciably. Since the collector load resistor is in effect already low, we cannot lower it much further. Fortunately, since the load resistor is low, it takes a higher shunt capacity to have an appreciable effect at high frequencies. Therefore the transistor coupling network tends to give equal response at a higher frequency even without the peaking coils in the circuit than in the case of a vacuum-tube network.

The output of Q_2 may be connected to another amplifier stage, or in a television receiver it might be connected to the picture tube. Additional peaking will be used in the output circuit of this stage in order to keep up the high-frequency response in this circuit. L_3 is a shunt-peaking coil, and L_4 a series-peaking coil as in the network between Q_1 and Q_2.

We run into an additional problem in transistor amplifiers at high frequencies that we do not encounter in vacuum-tube amplifiers. In a common-emitter circuit such as used for Q_1 and Q_2 in Fig. 12, we normally have a 180° phase shift in each stage. You will remember that when the input signal fed to Q_1 drives the base in a positive direction, it increases the forward bias across the emitter-base junction of the NPN transistor. This causes the number of electrons crossing the emitter-base junction to increase and hence the number of electrons reaching the collector will increase. When the number of electrons reaching the collector and flowing through L_1 and R_4 increases, this will cause the voltage drop across R_4 to increase. Therefore the voltage at the collector will swing in a negative direction. Thus with the input signal as shown in Fig. 14A, the collector voltage swings in the opposite direction as shown in Fig. 14B. We say the two signals are 180° out-of-phase.

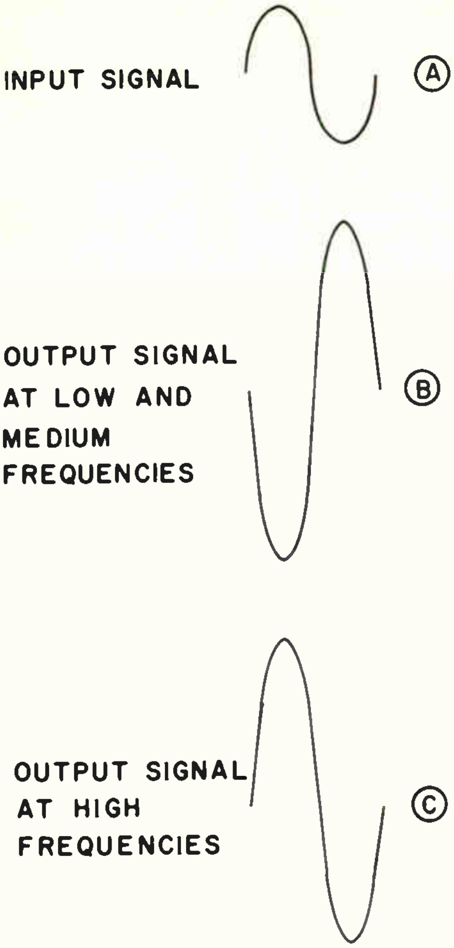

Fig. 14. Phase relationships between input and output signals at low, medium and high frequencies in common emitter amplifiers.

The base of a germanium transistor is usually about one thousandth of an inch thick. The base of a silicon transistor is about one ten-thousandth of an inch thick. It takes the electrons a certain length of time to cross the base of the transistor. It will take the electrons longer to cross the base of the germanium transistor because it is thicker than the silicon transistor. Therefore consider what can happen when the time it takes the electrons to travel through the base is considered. If the signal applied to the base is a low-frequency signal or a medium-frequency signal, the time it takes the electrons to cross the base compared to the time of one cycle is relatively short. The output signal will be 180° out-of-phase with the input signal as shown in A and B of Fig. 14. However, at high frequencies, the electrons may be delayed sufficiently in travelling through the base of the transistor to cause a phase shift between the output signal voltage at medium and low frequencies and the output signal voltage at high frequencies. As a matter of fact, at some high frequency it will take the electrons so long to cross the base that instead of the signals being 180° out-of-phase, they will be in-phase because the electrons are delayed by one half cycle in travelling through the base region. When this happens, the output voltage in the collector circuit of Q_1 will be in-phase with the input voltage applied to the base of Q_1.

You will remember that in a transistor there is a capacity between the collector and the base. A signal is fed from the collector of the transistor back to the base through this capacity. When the output signal is 180° out-of-phase with the input signal, the signal fed back to the base through the collector-base capacity, simply reduces the amplitude of the input signal. This is a form of degeneration; the output from the transistor would not be as high as it would be without this feedback signal. However, at high frequencies where the output signal may be in-phase with the input signal, the signal fed from the collector back to the base will be in-phase with the input signal. This will reinforce the input signal which in turn produces a higher amplitude output signal which in turn builds up the input signal still further. Thus the transistor may go into oscillation and the output signal fed back to the input circuit will take control of the transistor so that it begins producing a high-frequency signal without any input. In circuits where there is a possibility of oscillation occurring, some kind of neutralization must be employed so that a signal that is 180° out-of-phase with the feedback signal, can be fed back into the base circuit to cancel out the signal fed from the collector back to the base through the collector-base capacitance.

FIELD-EFFECT TRANSISTORS

Both the junction-type and the insulated-gate field-effect transistors can be used in wide-band amplifiers. The problems in an amplifier using field-effect transistors are almost identical to those encountered in equipment using vacuum tubes. The output capacity of the first stage plus the input capacity of the second stage along with stray wiring capacity tend to limit the high-frequency response of the amplifier.

A typical two-stage compensated amplifier using junction-type field-effect transistors is shown in Fig. 15. Notice the similarity between this and a vacuum-tube two-stage amplifier.

The peaking coil L_1 in the drain circuit of Q_1 is used to form a parallel-resonant circuit in the drain circuit, to keep the output from Q_1 from falling off at high frequencies. The series-peaking coil L_2 is used to resonate with the input capacity of Q_2 to form a series-resonant circuit to keep up the amplitude of the high-frequency signals fed to the gate of Q_2. In the output circuit of Q_2 we have shown series peaking used between the drain and the following stage.

In many amplifiers using field-effect transistors you will find that series peaking only is used. The one type of peaking is frequently all that is required to obtain the high frequency response required. The value of the resistor R_3, in the drain circuit of Q_1, may be reduced in order to

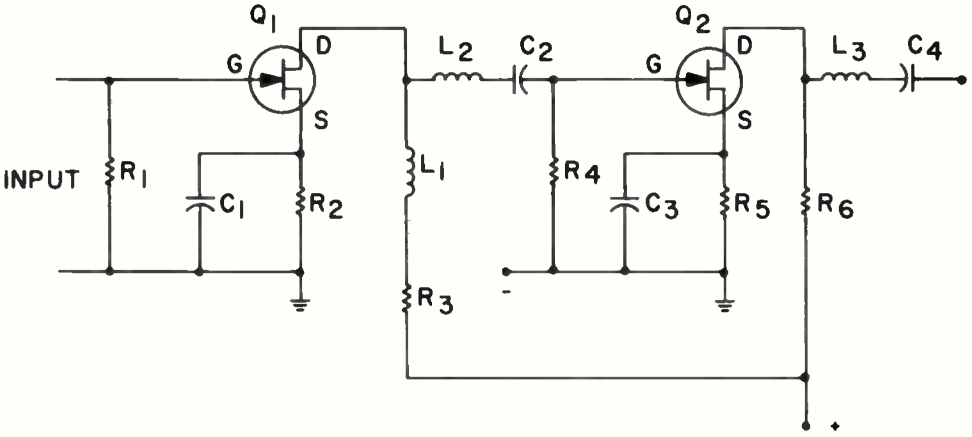

Fig. 15. Compensated amplifier using field-effect transistors.

increase the frequency at which the capacity shunting the output of Q_1 begins to have an appreciable effect on the impedance of the drain circuit of Q_1. You have essentially the same situation as you had with the resistor in the plate circuit of a tube-type amplifier. Reducing the size of the resistor increases the frequency at which the reactance of the output capacitance becomes equal to the resistance of the resistor.

One of the big advantages of the field-effect transistor is that it has a high input resistance. Therefore, the input resistance of Q_2 has little or no loading effect on the output resistance of Q_1. In fact, as far as the performance of the circuit is concerned, it is practically identical to the performance of a two-stage vacuum tube amplifier. Field-effect transistors are able to combine most of the advantages of vacuum tubes along with most of the advantages of transistors and should become increasingly important in the future in electronic equipment.

SELF-TEST QUESTIONS

(l) Why is the value of the plate-load resistor in a wide-band amplifier kept low?

(m) Why is there a limit to the size of grid resistor that can be used in a vacuum-tube amplifier?

(n) How does L_1 in the circuit shown in Fig. 5 help improve the high-frequency response of the amplifier?

(o) How does the peaking coil L_1 in the circuit shown in Fig. 8 help improve the high-frequency response of the amplifier?

(p) What do we mean by series-shunt peaking?

(q) Does capacity shunting have as great an effect on high-frequency response in transistor amplifiers as it does in vacuum-tube amplifiers?

(r) Are there any problems encountered at high frequencies in transistor amplifiers that are not likely to be encountered in vacuum-tube amplifiers?

(s) Are the high-frequency problems encountered in field-effect transistors more like those encountered in vacuum tubes or like those encountered in bipolar transistors?

Extending the Low-Frequency Response of an Amplifier

You will remember that when we studied low-frequency amplifiers we pointed out that the output from an amplifier falls off at low frequencies as well as at high frequencies. The low-frequency response of an amplifier falls off for several reasons. One reason is the reactance of the coupling capacitor used to couple the two stages together increases as the frequency decreases. At some low frequency, the reactance of the capacitor will become so high that it will act like a voltage divider along with the input resistance in the second stage of the amplifier. Thus not all of the amplified signal produced by the first stage is fed to the input of the second stage.

In Fig. 16 we have shown schematic diagrams of three R-C coupled amplifiers. The circuit shown in A is made up of two vacuum tubes, the one at B has two transistors and the one at C has two

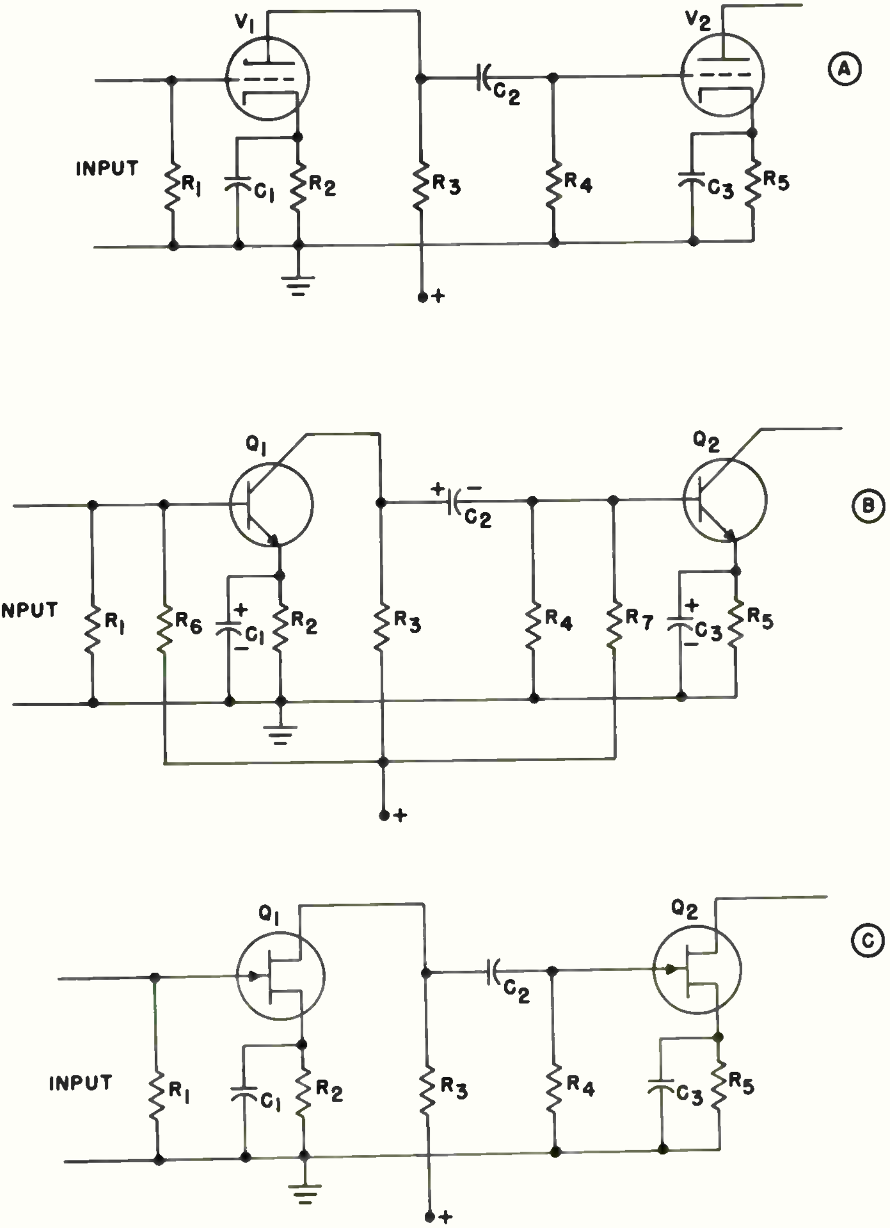

Fig. 16. Basic R-C coupled amplifiers.

field-effect transistors. In each case C_2 is the coupling capacitor between the two stages. The reactance of this capacitor will at some low frequency become equal to the input resistance in the following stage. When this happens, only 70.7% of the voltage developed in the output of the first stage will be fed to the input of the second stage. At lower frequencies, the amount of signal developed by the first stage that reaches the second stage will become increasingly smaller.

In the case of the vacuum-tube amplifier shown in Fig. 16A we can use a large value of grid resistance, R_4, in the input of the second stage. By using as large a resistance as possible in this circuit, we can reduce to a low value the frequency at which the reactance of C_2 becomes equal to the resistance of R_4. In the case of the transistor amplifier shown in Fig. 16B, however, there is not much we can do about increasing the value of the base resistor R_4. The transistor itself draws a certain base current. Thus the transistor itself has a low input resistance. Therefore, this resistance is always in parallel with R_4 and increasing the value of R_4 will have little effect on increasing the actual input resistance of Q_2. We get around the low input resistance of Q_2 by using a high capacity electrolytic capacitor between Q_1 and Q_2 as the coupling capacitor. Since transistors are operated at relatively low voltages we can use a capacitor with quite a high capacity, and still keep the physical size of the capacitor quite small.

In the field-effect transistor circuit shown in Fig. 16C, once again we can increase the value of R_4, the resistance between the gate of Q_2 and the source, to as high a value as possible. Since there is little or no gate current in a field-effect transistor the value of R_4 can be made quite large and increase the input resistance of the second stage. Thus the low-frequency limit of the amplifier can be extended to quite a low value. This is particularly true in the case of the insulated-gate field-effect transistor, since for all practical purposes there is no gate current at all in these transistors.

REDUCING THE EFFECT OF THE COUPLING CAPACITOR

The equivalent circuit of the coupling network used between the two stages in each of the examples shown in Fig. 16 can be redrawn as shown in Fig. 17. In the case of Fig. 16A, using the two vacuum tubes, R_3 is the plate load resistor of V_1, and R_4 is the grid resistor of V_2. In the case of the transistor circuit shown in Fig. 16B, R_3 is the collector resistor of Q_1. R_4 is the resistor connected between the base of Q_2 and ground. In the case of the circuit shown in Fig. 16C where we've used the field-effect transistors, R_3 is the resistor connected between the drain of Q_1 and B+, and R_4 is the resistor connected between the gate of Q_2 and ground.

You can readily see from the circuit shown in Fig. 17 that the output voltage developed at the output of the first stage

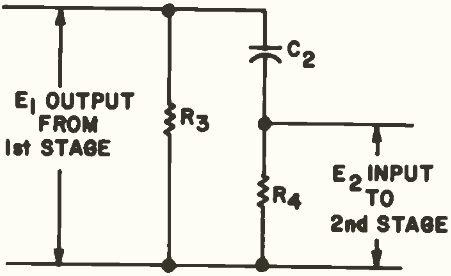

Fig. 17. Equivalent circuit of coupling network at low frequencies.

is fed to the series combination of C_2 and R_4. At high frequencies and middle frequencies, the capacitive reactance of C_2 is so small compared to the resistance of R_4 that practically all of the signal developed at the output of the first stage is fed to the input of the second stage. For all practical purposes, C_2 simply acts like a short circuit.

However, at lower frequencies, the reactance of C_2 begins to become appreciable and it cannot be ignored. At some low frequency, the reactance of C_2 will become equal to the resistance of R_4. Since we have equal capacitive reactance and resistance in this circuit, we will have a current flowing that leads the voltage applied by 45°. Furthermore, since the voltage across C_2 plus the voltage across R_4 must be equal to the voltage across R_3, we have a drop in the voltage across R_4. This means that the voltage applied to the input of the second stage decreases and at the same time we have a phase shift.

The relationship between the output voltage of the first stage which we have labeled E_1, and the input voltage applied to the second stage, which we have labeled E_2, can be seen from the vector diagram of Fig. 18. Notice first, that the voltage E_2 is in-phase with the current I. This is as we might expect because in a resistance, the voltage and current are always in-phase. Therefore the voltage E_2 leads the voltage E_1 by 45°. Notice also that the voltage E_C, which is the voltage across the capacitor, is equal to the voltage E_2. The vector sum of the voltage E_2 and E_C will be equal to the voltage of E_1.

Not only is the drop in voltage across R_4 important, because this will reduce the amplitude of low-frequency signals, but in many applications, the phase shift is just as big a problem. This is particularly true in video amplifiers in television receivers. They must be able to handle very low-frequency signals without any attenuation or phase shift. A phase shift will displace the video information in part of the picture and cause smearing. Therefore it is desirable to keep the drop in low-frequency response and the phase shift as low as possible.

Obviously one of the simplest ways of preventing problems of low frequencies is to use a large value of coupling capacitor. We do this when we design an amplifier to have good low-frequency response. However, in most cases, where you are interested in the low-frequency response of an amplifier, you are also interested in the high-frequency response. Large capacitors also have a higher capacity to ground. Thus there is a limit to how large a coupling capacitor you can use to improve the low-frequency response with-

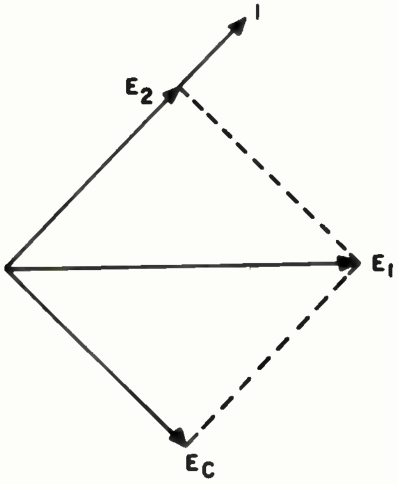

Fig. 18. Vector diagram of voltages at output of first stage and input of second stage.

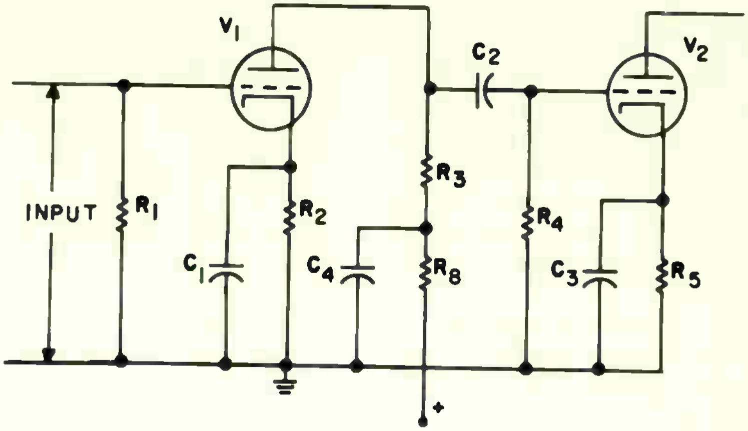

Fig. 19. A two stage amplifier with low-frequency compensation in the plate circuit of V_1.

out running into problems with the high-frequency response. Therefore while we can improve the low-frequency response, to some extent, by using a large coupling capacitor, there is a limit as to how far we can go.

LOW-FREQUENCY COMPENSATION

Regardless of how large a coupling capacitor and of how large a resistance we are able to put into the input of the second stage, the reactance of the capacitor will still increase as the frequency decreases. In some amplifiers where we must amplify very low frequencies of only a few Hertz, with essentially the same gain that we have in the middle-frequency range, we usually have to add something to the circuit to compensate for the fact that the coupling capacitor reactance becomes appreciable at these low frequencies.

In Fig. 19 we have shown how an additional resistor and capacitor can be added in the plate circuit of V_1 in the amplifier shown in Fig. 16A, to compensate for an increase in the reactance of C_2 at low frequencies. In this circuit, the low-frequency compensating network that has been added consists of R_8 and C_4. Let's see how the addition of these two components can improve the gain of the amplifier at low frequencies.

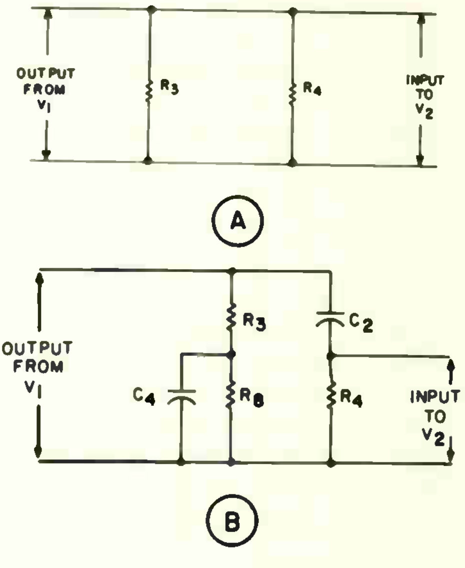

Fig. 20. Equivalent circuit of low-frequency compensation network. "A" is for middle and high frequencies. "B" is for low frequencies.

In Fig. 20A we have shown the equivalent circuit of the coupling network between V_1 and V_2 and the low frequency compensation network at middle and high frequencies. Notice that we have omitted C_2 because in the middle-frequency range, the reactance of C_2 is so low that it can be ignored. Also the value of C_4 is selected so that in the middle and higher frequencies its reactance is very low. It is so low that the end of R_3 that connects to the junction of C_4 and R_8 is in effect connected to ground through C_4. This places R_3 and R_4 directly in parallel. The parallel resistances of these two resistors is the plate load of V_1.

As we pointed out previously, in most amplifiers where we are interested in good low-frequency response we are also interested in good high-frequency response. You will remember that we are going to use a low value plate-load resistor in order to improve the high-frequency response. Therefore, R_3 in Fig. 19 will be a low value resistor. Since at the middle frequencies, R_3 is in effect in parallel with R_4, and R_4 will be many times the value of R_3, the plate load is in effect R_3 alone. For all practical purposes we could omit R_4 in the equivalent circuit shown in Fig. 20A.

At low frequencies, the reactance of C_2 becomes appreciable and it cannot be ignored. At the same time, the reactance of C_4 also becomes appreciable so that it no longer effectively grounds the one end of R_3. Therefore, the plate load for V_1 becomes the combination of R_3 in-series with the parallel combination of R_8 and C_4. In other words, the plate load resistance of V_1 increases. When the plate load of the tube increases, the voltage developed in the plate circuit will increase and this compensates for the loss in voltage across the coupling capacitor C_2.

Not only does the compensating network compensate for the drop in voltage fed to the input of the second stage, but it also improves on the phase shift that occurs at low frequencies. Let's consider how this can happen.

Going back to the equivalent circuit shown in Fig. 20A, remember that the signal current from the vacuum tube develops the voltage across R_3, in other words, across the plate load resistance. This voltage in turn causes a current to flow across the coupling capacitor C_2 and the grid resistor R_4 developing a voltage across R_4. Now consider what happens in the equivalent shown in Fig. 20B. The signal current from the tube flows through the plate load consisting of R_3 in series with the parallel combination of R_8 and C_4. Since the circuit is a capacitive circuit, the voltage developed across this circuit will lag the current. Thus we have a low frequency signal voltage in the plate circuit of V_1 that is lagging the signal current. This lagging signal voltage causes a current to flow through C_2 and R_4. Since the circuit consisting of C_2 and R_4 is capacitive, the current flowing will lead the voltage. By the proper selection of C_4 and R_8 we can cause the phase shift in this network to equal or compensate for the phase shift in the network consisting of C_2 and R_4. Therefore the current flowing through C_2 and R_4 will be in-phase with the signal current supplied by the tube. This means that the signal voltage developed across R_4 will then be in-phase with the signal current supplied by the tube at low frequencies. Since it is already in-phase with the signal current at middle and high frequencies we have compensated for the low-frequency phase shift.

Low-frequency compensation can also be used in circuits where transistors or

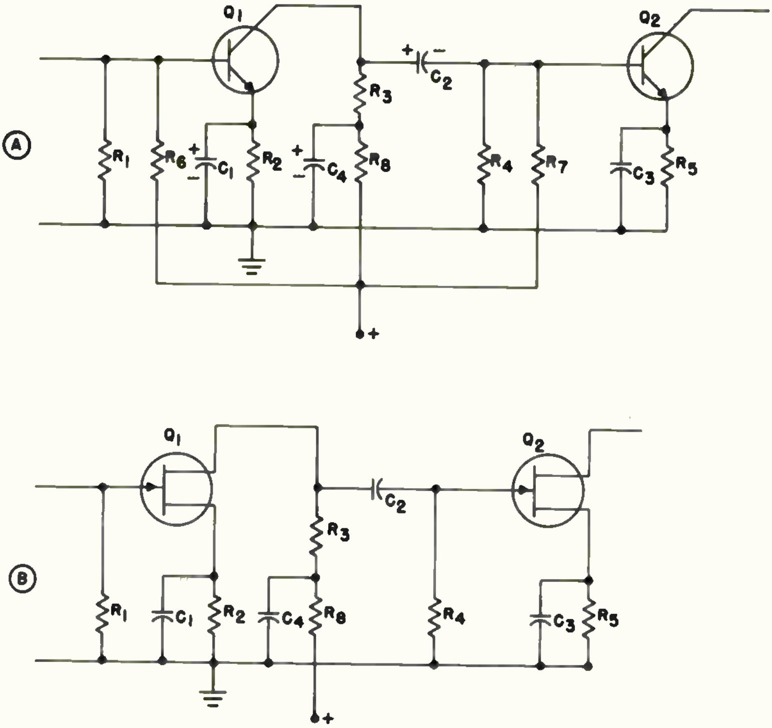

Fig. 21. Low-frequency compensation is shown in a transistor amplifier at A, and in a field-effect transistor amplifier in B.

field-effect transistors have been employed. In the circuit shown in Fig. 21A, we have shown low-frequency compensation in the collector circuit of Q_1. Notice that once again we have added the resistor R_8 in series with the collector-load resistor R_3 and the additional capacitor C_4 in the collector circuit. Low-frequency compensation is not as effective in transistor amplifiers as in vacuum-tube amplifiers.

In the diagram shown in Fig. 21B, we have added low-frequency compensation to the amplifier using field-effect transistors. The additional resistor R_8 is added in the drain circuit of Q_1 along with the additional capacitor C_4. The operation of these low-frequency compensating circuits is exactly the same as in the case of the low-frequency compensating circuit in the vacuum-tube amplifier and is equally effective.

LOW-FREQUENCY DEGENERATION

Going back to the amplifiers shown in Fig. 16, in addition to the coupling capacitor C_2, the bypass capacitors C_1 and C_3 may cause a drop in the low-frequency response. Considering first the vacuum-tube amplifier shown in Fig. 16A, C_1 is the cathode bypass for V_1. The purpose is to maintain the cathode voltage on V_1 constant. At medium and high-frequencies it acts as a bypass capacitor so that the signal current in effect flows through it and R_2 is effectively bypassed. Therefore the voltage across R_2 remains constant. However, at low frequencies, the reactance of C_1 increases. As a result, part of the signal current flows through R_2. This causes a signal voltage to appear at the cathode that is in-phase with the voltage applied to the grid of the tube. This reduces the grid-to-cathode signal voltage so that the output from the stage goes down. This effect can be kept at a minimum by using a large capacitor, usually an electrolytic capacitor, to provide effective bypassing at low frequencies. Another method of eliminating this problem is to eliminate the bypass capacitor altogether. This will reduce the gain of the stage at medium frequencies as well as high frequencies, but the degenerative effect of the unbypassed cathode is constant at all frequencies. Thus the gain of the stage is reduced an equal amount at all frequencies rather than at low frequencies only.

Exactly the same situation exists in the case of the emitter bypass capacitor C_1 in the transistor amplifier circuit shown in Fig. 16B, and the source bypass capacitor C_1 in the field-effect transistor circuit shown in Fig. 16C. These capacitors become degenerative at low frequencies and will reduce the low-frequency response of the stage. By using large electrolytic capacitors the effect can be kept at a minimum so that the response of the amplifier may be satisfactory down to a frequency of only a very few cycles per second. Also the bypass capacitor may be omitted, as in the case of the tube amplifier, introducing a degenerative effect at all frequencies so as to level off the response of the amplifier.

SELF-TEST QUESTIONS

(t) What part is the primary cause of poor low-frequency response in a two-stage amplifier?

(u) In addition to a drop in gain at low frequencies, what other problem is frequently encountered?

(v) What method is used to improve the low-frequency response of amplifiers?

(w) Is low-frequency compensation equally effective in vacuum-tube and transistor-amplifier circuits?

(x) Is low-frequency compensation effective in improving the low-frequency response in an amplifier using field-effect transistors?

(y) What do we mean by cathode degeneration?

Typical Wide-Band Amplifiers

In this section of the lesson we will look at a few typical wide-band amplifiers such as you might encounter in electronic equipment. We will also discuss printed circuit wiring since the trend today in modern electronic equipment is to use printed circuit wiring. This type of wiring is particularly advantageous in wide-band amplifiers because the stray capacities in the circuit can be kept constant from one amplifier to another, and therefore it is quite easy to manufacture amplifiers with almost identical characteristics.

In transistorized equipment, as we mentioned previously, it is not quite as easy to compensate for high-frequency losses as it is in vacuum-tube amplifiers. Therefore we will look at some circuits found only in transistorized equipment that get around some of these disadvantages.

In the preceding section of the lesson we discussed low-frequency compensation. As you will remember, low-frequency compensation is needed primarily because the reactance of the coupling capacitor between stages increases as the frequency goes down. This problem can be overcome by the use of direct coupling; in this type of coupling, the capacitor is omitted entirely and hence any problems created by it are avoided. We will look at direct-coupled amplifiers so you will be familiar with this type of circuit.

There is no doubt that television receivers make more use of wide-band amplifiers than any other electronic equipment. This is simply due to the fact that there are so many television receivers manufactured every year. Therefore we'll start our study of typical wide-band amplifiers with a look at a typical video amplifier which is a wide-band amplifier.

A TYPICAL VIDEO AMPLIFIER

In Fig. 22 we have shown the sche-

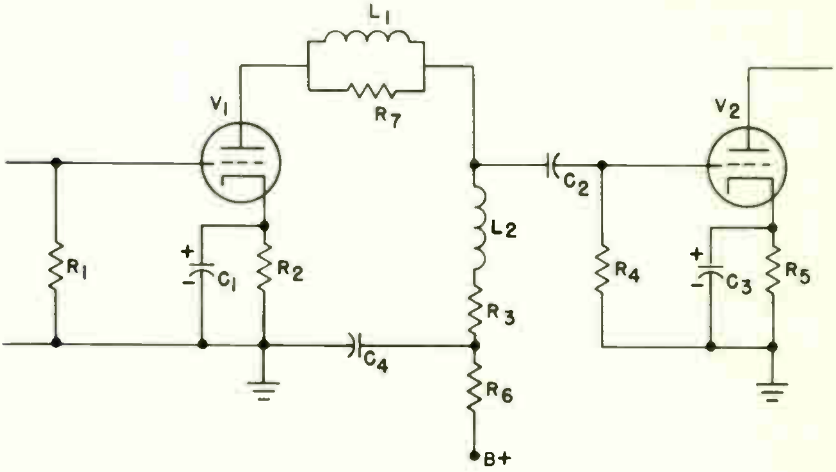

Fig. 22. A typical wide-band amplifier.

matic diagram of a typical wide-band amplifier such as might be used for video amplification in a television receiver. Notice that to improve the high-frequency response of the amplifier both series and shunt peaking have been used. Notice that across the series-peaking coil L_1, we have a shunt resistor. This is to reduce the Q of the coil and prevent oscillation, and at the same time broaden the response of the series-resonant circuit.

L_2 is a shunt-peaking coil and is used to form a parallel-resonant circuit to increase the value of the plate load at high frequencies.

Low-frequency compensation is provided by C_4 and R_6 connected in the plate circuit of V_1. This is similar to the low-frequency compensating network shown earlier. We have shown electrolytic capacitors in the cathode circuits of both stages as the cathode bypass capacitors. You can tell from the schematic when an electrolytic capacitor is used because the polarity of the capacitor is usually indicated. Notice that the polarity signs indicate that the positive side of the capacitor is connected to the cathode of the tube and the other side to ground. Electrons flow from ground through the cathode resistor to the cathode of the tube, and in so doing develop a voltage across the bias resistor having a polarity such that the cathode end is positive. The electrolytic capacitors must be connected with this polarity.

In some wide-band amplifiers, electrolytic cathode bypass capacitors may be shunted by small paper capacitors or ceramic capacitors. You might find a bypass cathode capacitor with a capacity of about 100 mfd shunted by a .001 mfd ceramic capacitor. This is often done because electrolytic capacitors are sometimes rather poor bypass capacitors at high frequencies. Therefore at low frequencies the electrolytic capacitor acts as the bypass capacitor, but at high frequencies where the electrolytic becomes a rather inefficient bypass, the ceramic capacitor has a low enough reactance to bypass the cathode resistor effectively.

TRANSISTOR WIDE-BAND AMPLIFIERS

A transistor video amplifier using PNP transistors is shown in Fig. 23. L_1 is the

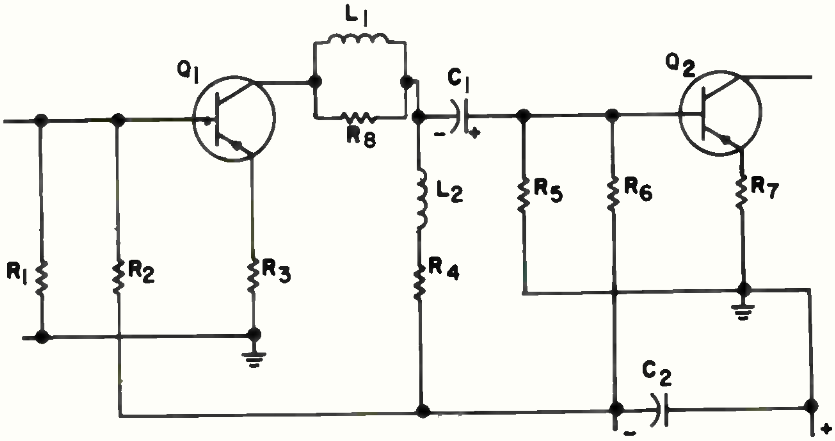

Fig. 23. A transistor wide-band amplifier.

series-peaking coil, and it is loaded by R_8 to reduce the Q of the coil and broaden the response of the circuit. L_2 is the shunt-peaking coil.

The coupling capacitor C_1 is an electrolytic capacitor; a large value of capacitor is used to provide the required low-frequency response. Notice that the emitter resistors R_3 and R_7 are not bypassed. In order to prevent low-frequency degeneration due to the reactance of bypass capacitors across the emitter resistors, the capacitors are simply omitted. As we mentioned previously this introduces degeneration at all frequencies but tends to flatten the gain of the amplifier.

Feedback Circuits. Transistor amplifiers do not lend themselves to improving frequency response by means of peaking coils nearly as well as do vacuum-tube amplifiers. The same is true of improving the low-frequency response; increasing the size of the base resistor of the second stage in a transistor amplifier actually has little effect on the input resistance of the stage. The base current of the transistor primarily determines the input resistance.

In the case of the equivalent coupling circuit for the low-frequency response shown in Fig. 17, in a transistor amplifier R_3 and R_4 are actually shunted by other resistors that should be considered. R_3 is shunted by a resistance which is the output resistance of Q_1, and R_4 is shunted by a resistance which is the input resistance of Q_2. The output resistance of a transistor in a common-emitter circuit is probably around 20,000 ohms whereas the input resistance of a common-emitter circuit is quite low, usually in the vicinity of a few hundred ohms at the most.

The frequency response of transistor amplifiers can frequently be improved by means of feedback circuits. Feedback, of course, must be degenerative feedback and it operates on the principle that as the output signal from the amplifier increases, the amount of feedback must increase. This in turn will tend to reduce the overall gain of the amplifier more at a frequency where the output is higher than it would at another frequency where the output signal is low, and hence the feedback signal is low.

In Fig. 24 we have shown the sche-

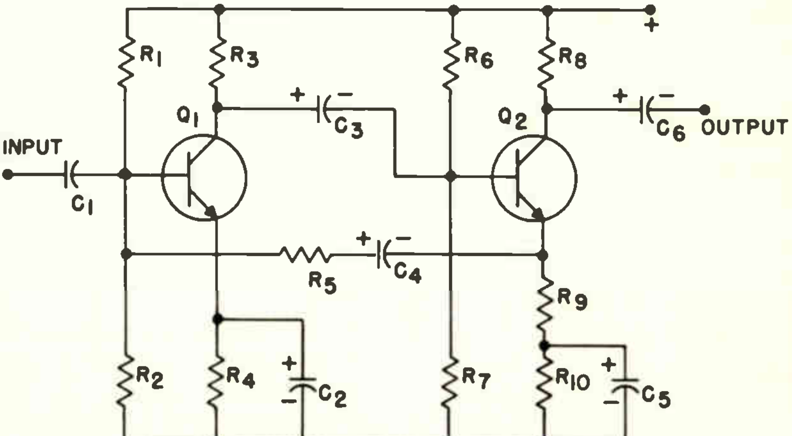

Fig. 24. Improving the frequency response by means of feedback.

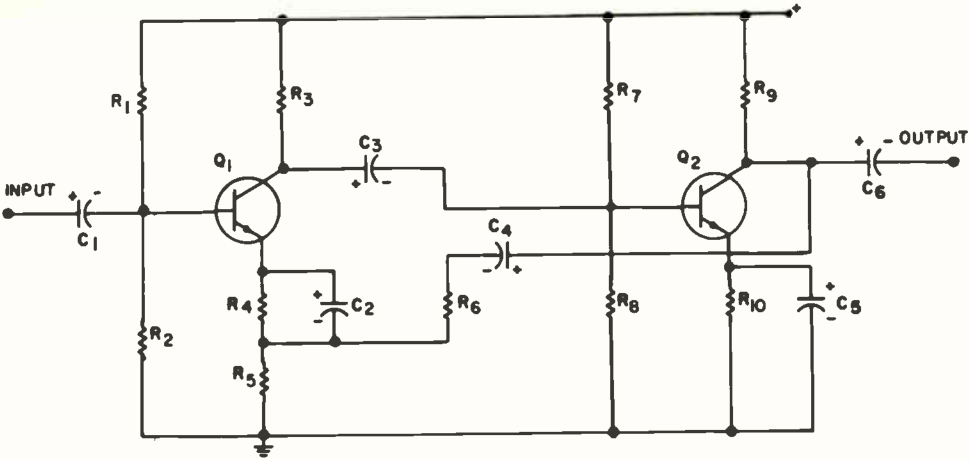

Fig. 25. A second feedback circuit.

matic diagram of a circuit that could be used to improve the frequency response of a two-stage transistor amplifier. The circuit is quite similar to the transistor amplifier shown previously except that the feedback network consists of C_4 and R_5. This provides negative feedback back from the emitter of Q_2 back to the base of Q_1.

Consider what happens as a signal passes through the amplifier. When the signal applied to the base of Q_1 swings in a positive direction, the forward bias across the emitter-base junction of Q_1 will be increased. This will cause the current through the transistor to increase and hence the voltage drop across R_3 will increase. As the voltage drop across R_3 increases, the signal voltage at the collector of Q_1 will swing in a negative direction. Thus for a positive input signal we have an amplified negative signal in the output of Q_1.

The negative signal from Q_1 is fed to the base of Q_2 through the coupling capacitor C_3. The negative-going signal reduces the forward bias across the emitter-base junction of Q_2. Thus the current flowing through Q_2 decreases. When this happens the voltage drop across the emitter resistor R_9 will decrease. The voltage across R_{10} is held essentially constant by C_5. The decrease in signal voltage across R_9 is actually a negative signal. This negative signal is fed through C_4 and R_5 back into the base of Q_1 and subtracts from the original positive signal.

In this circuit, as the gain tends to rise at middle frequencies, the amount of signal fed back from the emitter of Q_2 to the base of Q_1 increases thus tending to reduce the overall gain of the amplifier. On the other hand, if the signal starts to fall off at the high frequencies or at the low frequencies, any amount of feedback will also go down so that the overall gain of the two-stage amplifier will tend to increase.

Another example of feedback which is used to improve the frequency response of a transistor is shown in Fig. 25. Here the signal feedback is taken from the collector of the second transistor Q_2 and fed through a resistor-capacitor network back into the emitter of the first transistor Q_1. To see how this feedback circuit works, let's follow the signal phases through the amplifier.

When a signal drives the base of Q_1 in a positive direction, current through the transistor increases causing a voltage drop across the collector-load resistor R_3 to increase. When this voltage drop increases, the net voltage between the collector of Q_1 and ground swings in a negative direction. Thus in the common-emitter circuit, we always have the situation of a 180° phase shift between the input and output signals. Now the negative-going signal is fed from C_3 to the base of Q_2 and this causes the current through Q_2 to decrease. When the current through Q_2 decreases, the voltage drop across R_9 decreases causing the collector of Q_2 to swing in a positive direction. Once again we have the 180° phase shift in the common-emitter circuit so that we have a positive-going signal produced in the collector circuit of Q_2.

This positive signal is then fed through C_4 and R_6 into the emitter circuit of Q_1. The resistors R_6 and R_5 actually act as a voltage-divider network so that the portion of the signal developed across R_5 will be fed into the emitter circuit of Q_1. Thus when the signal applied to the base of Q_1 swings in a positive direction we also have the emitter of Q_1 swinging in a positive direction due to the feedback signal. This reduces the net base-to-emitter signal voltage so that the increase in current through Q_1 will not be as great as it would be without the feedback.

As in the case of the previous amplifier, when the output from Q_2 begins to increase, the amplitude of the feedback signal will also increase and this in turn tends to reduce the gain of the amplifier to keep the output constant. On the other hand, if the output of Q_2 begins to fall off, then the amount of feedback voltage goes down so that the gain of the amplifier tends to increase and thus level off the overall frequency response of the amplifier.

DIRECT-COUPLED AMPLIFIERS

All of the problems introduced by the coupling capacitor used between two stages can be eliminated by using direct-coupled amplifiers. In the case of a vacuum-tube amplifier, the sole purpose of the coupling capacitor between the two stages is to keep the positive voltage applied to the plate of the tube off the grid of the following tube. We do this so the grid can be operated at dc ground potential and the cathode at a small positive voltage. In this way bias can be obtained for the tube. However, there is no reason why we cannot let the grid operate at a fairly high positive potential and simply operate the cathode at a still higher positive voltage. This will mean that the cathode will be positive with respect to the grid, or in other words, the grid will be negative with respect to the cathode.

A circuit where this is done is shown in Fig. 26. This type of amplifier is called a direct-coupled amplifier. Notice that there is no coupling capacitor used between V_1 and V_2. The circuit of V_1 is more or less conventional, but the circuit of V_2 is somewhat different from the amplifiers you have seen previously. Notice that the grid of V_2 is connected directly to the plate of V_1. It is obvious that with this type of connection we don't have to worry about an increase in coupling capacitor reactance at low frequencies, because there is no coupling capacitor. However, the plate of V_1 must have a positive voltage applied to it, and

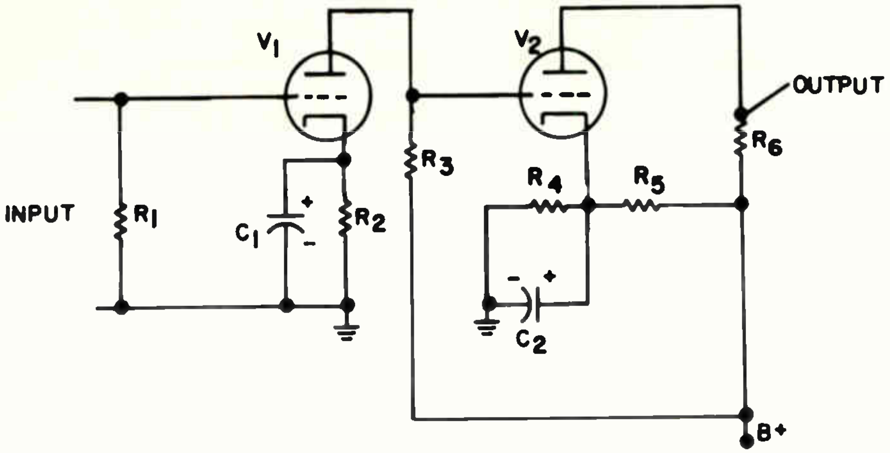

Fig. 26. A direct-coupled vacuum-tube amplifier.

therefore the grid of V_2 will have a positive voltage applied to it. By means of a voltage divider consisting of R_4 and R_5, we have obtained a positive voltage for the cathode of V_2, which is slightly higher than the positive voltage applied to the grid of V_2. C_2 keeps the cathode of V_2 at signal ground potential. Thus we have the signal applied directly between the cathode and grid of V_2. C_2 can be made very large so its reactance is negligible even at very low frequencies. Even if its reactance does start to rise, the value of R_4 is usually somewhat higher than the cathode resistor of a conventional R-C coupled stage. Thus the capacitor does not have to bypass such a low value resistor and more effective bypassing can be obtained.

One disadvantage of this type of amplifier is that aging of one tube appreciably affects the operation of the other. For example, if the emission of V_1 drops, the plate current drawn by this tube will drop. This means that the voltage drop across R_3 will decrease, and therefore the plate voltage on V_1 will increase. This increase in voltage might be enough to swing the grid of V_2 positive with respect to the cathode. Needless to say, when this happens, V_2 starts drawing a higher than normal current. Fortunately, when the tube starts drawing a higher than normal current, the voltage drop across R_4 increases and this tends to compensate for the increase in grid voltage to some extent. In some direct-coupled amplifiers you will find that the plate-load resistor R_3 is returned to a lower voltage than the plate-load resistor R_6. This makes it possible to use a lower value resistor for R_3 and thus tends to give better high-frequency response. You will remember that one of the first steps we did in order to get good high-frequency response from an amplifier was reduce the value of the plate-load resistor. This doesn't actually bring up the response but it does reduce the middle and lower frequencies so that we get a constant gain over a wider frequency range.

TRANSISTOR DIRECT-COUPLED AMPLIFIERS

Transistors lend themselves very well to direct coupling. An example of several transistors used in a direct-coupled circuit

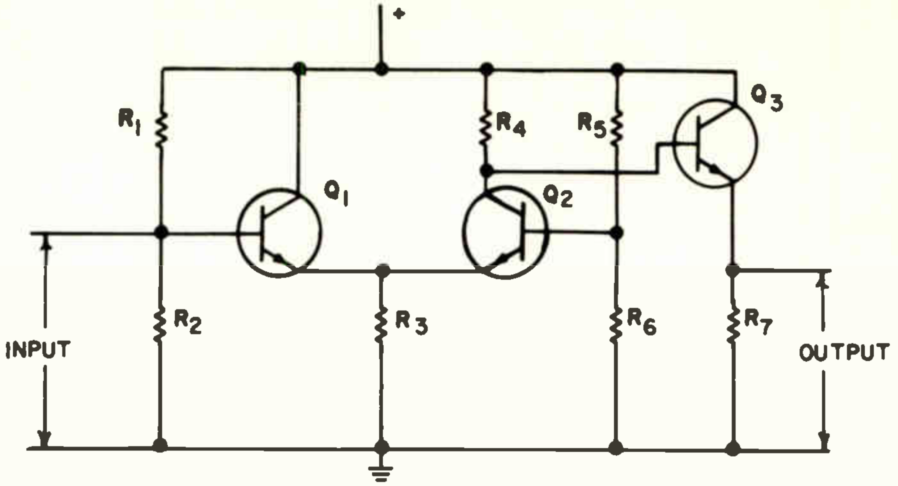

Fig. 27. Transistor direct-coupled stages.

is shown in Fig. 27. The resistors R_1 and R_2 provide a forward bias across the emitter-base junction of the NPN transistor Q_1. Forward bias across the emitter-base junction of Q_2 is provided by R_5 and R_6.

To see how the amplifier works, let's consider what happens when an input signal is applied between the base of Q_1 and ground. When the signal swings the base of Q_1 in a positive direction, current through Q_1 will increase. This causes the voltage drop across R_3 to increase. The increased voltage drop across R_3 increases the emitter voltage on Q_2 thus reducing the forward bias across the emitter-base junction of Q_2. Hence the current through this transistor goes down, and the voltage drop across R_4 will decrease. Therefore the collector of Q_2 will swing in a positive direction.

The collector of Q_2 is connected directly to the base of Q_3 which is used in an emitter-follower circuit. The dc voltage developed across R_7 is relatively low, so the output can be fed directly to the base of another amplifier configuration like Q_1 and Q_2. Of course, the varying signal fed to the base of Q_3 will cause the voltage across R_7 to vary.

The combination of transistors Q_1 and Q_2 is called a differential amplifier. This type of amplifier is widely used in integrated circuits that are used in some television receivers. The purpose of using the emitter follower after Q_2 is to reduce the dc voltage level. If we simply fed the base of a second differential amplifier pair from the collector of Q_2, the base of the following transistor would be at a higher potential than the base of Q_1. Thus for each two-stage differential amplifier we went through, the voltage would be gradually increasing. However, by using an emitter follower, the dc voltage across the emitter-resistor R_7 is quite low so that we can get back down to a low base voltage such as we had on Q_1 originally. By using a two-stage differential amplifier followed it by an emitter follower we can cascade groups of these stages any number of times to get the gain we need, while the operating voltage requirements are quite low.

PRINTED CIRCUIT BOARDS

One of the most common problems encountered in the early days of television, and when manufacturers first began to build wide-band amplifiers for other uses, was getting consistent results. In building a wide-band amplifier, stray capacities have an appreciable effect on the high-frequency response of the amplifier. One amplifier might have good frequency response up to 5 MHz and the next one built by the manufacturer, with the same parts and tubes, might have as good a response to only 4 MHz (or less). Often this is due simply to parts being put in slightly different positions and wires that were routed slightly different by the person who assembled the equipment.

Problems of this type have been almost completely eliminated by the use of printed circuit boards in the assembly of wide-band amplifiers. In the printed circuit board the wiring is actually on a phenolic or glass epoxy-type base. The wiring consists of copper strips that are glued to the base.

In manufacturing a printed circuit board the manufacturer starts off with a board that may have been made out of a phenolic material that is 1/16th of an inch thick. This material has a thin sheet of copper firmly glued to one side. The basic boards are available in sheets that are 4′ wide by 8′ long. The manufacturer cuts the desired size board from sheets of this type. In manufacturing the board for use in wide-band amplifiers, the wiring on the board is etched. To do this we simply draw the circuit and then transfer it photographically to the copper circuit board. The board is then placed in an etching solution and the undesired copper is etched away leaving only the copper desired to make the connections between the various parts on the board. The parts needed are then mounted on the other side of the board and connected to the copper wiring by inserting the part leads through holes that have been drilled or punched in the board. The leads to the various parts are then soldered to the copper wiring.

The advantage of an etched circuit board, of course, is that all parts fall into exactly the same place, the wiring falls in exactly the same place and hence distributed and stray capacities remain essentially constant from one board to the next. Thus assuming we hold the parts tolerances to a reasonable value, we can expect the frequency-response and gain of one amplifier to be essentially the same as the next one we manufacture.

In Fig. 28 we have shown a photograph of the circuit board containing the video amplifier of the Conar Model 600 Color Television Receiver. Notice that the tubes and parts are all mounted on one side of the circuit board and the wiring which interconnects all these components is in the form of copper on the other side of the board. The use of the printed circuit board ensures that video amplifiers of the various sets will have essentially the same frequency response.

One of the disadvantages of circuit boards is that they sometimes develop cracks. This may be due to rough handling of the equipment in which they are used. Sometimes the crack is so thin that you can't see it; sometimes we refer to this as a hairline crack. The crack in the circuitry may cause the equipment to perform intermittently.

Hairline cracks are quite difficult to locate, but they usually can be located by putting a little pressure on the board in various spots. You can do this with some

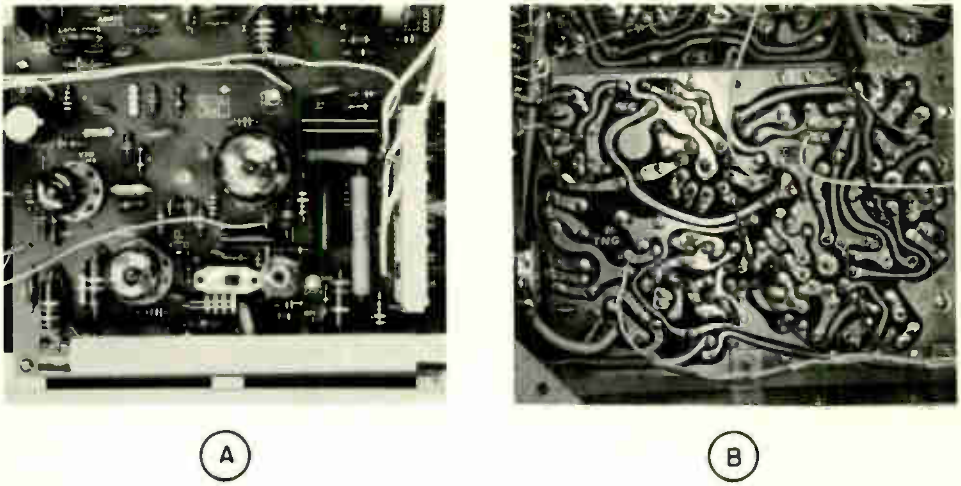

Fig. 28. Video amplifier on an etched circuit board. This type of wiring is referred to as printed wiring.

insulated tool; you will find that as you push in a certain spot the intermittent can be made to occur. Look for a hairline break in the copper wiring somewhere near this point. If you cannot find it, simply flow solder over the copper conductors in the area where you think the break is located and then try flexing the board again and see if the trouble is eliminated. The solder will usually bridge right across the crack and eliminate the intermittent.

Sometimes in repairing equipment in which a printed circuit board is used you'll accidentally pull the copper loose from the board. The copper is only glued to the board and can be easily knocked off by applying too much heat when you are replacing a part. In this case, you can effect a repair simply by taking a piece of wire and soldering the wire in place to complete the circuit between the two points from which the copper has been accidentally removed. Use a short direct piece of wire so you do not upset the performance of the board.

Printed circuit boards have added much insofar as obtaining consistent performance from wide-band amplifiers is concerned. They are not particularly difficult to work on as long as you make repairs quickly and avoid applying excessive heat or force to the board. Some servicemen do not like to work on printed circuit boards because it is somewhat more difficult to trace out the circuit than with the older style of hand wiring, but with a little practice you can learn to do this. Since most modern radio and TV receivers use printed circuitry it is important that you learn to work with this type of equipment.

SELF-TEST QUESTIONS

(z) What system is frequently used in transistor amplifiers to improve the overall frequency response of the amplifier?

(aa) How can you repair a "hairline" crack in a printed circuit board?

(ab) How can you repair a printed circuit board in which a piece of the copper has been accidentally removed?

(ac) What is the advantage of using an emitter follower after a differential amplifier such as shown in Fig. 27?

(ad) In the direct-coupled amplifier shown in Fig. 26, how is the high positive voltage on the grid of V_2 overcome?

(ae) What type of high-frequency compensation is used in the circuit shown in Fig. 23?

(af) What components form the low-frequency compensating network in the amplifier shown in Fig. 22?

LOOKING AHEAD

You can look forward to servicing many amplifiers in your career as an electronics technician. You will find amplifiers used in all types of electronic equipment. Wide-band amplifiers will be found in many different applications. Make sure that you understand wide-band amplifiers before leaving this lesson and going on to the next. A small amount of additional time spent on this lesson may save you a great deal of time later when you start working on equipment of this type.

Answers to Self-Test Questions

(a) A common logarithm is a number which tells us the power to which 10 must be raised in order to equal a given number.

(b) The characteristic.

(c) The mantissa.

(d) Two. The characteristic will be one less than the number of digits in the number. Since all numbers between 100 and 999 have three digits, the characteristic will be 2.

(e) The logarithm of 7 is .8451. The characteristic is 0, so it is simply omitted.

(f) The logarithm of 700 is 2.8451. The mantissa is the same as for the logarithm of 7 or for the logarithm of 70 for that matter. The characteristic, which is 2, indicates that the number is somewhere between 100 and 999.

(g) The logarithm of 41.7 is 1.6201. We find this logarithm by locating 41 in the N column of the log table and then moving over to the column under 7 where we see that the mantissa is .6201. 41 has two digits in it so we know that the characteristic must be 1 and therefore the complete logarithm is 1.6201.

(h) The bel is a power ratio. It is equal to the logarithm of the ratio of one power to another power.

(i) The decibel is one tenth of a bel. A decibel is a power ratio and it is equal to ten times the logarithm of one power divided by another. It is expressed by the formula:

$$\text{db} = 10 \log \frac{P_1}{P_2}$$

(j) 7.782 db. To find the change in db we let P_1 equal 222 watts and P_2 equal 37 watts. Now we substitute these values in the decibel power formula and we get:

$$\text{db} = 10 \log \frac{222}{37}$$

dividing 37 into 222 gives us 6 so the change in db equals

$$\text{db} = 10 \log 6 = 10 \times .7782 = 7.782$$

(k) 6 db. To find the answer we use the voltage formula:

$$\text{db} = 20 \log \frac{E_1}{E_2}$$

and we substitute 150 volts for E_1 and 75 volts for E_2 so that we have:

$$\begin{aligned} \text{db} &= 20 \log \frac{150}{75} \\ &= 20 \log 2 \\ &= 20 \times .301 \\ &= 6.0 \text{ db} \end{aligned}$$

(l) To increase the frequency at which the reactance of the shunt capacities becomes equal to the resistance of the plate-load resistor.

(m) If we use too large a grid resistor in a vacuum-tube amplifier, electrons accidentally striking the grid and flowing through the resistor may build up an appreciable bias in the grid of the tube. Another possibility is that the tube may have a small amount of gas. The gas molecules striking the grid will cause a current to flow through the grid resistor that will place a positive bias on the grid of the tube. If we use too large a grid resistor this positive bias may be high enough to cause an excessive current to flow through the tube and destroy the tube.

(n) At high frequencies L_1 resonates with the capacity in the circuit and hence tends to increase the value of the plate load of V_1. Thus the effect of the shunting capacity is reduced.

(o) L_1 is a series-peaking coil. It separates the shunt capacity in the output of V_1 from the shunt capacity in the input of V_2. It forms a series-resonant circuit with the capacity in the input of V_2 and hence builds up the voltage applied to the grid of V_2 at high frequencies.

(p) By series-shunt peaking we mean a combination of shunt peaking such as shown in Fig. 5 and series peaking such as shown in Fig. 8. A series-shunt compensated amplifier is shown in Fig. 10.

(q) No. The low output resistance of the first stage along with the low input resistance of the second stage reduces the effective value of the collector-load resistor in the first amplifier stage. Therefore it takes a larger shunt capacity to produce a capacitive reactance equal to the resistance of the emitter load. As a result, the response of a transistor amplifier frequently starts to fall off at a somewhat higher frequency than the response of a vacuum-tube amplitier.

(r) Yes, the time that it takes the electrons to cross the base of a transistor may become equal to the period of one half cycle at some high frequency. When this happens, instead of getting a 180° phase shift in the common-emitter transistor circuit, we get a 360° phase shift so that the signal in the emitter circuit will be in-phase with the signal in the base circuit. This will cause positive feedback through the transistor and cause the transistor to go into self oscillation.

(s) More like those encountered in vacuum tubes. Because of the high input and output resistances of the field-effect transistor, the field-effect transistor resembles a vacuum tube more closely in performance than it does a transistor. Thus series and shunt peaking are quite effective in improving the high-frequency response of an amplifier using field-effect transistors.

(t) The reactance of the coupling capacitor used between the two stages becomes too high.

(u) Phase shift.

(v) Low-frequency compensation. This usually consists of adding a resistance and a capacitance in the output circuit of the first stage. By selecting the correct value of resistance and capacitance, both the gain and the phase shift can be improved.

(w) No, it is more effective in vacuum-tube circuits, but can be used to some extent in transistor circuits.

(x) Yes. Field-effect transistors have characteristics similar to vacuum tubes and low-frequency compensation is equally effective in the two.

(y) By cathode degeneration we are referring to the reactance of the cathode bypass capacitor becoming so high that the capacitor is no longer an effective bypass. This occurs at very low frequencies and causes poor low-frequency response. It can be overcome by omitting the cathode bypass capacitor so that the degeneration becomes constant at all frequencies. This levels off the gain of the amplifier.

(z) Negative feedback. In a two-stage amplifier, a signal is taken from the second stage and fed back to the first stage to detract from the original signal applied to the first stage. Thus if the output signal of an amplifier tends to increase, the feedback increases reducing the overall gain of the amplifier. On the other hand, if the output tends to fall off, the feedback signal decreases, allowing the amplifier gain to increase.

(aa) By applying a small amount of pressure to the circuit board you can frequently isolate the area in which the crack exists. Then by flowing solder over the copper in that area you can frequently bridge the gap.

(ab) You can bridge the copper by means of a piece of hookup wire. The two ends of the hookup wire are simply soldered in place so that the wire takes the place of the copper that has been accidentally removed.

(ac) It reduces the dc voltage level in the circuit so that the next differential amplifier pair can be operated at the same dc potential as the first. This keeps the power supply requirements quite modest.

(ad) The bias network consisting of R_4 and R_5 places the cathode of V_2 at a higher positive potential than the grid. Thus even though the grid is positive with respect to ground, it is still negative with respect to the cathode.

(ae) Both series and shunt peaking are used.

(af) R_6 and C_4.

Lesson Questions

Be sure to number your Answer Sheet B204.

Place your Student Number on every Answer Sheet.

Most students want to know their grade as soon as possible so they mail their set of answers immediately. Others, knowing they will finish the next lesson within a few days, send in two sets of answers at a time. Either practice is acceptable to us. However, don't hold your answers too long; you may lose them. Don't hold answers to send in more than two sets at a time, or you may run out of lessons before new ones can reach you.

1. What is the logarithm of 2000?

2. Suppose the power output from power amplifier A is increased from 100 to 200 watts, and the power output from power amplifier B is increased from 1 to 5 watts. Which change is the larger change in decibels?

3. Why can the coupling capacitor used between two resistance-capacitance coupled stages be ignored at the middle and high frequencies?

4. What limits the high-frequency response of an R-C coupled amplifier?

5. What effect does reducing the size of the plate load resistor in an amplifier to extend the high-frequency response have on the gain at the middle and low frequencies?

6. Name the two types of peaking used to extend the high-frequency response of an amplifier.

7. Why can we not increase the size of the base resistor R_4 in a transistor amplifier such as shown in Fig. 16B to improve the low-frequency response of the two stage amplifier?

8. Why is an electrolytic capacitor used as a cathode bypass or an emitter bypass sometimes shunted by a paper or a ceramic capacitor?

9. What method can be used other than peaking coils and low-frequency compensation to improve the frequency response of an amplifier?

10. In the direct coupled transistor amplifier circuit shown in Fig. 27, what primary purpose does Q_3 serve?

REVERE OUR LAWS

Let every American, every lover of liberty, every well-wisher to his posterity swear by the blood of the Revolution never to violate in the least particular the laws of the country - Let every man remember that to violate the laws is to trample on the blood of his father, and to tear the charter of his own and his children's liberty.

Let reverence for the laws be breathed by every American mother to the lisping babe that prattles on her lap; let it be taught in schools, in seminaries, and in colleges; let it be written in primers, spelling books and in almanacs; let it be preached from the pulpit, proclaimed in legislative halls and enforced in courts of justice. And in short, let it become the political religion of the nation; and let the old and the young, the rich and the poor, the grave and the gay of all sexes and tongues and colors and conditions, sacrifice unceasingly upon its altars.

STUDY SCHEDULE

KL4M373 **1974 EDITION** **Litho in U.S.A.**

RADIO RULES AND REGULATIONS

All forms of rf radiation are subject to the control of the Federal Communications Commission (FCC). Control of rf radiation is necessary in order to keep radio transmissions from interfering with one another, and in order to insure that the various groups that use rf energy will have sufficient frequencies available to them to carry on their functions.

For instance, the military must have special frequencies reserved so that it can carry out vital communications and other functions. In order to make sure that these frequencies are not interfered with, all those who use rf energy are licensed, and also, the various types of equipment they use are assigned frequencies that will not interfere with other essential services. The different uses that are made of rf energy are referred to as "services." Thus, we have "Amateur Service," Television Service, "FM Service," and so on.

The usual procedure is to license both the station and the operator. The licensing regulations for equipment are designed to insure that the equipment will do the job for which it is designed without interfering with other services. The licensing of operators helps make sure that the users of radio transmitters are familiar with the regulations relating to their use, and that they will be able to use them properly for their intended purpose.

The object of this book is to tell you where you can find the information that is necessary to obtain these licenses and what the licenses permit you to do. Most of this information is contained in the Rules and Regulations issued by the FCC. Your main problem in dealing with these extensive regulations will be to find what you want to know in them. This book will give you a good idea of where to look.

ORGANIZATION OF THE RULES AND REGULATIONS OF THE FCC

The various topics covered by the rules and regulations of the FCC are issued in separate parts. These parts have been gathered together in ten (10) separate volumes for publication. The contents of these ten volumes are as follows:

Volume 1

Part 0 -- Commission Organization.
Part 1 -- Practice and Procedure.
Part 13 -- Commercial Radio Operators.
Part 17 -- Construction, Marking, and Lighting of Antenna Structures.
Part 19 -- Employee Responsibilities and Conduct.

Volume 2

Part 2 -- Frequency Allocations and Radio Treaty Matters; General Rules and Regulations.
Part 5 -- Experimental Radio Services (other than Broadcast).
Part 15 -- Radio Frequency Devices.
Part 18 -- Industrial, Scientific, and Medical Equipment.

Volume 3

Part 73 -- Radio Broadcast Services.
Part 74 -- Experimental, Auxiliary, and Other Program Distributional Services.

Volume 4

Part 81 -- Stations on Land in the Maritime Services.
Part 83 – Stations on Shipboard in the Maritime Services.
Part 85 -- Public Fixed Stations and Stations of the Maritime Services in Alaska.

Volume 5

Part 87 -- Aviation Services.
Part 89 -- Public Safety Radio Services.
Part 91 -- Industrial Radio Services.
Part 93 -- Land Transportation Radio Services.

Volume 6

Part 95 -- Citizens Radio Service.
Part 97 -- Amateur Radio Service.
Part 99 -- Disaster Communications Service.

Volume 7

Part 21 – Domestic Public Radio Services (other than Maritime Mobile).
Part 23 -- International Fixed Public Radiocommunication Services.
Part 25 – Satellite Communications.

Volume 8

Part 31 -- Uniform System of Accounts for Class A and Class B Telephone Companies.
Part 33 -- Uniform System of Accounts for Class C Telephone Companies.

Volume 9

Part 34 – Uniform System of Accounts for Radiotelegraph Carriers.
Part 35 - Uniform System of Accounts for Wire-Telegraph and Ocean-Cable Carriers.

Volume 10

Part 41 -- Telegraph and Telephone Franks.
Part 42 -- Preservation of Records of Communication Common Carriers.
Part 43 -- Reports of Communication Common Carriers and Certain Affiliates.
Part 51 – Occupational Classification and Compensation of Employees of Telephone Companies.
Part 52 -- Classification of Wire-Telegraph Employees.
Part 61 -- Tariffs.
Part 62 -- Application to Hold Interlocking Directorates.
Part 63 – Extension of Lines and Discontinuance of Service by Carriers.
Part 64 -- Miscellaneous Rules Relating to Common Carriers.
Part 66 -- Applications Relating to Consolidation, Acquisition, or Control of Telephone Companies.
Part 67 -- Jurisdictional Separations.

You can see that the first seven volumes contain the information you are most likely to need. In fact, you will usually find that the material is grouped in these volumes in such a way that you will not need to get all of the first seven volumes in order to cover a particular field. You should find it a good investment in both time and money to buy and study the Rules and Regulations that apply to the particular field you are working in.

Copies of these volumes are not on sale

by the FCC. To buy a copy, you should write to the Superintendent of Documents, Government Printing Office, Washington, D. C. 20402.

When you buy a copy of the regulations, the corrections for that volume are sent to you, as issued, as part of the price of the volume. This arrangement helps insure that the outstanding volumes will all be complete and up to date.

Licensing Requirements

As mentioned earlier, usually both the station and the operator of a transmitting radio station must be licensed. Since the main object of the licensing requirements is to make sure that radio transmissions are carefully controlled, there is no need for licensing radio receivers. In this section, we will discuss the requirements for both operator and station licenses. These licenses can be thought of as being of either one of two types: commercial or amateur.

COMMERCIAL OPERATOR LICENSES

Several different classes of operator licenses are issued to those who work in the commercial radio services. All but one of these licenses require the applicant to pass a written examination.

Examination Elements. The written examination for a particular class of commercial operator's license consists of one or more of the following parts, called Elements, that are described in Section 13.21 of the Rules of the FCC.

The elements are as follows:

1. **Basic Law. Provisions of laws, treaties and regulations with which every operator should be familiar.**
2. **Basic operating practice. Radio operating procedures and practices generally followed or required in communicating by means of radiotelephone stations.**
3. **Basic radiotelephone. Technical, legal and other matters applicable to the operation of radiotelephone stations other than broadcast.**
4. **Advanced radiotelephone. Advanced technical, legal and other matters particularly applicable to the operation of the various classes of broadcast stations.**
5. **Radiotelegraph operating practice. Radio operating procedures and practices generally followed or required in communicating by means of radiotelegraph stations primarily other than in the maritime mobile services of public correspondence.**
6. **Advanced radiotelegraph. Technical, legal and other matters applicable to the operation of all classes of radiotelegraph stations, including operating procedures and practices in the maritime mobile services of public correspondence, and associated matters such as radio-navigational aids, message traffic routing and accounting, etc.**
7. **Aircraft radiotelegraph. Basic theory and practice in the operation of radio communication and radio-navigational systems in general use on aircraft.**
8. **Ship radar techniques. Specialized theory and practice applicable to the proper installation, servicing and maintenance of ship radar equipment in general use for marine navigational purposes.**
9. **Basic Broadcast. Basic regulatory matters applicable to the operation of standard commercial FM, and noncommercial educational FM broadcast stations.**

Classes of Licenses. The different classes of operators' licenses, and the examinations they require are set forth in Section 13.22 as follows:

(a) Radiotelephone Second Class Operator License:

1. **Ability to transmit and receive spoken messages in English.**
2. **Written examination elements: 1, 2, and 3.**

(b) Radiotelephone First Class Operator License:

1. **Ability to transmit and receive spoken messages in English.**
2. **Written examination elements: 1, 2, 3, and 4.**

(c) Radiotelegraph Second Class Operator License:

1. Ability to transmit and receive spoken messages in English.
2. Transmitting and receiving code test of twenty (20) words per minute plain language and sixteen (16) code groups per minute.
3. Written examination elements: 1, 2, 5, and 6.

(d) Temporary limited radiotelegraph Second Class Operator License:

1. Ability to transmit and receive spoken messages in English.
2. Transmitting and receiving code test of twenty (20) words per minute plain language and sixteen (16) code groups per minute.

(e) Radiotelegraph First Class Operator License:

1. Ability to transmit and receive spoken messages in English.
2. Transmitting and receiving code test of twenty-five (25) words per minute plain language and twenty (20) code groups per minute.
3. Written examination elements: 1, 2, 5, and 6.

(f) Radiotelephone Third Class Operator Permit:

1. Ability to transmit and receive spoken messages in English.
2. Written examination elements: 1 and 2.

(g) Radiotelegraph Third Class Operator Permit:

1. Ability to transmit and receive spoken messages in English.
2. Transmitting and receiving code test of twenty (20) words per minute plain language and sixteen (16) code groups per minute.
3. Written examination elements: 1, 2, and 5.

(h) Restricted Radiotelephone Operator Permit:

No oral or written examination is required for this permit. In lieu thereof, applicants will be required to certify in writing to a declaration which states that the applicant has need for the requested permit; can receive and transmit spoken messages in English; can keep at least a rough written log in English or in some other language in general use that can be readily translated into English; is familiar with the provisions of treaties, laws, and rules and regulations governing the authority granted under the requested permit; and understands that it is his responsibility to keep currently familiar with all such provisions.

Section 13.45 provides that in computing the number of code groups in a code test, "Each five characters shall be counted as one word or code group. Punctuation marks or figures count as two characters."

Additional requirements also apply to applicants for Radiotelegraph First Class Operator Licenses. They must be at least 21 years old at the time the license is issued, and have at least 1 year's service as a radiotelegraph operator.

Examination Procedures. All written examinations must be handwritten in ink, but diagrams may be in pencil. It takes a grade of 75% to pass. Each element must be passed separately, and an applicant who fails any element may not be re-examined on that element for a period of 2 months. However, if you pass some elements and fail others, you do not need to be re-examined except on the elements you fail. Also, if you hold one class of license, and wish to qualify for another class, you need to pass only the additional elements that are contained in the requirements for the new licenses.

Your NRI course contains nearly all of the technical information that you will need in order to answer the questions on the FCC examinations. However, it is frequently helpful to use an examination study guide, which is put out by the FCC. This study guide has the information covered by the elements of the examination organized into the general headings covered. You can buy a copy of this study guide, which is called, "Study Guide and Reference Material for Commercial Radio Operator Examinations," from the Superintendent of Documents, Government Printing Office, Washington, D. C. 20402.

A restricted radiotelephone operator's permit is usually issued for life, but other commercial operator's licenses run for 5 years. Most other licenses may be renewed within the last year of their term if the holder has completed sufficient service as a radio operator using the license. This arrangement makes it unnecessary for full-time operators who are actively engaged in communications to be reexamined every five years. In fact, first- and second-class licenses can often be renewed even without the service requirement.

You can see that the qualifications for an operator's license cover much more than simply the ability to operate radio equipment. Much of the licensing requirements have to do with the ability to understand the operation of rf transmitters well enough to be able to service them. For instance, in order to be permitted to service marine radar equipment, the holder of the first- or second-class operator's license must also pass a written examination on Element 8, and have his license specially endorsed to show that he is qualified to service this type of equipment.

Place of Examination. Operator examinations are held at the district offices and sub-offices of the Federal Communications Commission. These offices are located in cities all over the country. Table I shows the location of the various offices. The time of the examinations is not the same at the various offices. Therefore, if you wish to take an examination at an office near your home, write to the Engineer in Charge at that office to find out when the examination of the type you are interested in is to be given.

COMMERCIAL STATION LICENSES

Obtaining a station license for an AM, FM, or TV broadcast station is a long drawn-out affair. The procedure is set up to enable the applicants to *"satisfy the Commission that they are legally, technically, and financially qualified, and that operation of the proposed station would be in the public interest."*

Part 1 of the Commission's Rules contains the steps of the licensing procedure, and Part 73 contains the technical standards the station must be able to meet, and much other information that is needed in applying for a license.

For instance, the TV channel assignments by states and communities are contained in Part 73, so you can tell by referring to this part what channels are assigned to your community.

One of the first things you must do in applying for a broadcast AM, FM, or TV license is to determine what frequencies, if any, are available for assignment to your particular area. This may be much more difficult than it sounds. Frequently it requires the services of a competent engineer. Another step in the procedure, which can be highly technical, is the selection of a proper site for the transmitter.

Construction Permits. The first formal step in dealing with the Commission comes when applying for a construction permit. This application is made on a form that calls for information about the citizenship and character of the applicant, his financial, technical and other qualifications, as well as details about the transmitting equipment to be used, an-

tenna and studio locations, and the type of broadcasting to be undertaken. Information must also be supplied that will show what interference problems, if any, will be caused by the proposed station, and how and to what extent these problems are to be solved.

The procedures followed in processing the construction permit application include provisions for hearings, if necessary, for protesting of the granting of the permit by other interested parties, and for appealing any ruling.

Sometimes, of course, more than one applicant will be trying to obtain a license for a station in a given area. Also, other stations on the same frequency in different areas may protest the granting of a permit if they feel that there is a possibility of interference from the new station. Such parties would be possible sources of objection to the granting of a construction permit.

Once a construction permit is granted, the construction of the station must begin promptly, and finish within a specified time fixed by the Commission. After the station is completed, the builder conducts equipment tests, submits the station to an inspection by the Engineer in Charge of the radio district in which he is located, and applies to the Commission for a license.

The application for a license must *"show compliance with the terms and conditions of the construction permit."* When the license application is made, the usual procedure is to request authority for *"program tests."* This authority permits the applicant to commence broadcast operations while his application for a license is being processed. Of course, broadcasting cannot be started until the authority for *"program tests"* is actually given by the Commission.

Type-Accepted and Type-Approved Lists. You can see from even this brief description that licensing a radio transmitting station can be quite complicated.

For some services, matters are simplified considerably by the use of equipment on lists put out by the FCC called *"type-accepted"* and *"type-approved"* lists. "Type-approved" means that the engineers of the FCC have tested a model of the equipment to make sure it will perform properly. "Type-accepted" means that the equipment has been checked out by private engineers employed by the manufacturer, who then submit a request for type acceptance to the FCC. Either kind of approval by FCC has the same effect.

These lists are kept at each field office of the FCC, and by the manufacturers of the type-accepted and type-approved equipment. Selecting equipment from these lists greatly simplifies the problem of satisfying the requirements for a suitable transmitter. This is another of several technical problems to be solved in obtaining a broadcast station license.

AMATEUR OPERATOR LICENSES

Obtaining an amateur operator's license is covered in Volume VI of the Rules and Regulations. Let's look at some of the requirements.

Examination Elements. Examinations for amateur operator's licenses are also broken down into elements. These elements are set forth in Section 97.21 of the Rules as follows:

Examinations for amateur operator privileges will comprise one or more of the following examination elements.

(a) Element 1(A): Beginner's code test at five (5) words per minute;(b) Element 1(B):

General code test at thirteen (13) words per minute;

(c) Element 1(C): Expert's code test at twenty (20) words per minute;

(d) Element 2: Basic law comprising rules and regulations essential to beginners' operation, including sufficient elementary radio theory for the understanding of those rules;

(e) Element 3: General amateur practice and regulations involving radio operation and apparatus and provisions of treaties, statutes, and rules affecting amateur stations and operators;

(f) Element 4(A): Intermediate amateur practice involving intermediate level radio theory and operation as applicable to modern amateur techniques, including, but not limited to, radiotelephony and radiotelegraphy;

(g) Element 4(B); Advanced amateur practice involving advanced radio theory and operation as applicable to modern amateur techniques, including, but not limited to, radiotelephony, radiotelegraphy, and transmissions of energy for measurements and observations applied to propagation, for the radio control of remote objects and for similar experimental purposes.

Classes of Licenses. Sections 97.9 and 97.23 set out the examination requirements for the various classes of licenses.

All applicants must be U. S. citizens. There is no age restriction.

Applicants for original licenses will be required to pass the following examination elements:

(a) Amateur Extra Class: Elements 1(C), 3, 4(A), and 4(B);

(b) Advanced Class: Elements 1(B), 3, and 4(A);

(c) General Class and Conditional Class: Elements 1(B) and 3;

(d) Technician Class: Elements 1 (A) and 3.

(e) Novice Class: Elements 1(A) and 2.

In addition, applicants for Amateur Extra Class licenses must have held an amateur license other than a Novice or Technician for a period of two years.

Examination Procedures. Section 97.29 describes the manner of conducting examinations:

(a) The examination for Amateur Extra, Advanced, and General Classes of amateur operator licenses will be conducted by an authorized Commission employee or representative at locations and at times specified by the Commission.

(b) Unless otherwise prescribed by the Commission, an examination for the Conditional, Technician, or Novice Class license will be conducted and supervised by a volunteer examiner selected by the applicant. A volunteer examiner shall be at least 21 years of age and shall be the holder of an Extra, Advanced, or General Class Amateur Radio operator license, or shall hold a Commercial radiotelegraph operator license issued by the Commission, or shall be employed in the service of the United States as the operator of a manually operated radiotelegraph station.

The section continues with details about supervision, written portion of the examination, and administration of examinations by the Commission.

Section 97.27 states that: The examinations for Conditional Class will be available only under one or more of the following conditions:

(a) If the applicant's actual residence and proposed amateur station location are more than 175 miles airline distance from the nearest location at which examinations are conducted by an authorized Commission employee or representative at intervals of not more than 6 months for amateur operator license.

(b) If the applicant is shown by physician's certificate to be unable to appear for examination because of protracted disability.

(c) If the applicant is shown by certificate of the commanding officer to be in the armed forces of the United States at an Army, Navy, Air Force, or Coast Guard Station and, for that reason, to be unable to appear for examination at the time and place designated by the Commission.

(d) If the applicant demonstrates by sufficient evidence that his temporary residence is for a continuous period of at least 12 months outside the continental limits of the United States, its territories or possessions, irrespective of other provisions of this section.

Code Tests. Section 97.29 describes the Code Test Procedure:

The code test required of an applicant for an amateur radio operator license, in accordance with the provisions of §§97.21 and 97.23 shall determine the applicant's ability to transmit by hand key (straight key or, if supplied by the applicant, any other type of hand-operated key such as a semi-automatic or electronic key), and to receive by ear, in plain language, messages in the International Morse Code at not less than the prescribed speed, free from omission or other error for a continuous period of at least 1 minute during a test period of 5 minutes counting five characters to the word, each numeral or punctuation mark counting as two characters.

Grading of Examinations. Passing the code test for a particular class of examination is a must. Section 97.31 provides:

(a) Code tests for sending and receiving are graded separately. Failure to pass the required code test for either sending or receiving will terminate the examination.

(b) Seventy-four percent (74%) is the passing grade for written examinations. For the purpose of grading, each element required in qualifying for a particular license will be considered as a separate examination. All written examinations will be graded only by Commission personnel.

Eligibility for Re-examination. Section 97.33 says:

An applicant who fails examination for an amateur operator license may not take another examination for the same or a higher class amateur operators license within 30 days, except that this limitation shall not apply to an examination for an Advanced or General Class license following an examination conducted by a volunteer examiner for a Novice, Technician, or Conditional Class license.

Volunteer Examiners. Some of the examinations are not conducted by Commission employees, but by volunteer examiners. Holders of licenses obtained under a volunteer examiner may be required to submit to an examination conducted by an employee of the Commission, as set forth in Section 97.35.

The Commission may require a licensee holding a Novice, Technician, or Conditional Class of operator license to appear for a Commission-supervised license examination at a location designated by the Commission. If the licensee fails to appear for this examination when directed to do so, or fails to pass such examination, the Novice, Technician, or Conditional Class operator license previously issued shall be subject to cancellation, and upon cancellation, a new license will not be issued for the same class operator license as that cancelled.

A holder of a Conditional Class License, obtained on the basis of an examination under the provisions of 97.29(b), is not required to be re-examined when changing residence and station location to within regular examination area, nor when a new examination location is established within 175 miles airline distance from such licensee's residence and station location.

Another distinction that is made between amateur examinations conducted by a Commission employee and those that are not, is in the matter of examination credit. Provisions of Section 97.25 state that credit is not given toward a higher grade of license for elements that are passed during an examination conducted by a volunteer examiner:

(a) **An applicant for a higher class of amateur operator license who holds a valid amateur operator license issued upon the basis of an examination by the Commission will be required to pass only those elements of the higher class examination that were not included in the examination for the amateur license held when such application was filed. However, credit will not be allowed for licenses issued on the basis of an examination given under the provisions of § 97.29(b).**

(b) **An applicant for any class of amateur operator license, except the Extra Class, will be given credit for the telegraph code element if within five years prior to the receipt of his application by the Commission he held a commercial radiotelegraph operator license or permit issued by the Federal Communications Commission.**

(c) **An applicant for Amateur Extra Class operator license will be given credit for examination elements 1(C), 4(A), and 4(B) if he so requests and submits evidence of having held a valid amateur radio station or operator license issued by any agency of the U. S. Government during or prior to April 1917, and qualifies for or currently holds a valid amateur operator license of the General or Advanced Class.**

(d) **No examination credit, except as herein provided, shall be allowed on the basis of holding or having held any amateur or commercial operator license.**

AMATEUR STATION LICENSES

The granting of an amateur station license is much less complicated than the granting of a commercial station license. For instance, Section 97.37 provides:

> **A license for an amateur station will be issued in response to proper application therefor to a licensed amateur operator at a designated fixed location. An amateur station license may also be issued to an individual, not a licensed amateur operator (other than an alien or a representative of an alien or of a foreign government), who is in charge of a proposed amateur station for recreation under military auspices (only of the Armed Forces of the United States) which is to be located in approved public quarters but not operated by the United States Government.**

Location of Station. The license is not limited to one location or type of equipment. Section 97.43 sets forth the conditions for a more extensive installation along with those for a single location:

(a) **Every amateur station shall have a fixed transmitter location. Only one fixed transmitter location will be authorized and will be designated on the license for each amateur station, except that when remote control is authorized, the location of the remote control position as well as the location of the remotely controlled transmitter shall be considered as fixed transmitter locations and will be so designated on the station license. Unless remote control of the transmitting apparatus is authorized, such apparatus shall be operated only by a duly licensed amateur radio operator present at the location of such apparatus.**

(b) **Authority for operation of an amateur station with the licensed operator on duty at a specific remote control point in lieu of the remote transmitter location may be granted upon filing an application for an individual station license on FCC Form 610, or on FCC Form 610.B for an amateur club or military recreation station.**

NOTE: These conditions, six paragraphs (1) through (6) are not listed herein. The form should be obtained and the subsection studied when authorization by the Commission is desired.

(c) **An amateur transmitter may be operated from a remote control point in lieu of the remote transmitter location without special authorization by the Commission**

when there is direct mechanical control or direct control by wired connections of the transmitter from a point located in the same or closely adjoining building or structure provided there is full compliance with the conditions set forth in paragraphs (b) (1) through (6) of this section.

Antenna Systems. The antenna system that is used with an amateur transmitter must be within the limitations of the Rules and Regulations. Section 97.45 provides:

(a) Except as provided in paragraph (b) of this section, an antenna for a station in the Amateur Radio Service which exceeds the following height limitations may not be erected or used unless notice has been filed with both the FAA on FAA Form 7460-1 and with the Commission on Form 714 or on the license application form, and prior approval by the Commission has been obtained for:

(1) Any construction or alteration of more than 200 feet in height above ground level at its site (§17.7(a) of this chapter).

(2) Any construction or alteration of greater height than an imaginary surface extending outward and upward at one one of the following slopes (§17.7(b) of this chapter):

(i) 100 to 1 for a horizontal distance of 20,000 feet from the nearest point of the nearest runway of each airport with at least one runway more than 3,200 feet in length, excluding heliports and seaplane bases without specified boundaries, if that airport is either listed in the Airport Directory of the current Airman's Information Manual or is operated by a Federal military agency.

(ii) 50 to 1 for a horizontal distance of 10,000 feet from the nearest point of the nearest runway of each airport with its longest runway no more than 3,200 feet in length, excluding heliports and seaplane bases without specified boundaries, if that airport is either listed in the Airport Directory or is operated by a Federal military agency.

(iii) 25 to 1 for a horizontal distance of 5,000 feet from the nearest point of the nearest landing and takeoff area of each heliport listed in the Airport Directory or operated by a Federal military agency.

(3) Any construction or alteration on an airport listed in the Airport Directory of the Airman's Information Manual (§17.7(c) of this chapter).

(b) A notification to the Federal Aviation Administration is not required for any of the following construction or alteration:

(1) Any object that would be shielded by existing structures of a permanent and substantial character or by natural terrain or topographic features of equal or greater height, and would be located in the congested area of a city, town, or settlement where it is evident beyond all reasonable doubt that the structure so shielded will not adversely affect safety in air navigation. Applicants claiming such exemption shall submit a statement with their application to the Commission explaining the basis in detail for their finding (§17.14(a) of this chapter).

(2) Any antenna structure of 20 feet or less in height except one that would increase the height of another antenna structure (§17.14(b) of this chapter).

(c) Further details as to whether an aeronautical study and/or obstruction marking and lighting may be required, and specifications for obstruction marking and lighting when required, may be obtained from Part 17 of this chapter, "Construction, Marking, and Lighting of Antenna Structures." Information regarding the inspection and maintenance of antenna structures requiring obstruction marking and lighting is also contained in Part 17 of this chapter.

"Part 17 of this chapter" refers to Part 17 of the Rules and Regulations. This part describes the limitations placed on antenna structures, and the provisions that must be made for lighting them.

Transmitter Output. In the amateur service, transmitter output must also meet standards of performance set down by the FCC. These output standards are spelled out in Section 97.73 of the regulations:

Spurious radiation from an amateur station being operated with a carrier frequency below 144 megacycles shall be reduced or eliminated in accordance with good engineering practice. This spurious radiation shall not be of sufficient intensity to cause interference in receiving equipment of good engineering design including adequate selectivity characteristics, which is tuned to a frequency or frequencies outside the frequency band of emission normally required for the type of emission being employed by the amateur station. In the case of A3 emission (amplitude-modulated telephony – see Table III at the end of this book) the amateur transmitter shall not be modulated to the extent that interfering spurious radiation occurs, and in no case shall the emitted carrier wave be amplitude-modulated in excess of 100 percent. Means shall be employed to insure that the transmitter is not modulated in excess of its modulation capability for proper technical operation. For the purposes of this section, a spurious radiation is any radiation from a transmitter which is outside the frequency band of emission normal for the type of transmission employed, including any component whose frequency is an integral multiple or submultiple of the carrier frequency (harmonics and subharmonics), spurious modulation products, key clicks and other transient effects, and parasitic oscillations. When using amplitude modulation on frequencies below 144 megacycles, simultaneous frequency modulation is not permitted and when using frequency modulation on frequencies below 144 megacycles simultaneous amplitude modulation is not permitted. The frequency of the emitted carrier wave shall be as constant as the state of the art permits.

License Terms. The periods of operator and station licenses are set forth in section 97.59:

(a) An amateur operator license is valid for a period of 5 years from the date of issuance, except the Novice Class which is valid for a period of 2 years.

(b) An amateur station license is valid for a period of 5 years from the date of issuance, except that an amateur station license issued to a Novice Class amateur operator licensee is valid for a period of 2 years from the date of issuance.

(c) All amateur station licenses, regardless of when issued, will expire on the same date as the licensee's amateur operator license.

Citizens Radio Service

Licensing requirements for the Citizens Radio Service are quite simple. There is no operator's license required for the normal use of Citizens Radio equipment. However, a station license must be obtained, and a commercial radio operator's license of the proper grade is also required for manually operated telegraphy. A commercial license is also necessary for anyone making any adjustments to a Citizens Radio transmitter during installation, testing, or servicing which may cause the transmitter to operate off frequency or in some other manner that would violate the rules of the FCC. For this reason, many manufacturers make the frequency-determining components of their sets "tamper-proof." A tamper-proof transmitter is one that operates on the correct frequency if it operates at all. Sealed chasses with the frequency-determining components mounted in them, and crystal-controlled oscillators are two techniques that are used to make Citizens Radio transmitters tamper-proof.

Station licenses for Citizens Radio Service are issued by the FCC at Washington, D. C. 20554. Nearly all such licenses are issued by mail. The forms for these station licenses are frequently supplied by the manufacturer with the equipment itself, with much of the technical description of the equipment already filled out. This simple licensing procedure can be used because the manufacturers have their products type-accepted or type-approved before they are marketed.

Convenient licensing, and a certain amount of misunderstanding over the purpose of Citizens Radio have led to some misuse of this type of equipment. The Rules describe the purpose of this service in Section 95.1 as follows:

> **...to provide for private short-distance radiocommunications service for the business or personal activities of licensees, for radio signaling, for the control of remote objects or devices by means of radio; all to the extent that these uses are not specifically prohibited in this part. They also provide for procedures whereby manufacturers of radio equipment to be used or operated in the Citizens Radio Service may obtain type acceptance and/or type approval of such equipment as may be appropriate.**

Classes of Stations. Licenses are granted in the four classes shown in Table II. Besides the limitations of the four classes shown in Table II, each class of transmitter is limited as to the type of emission. Section 95.47 of the Rules sets out the types of emission that may be used:

(a) Except as provided in paragraph (e) of this section, Class A stations in this service will normally be authorized to transmit radiotelephony only. However, the use of tone signals or signaling devices solely to actuate receiver circuits, such as tone operated squelch or selective calling circuits, the primary function of which is to establish or establish and maintain voice communications, is permitted. The use of tone signals solely to attract attention is prohibited.

(b) Class B stations in this service are authorized to use amplitude or frequency modulation, or on-off unmodulated carrier, and may be used for radiotelephony, to control remote objects or devices by means of radio, or to remotely actuate devices which are used as a means of attracting attention.

(c) Class C stations in this service are authorized to use amplitude tone modulation or on-off unmodulated carrier only, for the control of remote objects or devices by radio or for the remote actuation of devices which are used solely as a means of attracting attention. The transmission of any form of telegraphy, telephony or record communications by a Class C sta-

CLASS	USE	FREQUENCY RANGE (MHz)	POWER (Max. Watts Input)
A	Voice	462.550 - 462.725 467.550 - 467.725	60
B	Voice and Control	462.525 - 467.475	5
C	Control	26.995 - 27.225 27.255 72.08 - 75.64	5 30 1
D	Voice	26.965 - 27.225 27.255	5

Table II. Classes of Citizens Radio stations, frequencies, and power limitations. *

*** There is no provision here for random communications in the amateur bands. We will discuss this subject in more detail a little later on.**

tion is prohibited. Telemetering, except for the transmission of simple, short duration signals indicating the presence or absence of a condition or the occurrence of an event, is also prohibited.

(d) Class D stations in this service are authorized to use amplitude voice modulation, including single sideband and/or reduced or suppressed carrier, for radiotelephone communications only. However, the use of tone signals or signaling devices solely to actuate receiver circuits, such as tone operated squelch or selective calling circuits, the primary function of which is to establish or establish and maintain voice communications, is permitted. The use of tone signals solely to attract attention or for the control of remote objects or devices is prohibited.

(e) Other types of emission not described in paragraph (a) of this section may be authorized for Class A citizens radio stations upon a showing of need therefor. An application requesting such authorization shall fully describe the emission desired, shall indicate the bandwidth required for satisfactory communication, and shall state the purpose for which such emission is required. For information regarding the classification of emissions and the calculation of bandwidth, reference should be made to Part 2 of this chapter.

EMISSION LIMITATIONS

Section 95.49 shows the other limitations that apply to the emissions of the different classes of Citizens Radio transmitters (for the meaning of the different types of emission, see Table III at the end of this text):

(a) Each authorization issued to a Class A citizens radio station will show, as a prefix to the classification of the authorized emission, a figure specifying the maximum bandwidth to be occupied by the emission.

(b) All operation of a Class B citizens radio station (including tolerance and bandwidth occupied by the emission) shall be confined to the frequency band 462.525-467.475 MHz.

(c) (1) Except as provided in subparagraph (2) of this paragraph and except in the case of Class B citizens radio stations operating only on the frequency 465.00 MHz (see §95.41(b)), the maximum authorized bandwidth of the emission of any station employing amplitude modulation (Type A2 or A3 emission) shall be 8kHz and the maximum authorized bandwidth of the emission of any station employing frequency or phase modulation (Type F2 or F3 emission) shall be 40 kHz. The use of Type F2 or F3 emission in the frequency band 26.96-27.28 MHz is not authorized.

(2) Effective November 1, 1967, the maximum authorized bandwidth of Class A stations employing frequency or phase modulation (Type F2 or F3 emission) will be 20 kHz. Class A stations authorized before November 1, 1967 may continue to operate with maximum 40 kHz bandwidth until November 1, 1971.

(d) The mean power of emission shall be attenuated below the mean output power of the transmitter in accordance with the following schedule:

(1) On any frequency removed from the assigned frequency by more than 50 percent up to and including 100 percent of the authorized bandwidth: At least 25 decibels;

(2) On any frequency removed from the assigned frequency by more than 100 percent up to and including 250 percent of the authorized bandwidth: At least 35 decibels;

(3) On any frequency removed from the assigned frequency by more than 250 percent of the authorized bandwidth, at least the amounts indicated in the following table:

Maximum authorized power input to final radio frequency stage:	Attenuation (db)
Over 3 watts	50
3 watts or less	[1]40

[1] In the case of Class B stations having a maximum power input to the final radio frequency stage of 3 watts or less, any emission appearing on any frequency within a band allocated to industrial, scientific, and medical equipment under the provisions of Part 2 of this chapter shall be attenuated at least 30 db.

(e) When an unauthorized emission results in harmful interference, the Commission may, in its discretion, require appropriate technical changes in equipment to alleviate the interference.

Modulation Requirements. The modulation of Citizens-Band transmitters is also limited as set out in Section 95.51:

(a) When the radio frequency carrier of a station in this service is amplitude modulated, such modulation shall not exceed 100 percent on positive or negative peaks.

(b) Except as provided in paragraph (c) of this section and except in the case of Class B citizens radio stations operating only on the frequency 465.00 MHz (see §95.41(b)), the frequency deviation of any frequency modulated transmitter operated in this service shall not exceed ±15 kHz and the simultaneous amplitude modulation and frequency or phase modulation of a transmitter is not authorized.

(c) Effective June 1, 1968, the maximum frequency deviation for Class A stations employing F2 or F3 emission is ±5 kHz: Provided, That stations authorized prior to November 1, 1967, located 100 miles or more from the center of urbanized areas of 200,000 or more population may continue to operate with a frequency deviation of ± 15 kHz until November 1, 1971.

(d) Class A stations authorized on or after November 1, 1967, shall be provided with a device which automatically will prevent modulation in excess of that specified in this subpart which may be caused by greater than normal audio level. Class A stations authorized before November 1, 1967, will be required to comply with the provisions of this paragraph by November 1, 1971: Provided, however, That the requirements of this paragraph shall not apply to transmitters authorized to operate as mobile stations with a maximum plate power input to the final radio frequency stage of 3 watts or less.

(e) Each transmitter of a Class A station which is equipped with a modulation limiter in accordance with the provisions of paragraph (d) of this section shall also be equipped with an audio low-pass filter. This audio low-pass filter shall be installed between the modulation limiter and the modulated stage and, at audio frequencies between 3 kHz and 20 kHz, shall have an attentuation greater than the attenuation at 1 kHz by at least:

$$60 \log_{10} (f/3) \text{ decibels}$$

where "f" is the audio frequency in kHz. At audio frequencies above 20 kHz, the attenuation shall be at least 50 decibels greater than the attenuation at 1 kHz.

OPERATING REQUIREMENTS

The operating requirements set out in subpart D of Part 95 of the Rules reflect some of the misunderstandings that have cropped up about the use of Citizens Radio equipment.

§95.83 Prohibited Uses.

(a) A Citizens radio station shall not be used:

(1) For engaging in radio communications as a hobby or diversion, i.e., operating the radio station as an activity in and of itself.

NOTE: The following are typical, but not all inclusive, examples of the types of communications evidencing a use of Citizens radio as a hobby or diversion which are prohibited under this rule:

"You want to give me your handle and I'll ship you out a card the first thing in the morning;" or "Give me your 10-20 so I can ship you some wallpaper." (Communications to other licensees for the purpose of exchanging so-called "QSL" cards.)

"I'm just checking to see who is on the air."

"Just calling to see if you can hear me. I'm at Main and Broadway."

"Just heard your call sign and thought I'd like to get acquainted;" or "Just passing through and heard your call sign so I thought I'd give you a shout."

"Just sitting here copying the mail and thought I'd give you a call to see how you were doing." (Referring to an intent to communicate based solely on hearing another person engaged in the use of his radio.)

"My 10-20 is Main and Broad Streets. Thought I'd call so I can see how well this new rig is getting out."

"Got a new mike on this rig and thought I'd give you a call to find out how my modulation is."

"Just thought I would give you a shout and let you know I am still around. Thanks for coming back."

"Clear with Venezuela. Just thought I'd let you know I was copying you up here."

"Thought I'd give you a shout and see if you knew where the unmodulated carrier was coming from."

"Just thought I'd give you a call to find out how the skip is coming in over at your location."

"Go ahead breaker. What kind of a rig are you using? Come back with your 10-20."

(2) For any purpose, or in connection with any activity, which is contrary to Federal, State, or local law.

(3) For the transmission of communications containing obscene, indecent, or profane words, language, or meaning.

(4) To carry communications for hire, whether the remuneration or benefit received is direct or indirect.

(5) To communicate with stations authorized or operated under the provisions of other parts of this chapter, with unlicensed stations, or with U. S. Government or foreign stations, except for communications pursuant to §§95.85(b) and 95.121 and, in the case of Class A stations, for communications with U. S. Government stations in those cases which require cooperation or coordination of activities.

(6) For any communication not directed to specific stations or persons, except for: (i) Emergency and civil defense communications as provided in §§95.85(b) and 95.121, respectively, (ii) test transmissions pursuant to §95.93, and (iii) communications from a mobile unit to other units or stations for the sole purpose of requesting routing directions, assistance to disabled vehicles or vessels, information concerning the availability of food or lodging, or any other assistance necessary to a licensee in transit.

(7) To convey program material for retransmission, live or delayed, on a broadcast facility.

NOTE: A Class A, Class B, or Class D station may be used in connection with the administrative, engineering, or maintenance activities of a broadcasting station; a Class A, Class B, or Class C station may be used for control functions by radio which do not involve the transmission of program material; and a Class A, Class B, or Class D station may be used in the gathering of news items or preparation of programs: Provided, That the actual or recorded transmissions of the Citizens radio station are not broadcast at any time in whole or in part.

(8) To interfere maliciously with the communications of another station.

(9) For the direct transmission of any material to the public through public address systems or similar means.

(10) To transmit superfluous communications,

i.e., any transmissions not necessary to communications which are permissible.

(11) For the transmission of music, whistling, sound effects, or any material for amusement or entertainment purposes, or solely to attract attention.

(12) To transmit the word "MAYDAY" or other international distress signals, except when a ship, aircraft, or other vehicle is threatened by grave and imminent danger and requests immediate assistance.

(13) For transmitting communications to stations of other licensees which relate to the technical performance, capabilities, or testing of any transmitter or other radio equipment, including transmissions concerning the signal strength or frequency stability of a transmitter, except as necessary to establish or maintain the specific communication.

(14) For relaying messages or transmitting communications for a person other than the licensee or members of his immediate family, except: (i) Communications transmitted pursuant to §§95.85(b), 95.87(b)(7), and 95.121; and, (ii) upon specific prior Commission approval, communications between citizens radio stations at fixed locations where public telephone service is not provided.

(15) For advertising or soliciting the sale of any goods or services.

(16) For transmitting messages in other than plain language. Abbreviations, including nationally or internationally recognized operating signals, may be used only if a list of all such abbreviations and their meaning is kept in the station records and made available to any Commission representative on demand.

(b) A Class D station may not be used to communicate with, or attempt to communicate with, any unit of the same or another station over a distance of more than 150 miles.

(c) A licensee of a Citizens radio station who is engaged in the business of selling Citizens radio transmitting equipment shall not allow a customer to operate under his station license. In addition, all communications by the licensee for the purpose of demonstrating such equipment shall consist only of brief messages addressed to other units of the same station.

§95.85 Emergency Use.

(a) All Citizens radio stations shall give priority to the emergency communications of other stations which involve the immediate safety of life of individuals or the immediate protection of property.

(b) Any station in this service may be utilized during an emergency involving the immediate safety of life or the immediate protection of property for the transmission of emergency communications. When so used, certain provisions in this part concerning use of frequencies (§95.41(d)); prohibited uses (§95.83(a)(5) and (6)); operation by or on behalf of persons other than the licensee (§95.87); and duration of transmissions (§95.91(a) and (b)) shall not apply. However, any emergency use that necessitate taking advantage of these exceptions to usual requirements shall be subject to the following conditions:

(1) As soon as possible after the beginning of such emergency use, notice shall be sent to the Commission in Washington, D.C., and to the Engineer in Charge of the radio district in which the station is located, stating the nature of the emergency and the use to which the station is being put.

(2) The emergency use of the station shall be discontinued as soon as possible, and the Commission in Washington, D.C., and the Engineer in Charge, shall be notified immediately when such special use of the station is terminated. If the emergency use is of less than 24-hour duration, a single notice containing all of the required information will serve to comply with the notice requirements of this paragraph.

(3) Discontinuance of such special use of the authorized facilities.

(c) If the emergency use under paragraph (b) of this section extends over a period of 12 hours or more, notice shall be sent to the Commission in Washington, D.C., as soon as it is evident that the emergency has or will exceed 12 hours. The notice should include the identity of the stations participating, the nature of the emergency, and the use made of the stations. A single notice covering all participating stations may be submitted.

§ 95.87 Operation by, or on behalf of, persons other than the licensee.

(a) Transmitters authorized in this service must be under the control of the licensee at all times. A licensee shall not transfer, assign, or dispose of, in any manner, directly or indirectly, the operating authority under this station license, and shall be responsible for the proper operation of all units of the station.

(b) Citizens radio stations may be operated only by the following persons, except as provided in paragraph (c) of this section:

(1) The licensee;

(2) Members of the licensee's immediate family living in the same household;

(3) The partners, if the licensee is a partnership, provided the communications relate to the business of the partnership;

(4) The members, if the licensee is an unincorporated association, provided the communications relate to the business of the association;

(5) Employees of the licensee only while acting within the scope of their employment;

(6) Any person under the control or supervision of the licensee when the station is used solely for the control of remote objects or devices, other than devices used only as a means of attracting attention; and

(7) Other persons, upon specific prior approval of the commission shown on or attached to the station license, under the following circumstances:

(i) Licensee is a corporation and proposes to provide private radiocommunication facilities for the transmission of messages or signals by on or behalf of its parent corporation, another subsidiary of the parent corporation, or its own subsidiary. Any remuneration or compensation received by the licensee for the use of the radiocommunication facilities shall be governed by a contract entered into by the parties concerned and the total of the compensation shall not exceed the cost of providing the facilities. Records which show the cost of service and its nonprofit or cost-sharing basis shall be maintained by the licensee.

(ii) Licensee proposes the shared or cooperative use of a Class A station with one or more other licensees in this service for the purpose of communicating on a regular basis with units of their respective Class A stations, or with units of other Class A stations if the communications transmitted are otherwise permissible. The use of these private radiocommunication facilities shall be conducted pursuant to a written contract which shall provide that contributions to capital and operating expense shall be made on a nonprofit cost-sharing basis, the cost to be divided on an equitable basis among all parties to the agreement. Records which show the cost of service and its nonprofit, cost-sharing basis shall be maintained by the licensee. In any case, however, licensee must show a separate and independent need for the particular units proposed to be shared to fulfill his own communications requirements.

(iii) Other cases where there is a need for other persons to operate a unit of licensee's radio station. Requests for authority may be made either at the time of filing of the application for station license or thereafter by letter. In either case, the licensee must show the nature of the proposed use and that it relates to an activity of the licensee, how he proposes to maintain control over the transmitters at all times, and why it is not appropriate for such other person to obtain a station license in his own name. The authority, if granted, may be specific with respect to the names of persons who are permitted to operate, or may authorize operation by unnamed persons for specific purposes. This authority may be revoked by the Commission in its discretion, at any time.

(c) An individual who was formerly a citizen radio station licensee shall not be permitted to operate any citizens radio station of the same class licensed to another person until such time as he again has been issued a valid radio station license of that class, when his license has been:

(1) Revoked by the Commission.

(2) Surrendered for cancellation after the institution of revocation proceedings by the Commission.

(3) Surrendered for cancellation after a notice of apparent liability to forfeiture has been served by the Commission.

§95.91 Duration of Transmissions.

(a) All communications or signals, regardless of their nature, shall be restricted to the minimum practicable transmission time.

The radiation of energy shall be limited to transmissions modulated or keyed for actual permissible communications, tests or control signals. Continuous or uninterrupted transmissions from a single station or between a number of communicating stations is prohibited except for communications involving the immediate safety of life or property.

(b) Communications between or among Class D stations shall not exceed 5 consecutive minutes. At the conclusion of this 5-minute period, or upon termination of the exchange if less than 5 minutes, the station transmitting and the stations participating in the exchange shall remain silent for a period of at least 5 minutes and monitor the frequency or frequencies involved before any further transmissions are made. However, for the limited purpose of acknowledging receipt of a call, such a station or stations may answer a calling station and request that it stand by for the duration of the silent period. The time limitations contained in this paragraph may not be avoided by changing the operating frequency of the station and shall apply to all transmissions of an operator who, under other provisions of this part, may operate a unit of more than one citizens radio station.

(c) The transmission of audible tone signals or a sequence of tone signals for the operation of the tone operated squelch or selective calling circuits in accordance with §95.47 shall not exceed a total of 15 seconds duration. Continuous transmission of a subaudible tone for this purpose is permitted. For the purposes of this section, any tone or combination of tones having no frequency above 150 Hertz shall be considered subaudible.

(d) The transmission of permissible control signals shall be limited to the minimum practicable time necessary to accomplish the desired control or actuation of remote objects or devices. The continuous radiation of energy for periods exceeding 3 minutes duration for the purpose of transmission of control signals shall be limited to control functions requiring at least one or more changes during each minute of such transmission. However, while it is actually being used to control model aircraft in flight by means of interrupted tone modulation of its carrier, a citizens radio station may transmit a continuous carrier without being simultaneously modulated if the presence or absence of the carrier also performs a control function. An exception to the limitations contained in this paragraph may be authorized upon a satisfactory showing that a continuous control signal is required to perform a control function which is necessary to insure the safety of life and property.

§95.93 Tests and Adjustments.

All tests or adjustments of citizens radio transmitting equipment involving an external connection to the radio frequency output circuit shall be made using a nonradiating dummy antenna. However, a brief test signal either with or without modulation, as appropriate, may be transmitted when it is necessary to adjust a transmitter to an antenna for a new station installation or for an existing installation involving a change of antenna or change of transmitters, or when necessary for the detection, measurement, and suppression of harmonic or other spurious radiation. Test transmissions using a radiating antenna shall not exceed a total of 1 minute during any 5-minute period, shall not interfere with communications already in progress on the operating frequency, and shall be properly identified as required by §95.95, but may otherwise be unmodulated as appropriate.

§95.95 Station Identification.

(a) The call sign of a citizens radio station shall consist of three letters followed by four digits.

(b) Each transmission of the station call sign shall be made in the English language by each unit, shall be complete, and each letter and digit shall be separately and distinctly transmitted. Only standard phonetic alphabets, nationally or internationally recognized, may be used in lieu of pronunciation of letters for voice transmission of call signs. A unit designator or special identification may be used in addition to the station call sign but not as a substitute therefor.

(c) Except as provided in paragraph (d) of this section, all transmissions from each unit of a citizens radio station shall be identified by the transmission of its assigned call sign at the beginning and end of each transmission or series of transmissions directed to or exchanged with a unit of the same station or units of other stations. Each required identification shall include not only the call sign of the station unit transmitting, but also the call sign of the station or stations with which the transmitting unit is communicating, or attempting to communicate. In the case of communications between units of the same station (intrastation), after identifying itself by its assigned call sign, the transmitting unit may identify the other units by unit designators. For communications between units of different stations (interstation), the complete sign of all stations involved must be transmitted. If the call sign of the station being called is not known, the name or trade name may be used, but when contact has been made the called station shall thereafter be identified by its call sign. Examples of proper identification procedure are set forth at the end of this paragraph. Where transmissions or exchanges of transmissions of greater length are permitted by this part, the identification shall also be transmitted at least every 15 minutes. Each transmission or exchange of transmissions conducted on different frequencies shall be fully and separately identified in accordance with the foregoing on each frequency used.

EXAMPLES OF PROPER IDENTIFICATION

Intrastation communications:

(1) Calling: "KZZ 0001 base, calling unit 2."
Response: "KZZ 0001 unit 2, to base, over."
Clearing: "KZZ 0001 base, clear with unit 2" and "KZZ 0001 unit 2, clear with base."

(2) Calling: "KZZ 0001 unit 1, calling unit 3."
Response: "KKZ 0001 unit 3, to unit 1, over."
Clearing: "KZZ 0001 unit 1, clear with unit 3" and "KZZ 0001 unit 3, clear with unit 1."

Interstation communications:
Calling: "KZZ 0001 calling KZZ 0002," or "KZZ 0001 calling KZZ 0002 unit 3" (if appropriate).
Response: "KZZ 0002 to KZZ 0001, over."
Clearing: "KZZ 0001 clear with KZZ 0002," and "KZZ 0002 clear with KZZ 0001."

(d) Unless specifically required by the station authorization, the transmission of a citizens radio station need not be identified when the station (1) is a Class A station which automatically retransmits the information received by radio from another station which is properly identified or (2) is not being used for telephony emission.

(e) In lieu of complying with the requirements of paragraph (c) of this section, Class A base stations, fixed stations, and mobile units when communicating with base stations may identify as follows:

(1) Base stations and fixed stations of a Class A radio system shall transmit their call signs at the end of each transmission or exchange of transmissions, or once each 15-minute period of a continuous exchange of communications.

(2) A mobile unit of a Class A station communicating with a base station of a Class A radio system on the same frequency shall transmit once during each exchange of transmissions any unit identifier which is on file in the station records of such base station.

(3) A mobile unit of Class A stations communicating with a base station of a Class A radio system on a different frequency shall transmit its call sign at the end of each transmission or exchange of transmissions, or once each 15-minute period of a continuous exchange of communications.

§95.105 Current copy of rules required.

Each licensee in this service shall maintain as a part of his station records a current copy of Part 95, Citizens Radio Service, of this chapter.

We have gone into the details of Citizens Radio operating requirements because of misunderstandings about this type of radio service and misuse of it. Each radio service has its own operating requirements as you will see in the next section. The Citizens Radio Service has less demanding requirements than other radio services but they are important nonetheless.

Operational Requirements

The operational requirements of radio stations fall into two types -- the technical operation, whereby the required technical standards are maintained, and the actual operation, or use, of the transmitter.

TECHNICAL OPERATION

The Technical operation requirements of the different classes of radio stations are set out in the Rules and Regulations. As an example of the kind of technical operation that is required, we can take the regulations that apply to standard AM broadcasting stations.

Determination of Operating Power. Section 73.51 tells how operating power is determined:

(a) Except as provided in paragraph (b) of this section, the operating power shall be determined by the direct method, i.e., as the product of the antenna resistance at the operating frequency (see §73.54) and the square of the antenna current at this frequency, measured at the point where the antenna resistance has been determined.

(b) The operating power shall be determined on a temporary basis by the indirect method described in paragraphs (c) and (d) of this section, in the following circumstances: (1) In an emergency, where the authorized antenna system has been damaged by causes beyond the control of the licensee or permittee (see §73.45), or (2) pending completion of authorized changes in the antenna system, or (3) if changes occur in the antenna system or its environment which affect or appear likely to affect the value of antenna resistance or (4) if the antenna current meter becomes defective (see §73.58). Prior authorization for determination of power by the indirect method is not required. However, an appropriate notation shall be made in the operating log.

(c) (1) Operating power is determined by the indirect method of applying an appropriate factor to the plate input power, in accordance with the following formula:

$$\text{Operating power} = E_p \times I_p \times F$$

Where:

E_p = Plate voltage of the final radio stage

I_p = Total plate current of the final radio stage

F = Efficiency factor

(2) The value of F applicable to each mode of operation shall be entered in the operating log for each day of operation, with a notation as to its derivation. This factor shall be established by one of the methods described in paragraph (d) of this section, which are listed in order of preference. The product of the plate current and plate voltage, or alternatively, the computed operating power, shall be entered in the operating log under an appropriate heading for each log entry of plate current and plate voltage.

(d) (1) If the transmitter and the power utilized during the period of indirect power determination are the same as have been authorized and utilized for any period of regular operation, the factor F shall be the ratio of such authorized power to the corresponding plate input power of the transmitter for regular conditions of operation, computed with values of plate voltage and plate current obtained from the operating logs of the station for the last week of regular operation. However, if the station has been regularly authorized for operation with directional antenna, and temporary authority has been granted for nondirectional operation with regularly authorized power, during the period that power is being determined indirectly, an adjusted factor F shall be employed, which is derived by dividing the factor, as determined above, by a constant (0.925 for authorized powers of 5 kw, or less; 0.95 for powers above 5 kw.).

(2) If a station has not been previously in regular operation with the power authorized for the period of indirect power determination, if a new transmitter has been installed, or if, for any other reason, the determination of the factor F by the method described in paragraph (d) (1) of this section is impracticable:

(i) The factor F shall be obtained from the transmitter manufacturer's letter or test report retained in the station's files, if such a letter or test report specifies a unique value of F for the power level and frequency utilized; or

(ii) By reference to the following table:

Factor (F)	Method of modulation	Max. rated carrier power	Class of amplifier
0.70	Plate	0.25-1.0 kw	
.80	Plate	5 kw. & over	
.35	Low level	0.25 kw. & over	B
.65	Low level	0.25 kw. & over	BC[1]
.35	Grid	0.25 kw & over	

[1] All linear amplifier operation where efficiency approaches that of Class C operation.

(3) When the factor F is obtained from the table, this value shall be used even though the operating power may be less than the maximum rated carrier power of the transmitter.

Maintenance of Operating Power. Section 73.52 tells within what limits the operating power is to be maintained:

(a) The operating power of each station shall be maintained as near as practicable to the licensed power and shall not exceed the limits of 5 percent above and 10 percent below the licensed power, except that in an emergency when due to causes beyond control of the licensee it becomes impossible to operate with full licensed power, the station may be operated with reduced power for a period not to exceed 10 days, provided the Commission and the Engineer in Charge of the radio district in which the station is located shall be notified immediately after the emergency develops and also upon the resumption of licensed power.

(b) In addition to maintaining the operating power within the above limitations, stations employing directional antenna systems shall maintain the ratio of the antenna currents in the elements of the system within 5 percent of that specified by the terms of the license or other instrument of authorization.

How Antenna Resistance and Reactance Is Determined. Section 73.54 prescribes these measurement standards, procedures and record keeping:

(a) The resistance of an omnidirectional series fed antenna shall be measured at the base of the antenna, without intervening coupling networks or components. For a shunt-excited antenna, the antenna resistance shall be measured at the point when the radiofrequency energy is fed to the slant wire or other feed wire circuit without intervening networks or components.

(b) The resistance and reactance of a directional antenna shall be measured at the point of common radiofrequency input to the directional antenna system. The following conditions shall obtain:

(1) The antenna shall be finally adjusted for the required radiation pattern.

(2) The reactance at the operating frequency and at the point of measurement shall be adjusted to zero, or as near thereto as practicable.

(c) (1) The resistance of an antenna shall be determined by the following procedure: A series of discrete measurements shall be made over a band of frequencies extending from approximately 25 kHz below the operating frequency to approximately 25 kHz above that frequency, at intervals of approximately 5 kHz. The measured values shall be plotted on a linear graph, with frequency as the abscissa and resistance as the ordinate. A smooth curve shall be drawn through the plotted values. The resistance value corresponding to the point of intersection of the curye and the ordinate representing the operating frequency of the station shall be the resistance of the antenna.

(2) For a directional antenna, the reactance of the antenna shall be determined by a procedure similar to that described in subparagraph (1) of this paragraph.

(d) The license of a station with a directional antenna, and authorized power of 5 kilowatts or less shall specify an antenna resistance 92.5 percent of that determined at the point of common input; for a station with directional antenna and authorized power exceeding 5 kilowatts the license shall specify an antenna resistance 95 percent of that determined at the point of common input.

(e) Applications for authority to determine power by the direct method shall specify the antenna or common point resistance, and shall include the following supporting information.

(1) Description of measurement method.

(2) A schematic diagram showing clearly all components of coupling circuits, the point of resistance measurement, location of antenna ammeter, connections to and characteristics of all tower lighting isolation circuits, static drains, and any other fixtures, sample lines, etc., connected to or supported by the antenna, including other antennas and associated circuits.

(3) Make and type of each calibrated instrument employed, manufacturer's rated accuracy, together with the date of last calibration of the instrument, the accuracy of the calibration, and the identity of the person or firm making the calibration.

(4) A tabulation of all measured data.

(5) Graph(s) plotted from this data.

(6) The qualifications of the engineer(s) making the measurements.

Modulation Requirements. Section 73.55 sets the modulation percentage requirements:

> The percentage of modulation shall be maintained as high as possible consistent with good quality of transmission and good broadcast practice. In no case is it to exceed 100 percent on negative peaks of frequent recurrence. Generally, it should not be less than 85 percent on peaks of frequent recurrence; but where necessary to avoid objectionable loudness modulation may be reduced to whatever level is necessary, even if the resulting modulation is substantially less than 85 percent on peaks of frequent recurrence.

Section 73.56 describes the requirements for modulation monitors:

(a) Each station shall have in operation, either at the transmitter or at the place the transmitter is controlled, a modulation monitor of a type approved by the Commission.

NOTE: Approved modulation monitors are included on the Commission's "Radio Equipment List, Part B, Aural Broadcast Equipment." Copies of this list are available for inspection at the Commission's office in Washington, D. C. and at each of its field offices.

(b) In the event that the modulation monitor becomes defective the station may be operated without the monitor pending its repair or replacement for a period not in excess of 60 days without further authority of the Commission: Provided, That:

(1) Appropriate entries shall be made in the maintenance log of the station showing the date and time the monitor was removed from and restored to service.

(2) The Engineer in Charge of the radio district in which the station is located shall be notified both immediately after the monitor is found to be defective and immediately after the repaired or replacement monitor has been installed and is functioning properly.

(3) The degree of modulation of the station shall be monitored with a cathode ray oscilloscope or other acceptable means.

(c) If conditions beyond the control of the licensee prevent the restoration of the monitor to service within the above allowed period, informal request in accordance with § 1.549 of this chapter may be filed with the Engineer in Charge of the radio district in which the station is operating for such additional time as may be required to complete repairs of the defective instrument.

(d) Each station operated by remote control shall continuously, except when other readings are being taken, monitor percent of modulation or shall be equipped with an automatic device to limit percent of modulation on negative peaks to 100.

Indicating Instruments. Section 73.58 describes the indicating instruments that are required:

(a) Each standard broadcast station shall be equipped with indicating instruments which conform with the specifications set forth in § 73.39 for measuring the dc plate circuit current and voltage of the last radio frequency amplified stage; the radio frequency base current of each antenna element; and, for stations employing directional antenna systems, the radio frequency current at the point of common input to the directional antenna.

(b) In the event that any one of these indicating instruments becomes defective when no substitute which conforms with the required specifications is available, the station may be operated without the defective instrument pending its repair or replacement for a period not in excess of 60 days without further authority of the Commission: Provided, That:

(1) Appropriate entries shall be made in the maintenance log of the station showing the date and time the meter was removed from and restored to service.

(2) The Engineer in Charge of the radio district in which the station is located shall be notified both immediately after the instrument is found to be defective and immediately after the repaired or replacement instrument has been installed and is functioning properly.

(3) If the defective instrument is the antenna current meter of a nondirectional station which does not employ a remote antenna ammeter, or if the defective instrument is the common point meter of a station which employs a directional antenna, and does not employ a remote common point meter, the operating power shall be determined by the indirect method in accordance with § 73.51 (c) and (d) during the entire time the station is operated without the antenna current meter or common point meter. However, if a remote antenna ammeter or a remote common point meter is employed and the antenna current meter or common point meter becomes defective, the remote meter may be used in determining operating power by the direct method pending the return to service of the regular meter, provided other meters are maintained at same value previously employed.

(c) If conditions beyond the control of the licensee prevent the restoration of the meter to service within the above allowed period, informal request in accordance with § 1.549 of this chapter may be filed with the Engineer in Charge of the radio district in which the station is located for such additional time as may be required to complete repairs of the defective instrument.

(d) Remote antenna ammeters and remote common point meters are not required; therefore, authority to operate without them is not necessary. However, if a remote antenna ammeter or common point meter is employed and becomes defective, the antenna base currents may be read and logged once daily for each mode of operation, pending the return to service of the regular remote meter.

Frequency Requirements. Section 73.59 sets out the frequency tolerance:

> The operating frequency of each station shall be maintained within 20 Hz of the assigned frequency.

§73.60 describes the frequency monitor requirements:

(a) The licensee of each station shall have in operation, either at the transmitter or at the place where the transmitter is controlled, a frequency monitor of a type approved by the Commission which shall be independent of the frequency control of the transmitter.

NOTE: Approved frequency monitors are included on the Commission's "Radio Equipment List, Part B, Aural Broadcast Equipment". Copies of this list are available for inspection at the Commission's office in Washington, D. C. and at each of its field offices.

(b) In the event that the frequency monitor becomes defective the station may be operated without the monitor pending its repair or replacement for a period not in

excess of 60 days without further authority of the Commission: Provided, That:

(1) Appropriate entries shall be made in the maintenance log of the station showing the date and time the monitor was removed from and restored to service.

(2) The Engineer in Charge of the radio district in which the station is located shall be notified both immediately after the monitor is found to be defective and immediately after the repaired or replacement monitor has been installed and is functioning properly.

(3) The frequency of the station shall be measured by an external source at least once each 7 days and the result entered in the maintenance log.

(c) If conditions beyond the control of the licensee prevent the restoration of the monitor to service within the above allowed period, informal request in accordance with § 1.549 of this chapter may be filed with the Engineer in Charge of the radio district in which the station is located for such additional time as may be required to complete repairs of the defective instrument.

You can see from these quotations from the Rules that nearly every aspect of the technical operation requirements for radio stations and equipment is closely regulated. These Rules help to insure that the many radio services and classes of stations will be able to perform their functions without interfering with one another.

OPERATING SCHEDULES

In addition to the equipment requirements in the operation of a radio transmitter, the operating or broadcasting schedule is also closely regulated by the FCC Rules.

Section 73.71 describes the minimum operating schedule for AM (standard broadcast) stations:

(a) All standard broadcast stations are required to maintain an operating schedule of not less than two-thirds of the total hours they are authorized to operate between 6 a.m. and 6 p.m., local standard time, and two-thirds of the total hours they are authorized to operate between 6 p.m. and midnight, local standard time, on each day of the week except Sunday: Provided, however, That stations authorized for daytime operation only need comply only with the minimum requirement for operation between 6 a.m. and 6 p.m.

(b) In the event that causes beyond a licensee's control make it impossible to adhere to the operating schedule in paragraph (a) of this section or to continue operating, the station may limit or discontinue operation for a period of not more than 10 days, without further authority of the Commission. However, the Commission and the Engineer in Charge of the radio district in which the station is located shall be immediately notified in writing if the station is unable to maintain the minimum operating schedule and shall be subsequently notified when the station resumes regular operation.

The "experimental period" in broadcasting is the time from 12 midnight to local sunrise (nighttime is the period from local sunset to 12 midnight). Section 73.72 provides for the control of operation of standard broadcast stations during this period:

The licensee of each standard broadcast station shall operate or refrain from operating its station during the experimental period as directed by the Commission in order to facilitate frequency measurement or for the determination of interference.

Section 73.73 provides for operation of stations pursuant to the schedule of operation specified by the FCC license.

If the license of a station specifies the hours of operation, the schedule so speci-

fied shall be adhered to except as provided in §§ 73.71 and 73.72.

LOGS

Much of the information about the operation of radio stations must be set down in the station logs. There are three separate logs: (1) Program log; (2) Operating log; and (3) Maintenance log. Section 73.111 covers the general requirements relating to logs for standard broadcast stations. Similar provisions apply to other commercial radio stations:

(a) The licensee or permittee of each standard broadcast station shall maintain program, operating and maintenance logs as set forth in §§ 73.112, 73.113, and 73.114. Each log shall be kept by the station employee or employees (or contract operator) competent to do so, having actual knowledge of the .facts required, who in the case of program and operating logs shall sign the appropriate log when starting duty, and again when going off duty.

(b) The logs shall be kept in an orderly and legible manner, in suitable form, and in such detail that the data required for the particular class of station concerned is readily available. Key letters or abbreviations may be used if proper meaning or explanation is contained elsewhere in the log. Each sheet shall be numbered and dated. Time entries shall be either in local standard or daylight saving time and shall be indicated accordingly.

(c) No log or preprinted log or schedule which becomes a log, or portion thereof, shall be erased, obliterated, or willfully destroyed within the period of retention provided by the provisions of this part. Any necessary correction shall be made only pursuant to §§ 73.112, 73.113, and 73.114, and only by striking out the erroneous portion, or by making a corrective explanation on the log or attachment to it as provided in those sections.

(d) Entries shall be made in the logs as required by §§ 73.112, 73.113, and 73.114. Additional information such as that needed for billing purposes or for the cueing of automatic equipment may be entered on the logs. Such additional information, so entered, shall not be subject to the restrictions and limitations in the Commission's rules on the making of corrections and changes in logs.

Section 73.115 provides for retaining the logs as records:

Logs of standard broadcast stations shall be retained by the licensee or permittee for a period of 2 years: Provided, however, That logs involving communications incident to a disaster or which include communications incident to or involved in an investigation by the Commission and concerning which the licensee or permittee has been notified, shall be retained by the licensee or permittee until he is specifically authorized in writing by the Commission to destroy them: Provided, further, That logs incident to or involved in any claim or complaint of which the licensee or permittee has notice shall be retained by the licensee or permittee until such claim or complaint has been fully satisfied or until the same has been barred by statute limiting the time for the filing of suits upon such claims.

Section 73.116 sets forth the rules about making the logs and records available:

The following shall be made available upon request by an authorized representative of the Commission:

(a) Program, operating and maintenance logs.

(b) Equipment performance measurements required by §73.47.

(c) Copy of most recent antenna resistance or common-point impedance measurements submitted to the Commission.

(d) Copy of most recent field intensity measurements to establish performance of directional antennas required by § 73.151.

SECRECY REQUIREMENTS

Most radio stations engaged in handling communications traffic are obliged to observe strict secrecy with regard to the content of the messages they handle. For instance, stations in the shipboard maritime service are governed by Section 83.174 of the Rules, which provide:

> **The master or the person responsible, as well as all persons who may have knowledge of the text or even of the existence of the radio communications transmitted or received by a station on board ship or of any information whatever obtained by means of the radiocommunication service of such station, shall be under the obligation of observing and insuring the secrecy of communications to the extent required by the Communications Act and the International Radio Regulations.**

Section 501 of the Communications Act provides:

> **Any person who willfully and knowingly does or causes or suffers to be done any act, matter, or thing, in this Act prohibited or declared to be unlawful, or who willfully or knowingly omits or fails to do any act, matter, or thing in this Act required to be done, or willfully and knowingly causes or suffers such omission or failure, shall, upon conviction, thereof, be punished for such offense, for which no penalty (other than a forfeiture) is provided in this Act, by a fine of not more than $10,000 or by imprisonment for a term not exceeding one year, or both; except that any person, having been once convicted of an offense punishable under this section, who is subsequently convicted of violating any provision of this Act punishable under this section, shall be punished by a fine of not more than $10,000 or by imprisonment for a term not exceeding two years, or both.**

Section 502 of the Communications Act provides:

> **Any person who willfully and knowingly violates any rule, regulation, restriction, or condition made or imposed by the Commission under authority of this Act, or any rule, regulation, restriction, or condition made or imposed by an international radio or wire communications treaty or convention, or regulations annexed thereto, to which the United States is or may hereafter become a party, shall, in addition to any other penalties provided by law, be punished, upon conviction thereof, by a fine of not more than $500 for each and every day during which such offense occurs.**

Section 605 of the Communications Act provides:

> **No person receiving or assisting in receiving, or transmitting, or assisting in transmitting, any interstate or foreign communications by wire or radio shall divulge or publish the existence, contents, substance, purport, effect, or meaning thereof, except through authorized channels of transmission or reception, to any person other than the addressee, his agent, or attorney, or to a person employed or authorized to forward such communication to its destination, or to proper accounting or distributing officers of the various communicating centers over which the communication may be passed, or to the master of a ship under whom he is serving, or in response to a subpoena issued by a court of competent jurisdiction, or on demand of other lawful authority; and no person not being authorized by the sender shall intercept any communication and divulge or publish the existence, contents, substance, purport, effect, or meaning of such intercepted communication to any person; and no person not being entitled thereto shall receive or assist in receiving any interstate or foreign communication by wire or radio and use the same or any information therein contained for his own benefit or for the benefit of another not entitled thereto; and no person having received such intercepted communication or having become acquainted with the contents, substance, purport, effect, or meaning of the same or any part thereof, knowing that such information was so obtained, shall divulge or publish the existence, contents, substance, purport, effect, or meaning of**

the same or any part thereof, or use the same or any information therein contained for his own benefit or for the benefit or another not entitled thereto: Provided, That this section shall not apply to the receiving, divulging, publishing, or utilizing the contents of any radio communication broadcast, or transmitted by amateurs or others for the use of the general public, or relating to ships in distress.

ORDER OF PRIORITY

Messages handled in the communications services all have places in the order of priority. The details of this order are slightly different for the different services. However, the general order of priority can be seen from the regulations that apply to radiotelegraph communications in the maritime mobile service. This priority is set forth in Section 83.177(a):

(a) The order of priority of radiotelegraph communications in the maritime mobile service of any frequency used for this service shall be as follows:

(1) Distress calls (including the international distress signal for radiotelegraphy), the international radiotelegraph alarm signal, the international radiotelephone alarm signal, distress messages, and distress traffic.

(2) Communications preceded by the international radiotelegraph urgency signal.

(3) Communications preceded by the international radiotelegraph safety signal.

(4) Communications relative to radio direction-finding bearings.

(5) Communications relative to the navigation and safe movement of aircraft.

(6) Communications relative to the navigation, movements, and needs of ships; including weather observation messages destined for an official meteorological service.

(7) Government communications for which priority right has been claimed.

(8) Service communications relating to the working of the radiocommunication service or to communications previously transmitted.

(9) All other communications.

Distress, alarm, urgent, and safety signals are described as follows:

§83.234 Distress Signals.

(a) The international radiotelegraph distress signal consists of the group "three dots, three dashes, three dots" (. . . - - - . . .), symbolized herein by SOS, transmitted as a single signal in which the dashes are slightly prolonged so as to be distinguished clearly from the dots.

(b) The international radiotelephone distress signal consists of the word MAYDAY, pronounced as French expression "m'aider".

(c) These distress signals indicate that a mobile station is threatened by grave and imminent danger and requests immediate assistance.

§83.245 Radiotelegraph and radiotelephone alarm signals.

(a) The international radiotelegraph alarm signal consists of a series of twelve dashes sent in one minute, the duration of each dash being four seconds and the duration of the interval between consecutive dashes one second. The purposes of this special signal is the actuation of automatic devices giving the alarm to attract the attention of the operator when there is no listening watch on the distress frequency.

(b) The international radiotelephone alarm signal consists of two substantially sinusoidal audio frequency tones transmitted alternately. One tone shall have a frequency of 2200 cycles per second and the other a frequency of 1300 cycles per second, the duration of each tone being 250 milliseconds. When generated by automatic means, the radiotelephone alarm signal shall be transmitted continuously for a period of at least 30 seconds, but not exceeding one minute; when generated by other means, the signal shall be transmitted as continuously as practicable over a period of approximately one minute. The purpose of this special signal is to attract the attention of the person on watch or to actuate automatic devices giving the alarm.

§83.247 Urgency signals.

(a) The urgency signal indicates that the calling station has a very urgent message to transmit concerning the safety of a ship, aircraft, or other vehicle, or the safety of a person. The urgency signal shall be sent only on the authority of the master or person responsible for the mobile station.

(b) In radiotelegraphy, the urgency signal consists of three repetitions of the group XXX, sent with the individual letters of each group, and the successive groups clearly separated from each other. It shall be transmitted before the call.

(c) In radiotelephony, the urgency signal consists of the word PAN, spoken three times and transmitted before the call.

(d) The urgency signal shall have priority over all other communications, except distress. All mobile and land stations which hear it shall take care not to interfere with the transmission of the message which follows the urgency signal.

§83.249 Safety signals.

(a) The safety signal indicates that the station is about to transmit a message concerning the safety of navigation or giving important meteorological warnings.

(b) In radiotelegraphy, the safety signal consists of three repetitions of the group TTT, sent with the individual letters of each group, and the successive groups clearly separated from each other. It shall be sent before the call.

(c) In radiotelephony, the safety signal consists of the word SECURITY, spoken three times and transmitted before the call.

(d) The safety signal and call shall be sent on one of the international distress frequencies (500 kHz radiotelegraph; 2182 kHz radiotelephone), or on the national distress frequency (156.80 MHz radiotelephone). However, stations which cannot transmit on a distress frequency may use any other available frequency on which attention might be attracted.

INSPECTIONS

All stations licensed by the FCC are subject to station inspection. For instance, the Rules provide even with respect to Citizens Radio stations, in Section 95.103:

> **All stations and records of stations in the Citizens Radio Service shall be made available for inspection upon the request of an authorized representative of the Commission made to the licensee or to his representative (see § 1.6 of this chapter). Unless otherwise stated in this part, all required station records shall be maintained for a period of at least 1 year.**

Similar provisions apply to broadcast stations in Section 73.97:

> **The licensee of any radio station shall make the station available for inspection by representatives of the Commission at any reasonable hour.**

The possibility of an inspection makes it particularly important to keep both the log books and the station equipment in good shape at all times. Many points covered by the Rules but not mentioned in this brief text may be checked on a station inspection. For this reason, it is especially important to get a copy of the rules that apply to the particular service you are engaged in to make sure that the station is operated according to these rules at all times. For example, posting of operator and station licenses may seem like an incidental thing of little importance, but the Rules specifically provide in Section 73.92 that this shall be done.

(a) The station license and any other instrument of station authorization shall be posted in a conspicuous place and in such manner that all terms are visible, at the place the licensee considers to be the principal control point of the transmitter. At all other control points listed on the station authorization, a photocopy of the station license and other instruments of station authorization shall be posted.

(b) The original operator license, or FCC

Form 759, of each station operator shall be posted at the place where he is on duty as an operator.

It is also important for the operator requirements set out in Section 73.93 to be met at all times:

(a) One or more operators holding a radio operator license or permit of a grade specified in this section shall be in actual charge of the transmitting system, and shall be on duty either at the transmitter location or at the remote control point. If operation by remote control has not been authorized, the transmitter, required monitors and other required metering equipment shall be readily accessible, clearly visible, and located sufficiently close to the operator at the normal operating position that deviations from normal indications of required instruments can be observed readily. If operation by remote control is authorized, the required controls and instruments shall be readily accessible, clearly visible, and located sufficiently close to the operator at the normal operating position that deviations from normal indications of required instruments can be observed readily.

(b) With the exception set forth in paragraph (f) of this section, adjustments of the transmitting system and inspection, maintenance, and required equipment performance measurements and required field strength measurements shall be performed only by a first class radiotelephone operator.

(c) A station using a non-directional antenna and with authorized power of 10 kilowatts or less shall have at least one first class radiotelephone operator, readily available at all times, either in full time employment, or, in the alternative, the licensee may contract in writing for the services on a part-time basis of one or more such operators. Signed contracts with part-time operators shall be kept in the files of the station and shall be made available for inspection upon request by an authorized representative of the Commission. A signed copy of contracts shall be forwarded to the Engineer in Charge of the radio district in which the station is located within three (3) days after the contract is signed.

(d) A station using a non-directional antenna, during periods of operation with authorized power in excess of 10 kilowatts, may employ first class radiotelephone operators, second class operators, or operators with the third class permit endorsed for broadcast station operation for routine operation of the transmitting system if the station has in full-time employment at least one first class radiotelephone operator and complies with the provisions of paragraphs (f) and (g) of this section.

(e) A station using a directional antenna system, which is required by the station authorization to maintain the ratios of the currents in the elements of the system within a tolerance which is less than 5 percent or the relative phases of those currents within a tolerance which is less than 3 degrees shall, without exception, employ first class radiotelephone operators who shall be on duty and in actual charge of the transmitting system as specified in paragraph (a) of this section during hours of operation with a directional radiation pattern. A station whose authorization does not specifically require therein the maintenance of phase and current relationships within closer tolerances than above specified shall employ first class radiotelephone operators for routine operation of the transmitting system during periods of directional operation, *Provided however*, That holders of second class licenses or third class permits endorsed for broadcast station operation, may be employed for routine operation of the transmitting system if the following conditions are met:

(1) The station must have in full-time employment at least one first class radiotelephone operator.

(2) The station shall be equipped with a type-approved phase (antenna) monitor fed by a sampling system installed and maintained pursuant to accepted standards of good engineering practice.

(3) At least once each day, 5 days each week, unless required more frequently by the terms of the station authorization, or rules governing operation by remote control (see Sections 73.67(a)(6) and 73.113(a)(4)) a

first class radiotelephone operator shall record the following observations in the station maintenance log for each directional radiation pattern used: (i) Common point current. (ii) Antenna base currents. (iii) Sample loop currents or remote antenna base currents and phase monitor indications. (iv) Antenna base current ratios, and remote antenna or sample loop current ratios, and the deviations in these ratios, in percent, from the licensed values. A station authorized to use the same directional radiation pattern during all hours of operation shall record these observations with successive readings not less than 12 hours apart.

(4) A partial proof of performance shall be made once each calendar year, with intervals between successive proofs not to exceed fourteen (14) months. The report of such proof measurements shall be prepared and filed as specified in paragraph (b) of Section 73.47.

(5) Field strength measurements shall be made at the monitoring points specified in the station authorization at least once each 30 days unless more frequent measurements are required by such authorization. The results of these measurements shall be entered in the station maintenance log. The licensee shall have readily available, and in proper working condition, field strength measuring equipment to perform these measurements.

(f) Subject to the conditions set forth in paragraphs (c), (d), and (e) of this section, the routine operation of the transmitting system may be performed by an operator holding a second class license or third class permit endorsed for broadcast station operation. Unless, however, performed under the immediate and personal supervision of an operator holding a first class radiotelephone license, an operator holding a second class license or third class permit endorsed for broadcast station operation, may make adjustments only of external controls as follows:

(1) Those necessary to turn the transmitter on and off;

(2) Those necessary to compensate for voltage fluctuations in the primary power supply;

(3) Those necessary to maintain modulation levels of the transmitter within prescribed limits;

(4) Those necessary to effect routine changes in operating power which are required by the station authorization;

(5) Those necessary to change between non-directional and directional or between differing radiation patterns, provided that such changes require only activation of switches and do not involve the manual tuning of the transmitter final amplifier or antenna phasor equipment. The switching equipment shall be so arranged that the failure of any relay in the directional antenna system to activate properly will cause the emissions of the station to terminate.

(g) It is the responsibility of the station licensee to insure that each operator is fully instructed in the performance of all the above adjustments, as well as in other required duties, such as reading meters and making log entries. Printed step-by-step instructions for those adjustments which the lesser grade operator is permitted to make, and a tabulation or chart of upper and lower limiting values of parameters required to be observed and logged, shall be posted at the operating position. The emissions of the station shall be terminated immediately whenever the transmitting system is observed operating beyond the posted parameters, or in any other manner inconsistent with the rules or the station authorization, and the above adjustments are ineffective in correcting the condition of improper operation, and a first class radiotelephone operator is not present.

(h) When lesser grade operators are used, in accordance with paragraphs (d) or (e) of this section, for any period of operation using authorized power in excess of 10 kilowatts, or using a directional radiation pattern, the station licensee shall designate one first class radiotelephone operator in full-time employment as the chief operator who, together with the licensee, shall be responsible for the technical operation of the station. The station licensee shall notify the Engineer in Charge of the radio district in which the station is located of the name and license number of the designated chief operator. Such notification shall be by letter within three (3) days of such designation. A copy of the notification shall be posted with the chief operator's license.

(1) An operator designated as chief operator for one station may not be so designated concurrently at any other standard broadcast station.

(2) The station licensee shall vest such authority in, and afford such facilities to the chief operator as may be necessary to insure that the chief operator's primary responsibility for the proper technical operation of the station may be discharged efficiently.

(3) At such times as a regularly designated chief operator is unavailable or unable to act as chief operator (e.g., vacations, sickness), the station licensee shall designate another first class radiotelephone operator as acting chief operator on a temporary basis. Within three days of the date such action is taken, the Engineer in Charge of the radio district in which the station is located shall be notified by the licensee by letter of the name and license number of the acting chief operator, and shall be notified by letter, again within three days of the date when the regularly designated chief operator returns to duty.

(4) The designated chief operator may serve as a routine duty transmitter operator at any station only to the extent that it does not interfere with the efficient discharge of his responsibilities as listed below. (i) The inspection and maintenance of the transmitting system including the antenna system and required monitoring equipment. (ii) The accuracy and completeness of entries in the maintenance log. (iii) The supervison and instruction of all other station operators in the performance of their technical duties. (iv) A reveiw of completed operating logs to determine whether technical operation of the station has been in accordance with the rules and terms of the station authorization. After review, the chief operator shall sign the log and indicate the date of such review. If the review of the operating logs indicates technical operation of the station is in violation of the rules or the terms of the station authorization, he shall promptly initiate corrective action. The review of each day's operating log shall be made within 24 hours, except that, if the chief operator is not on duty during a given 24 hour period, the logs must be reviewed within two hours after his next appearance for duty. In any case, the time before review shall not exceed 72 hours.

(i) The operator on duty at the transmitter or remote control point, may, at the discretion of the licensee and the chief operator, if any, be employed for other duties or for the operation of another radio station or stations in accordance with the class of operator's license which he holds and the rules and regulations governing such other stations; *Provided, however*, That such other duties shall not interfere with the proper operation of the standard broadcast transmitting system and keeping of required logs.

(j) At all standard broadcast stations, a complete inspection of the transmitting system and required monitoring equipment in use, shall be made by an operator holding a first class radiotelephone license at least once each day, 5 days each week, with an interval of no less than 12 hours between successive inspections. This inspection shall include such tests, adjustments, and repairs as may be necessary to insure operation in conformance with the provisions of this subpart and the current station authorization.

VIOLATION NOTICES

Special provisions are made by the FCC for monitoring radio stations. These monitoring, or listening, posts can tell if a radio transmitter is operating properly.

If there is some defect in the operation of a radio station that violates the Rules and Regulations of the FCC, a note of the violation is sent to the holder of the station license. The provisions of Section 83.601 apply to stations on land in the maritime service. However, similar provisions apply to the other services as well:

> Any person receiving official notice of a violation of the terms of the Communications Act, any legislative act, Executive order, treaty to which the United States is a party, terms of a station or operator license, or the rules and regulations of the Federal Communications Commission, shall, within 10 days from such receipt, send a written answer, in duplicate, to the office of the Commission originating the official notice. If an answer cannot be sent, or an acknowledgement made within such 10-day period by reason of illness or other unavoidable circumstances, acknowledgement and answer shall be made at the earliest practicable date with a satisfactory explanation of the delay. The answer to each notice shall be complete in itself and shall not be abbreviated by references to other communications or answers to other notices. The answer shall contain a full explanation of the incident involved and shall set forth the action taken to prevent a continuation or recurrence thereof. If the notice relates to lack of attention to, or improper operation of the station, or to log or watch discrepancies, the answer shall give the name and license number of the licensed operator on duty.

Be sure you know the requirements for answering violation notices that apply to the particular service that you are in. Failure to respond properly to a notice of violation can result in license suspension.

LICENSE RENEWALS

Of course, the normal thing to do with either a station or an operator's license is to have it renewed when it expires. You should know the license renewal requirements for whatever license you hold. For example, the Novice amateur license is not renewable. Therefore, if you wish to continue operating after your Novice license expires, you must make provisions for obtaining a higher class of amateur license.

The following are the provisions that apply to the renewal and replacement requirements for commercial radio operators. You can get the corresponding requirements for other kinds of licenses by referring to the volume of the FCC Rules that covers that particular service.

Higher Class License. Section 13.26 describes the canceling of a license by the issuance of a higher class license, as follows:

> If the holder of a license qualifies for a higher class in the same group, the license held will be canceled upon the issuance of the new license. Similarly, if the holder of a restricted operator permit qualifies for a first- or second-class operator license of the corresponding type, the permit held will be canceled upon issuance of the new license.

Renewals. Rules regarding renewals are set forth in Section 13.28 as follows:

> A restricted radiotelephone operator permit normally is issued for the lifetime of the holder and need not be renewed. A temporary limited radiotelegraph second-class operator license is not renewable. A license of any other class may be renewed without examination provided that the service record on the reverse side of the license (see §§ 13.91 to 13.94) shows at least two years of satisfactory service in the aggregate during the license term and while actually employed as a radio operator under that license. If this two-year renewal service requirement is not fulfilled, but the service record shows at least one year of satisfactory service in the aggregate during the last three years of the license term and while actually employed as a radio operator under that license, the license may be renewed upon the successful completion of a renewal examination, which may be taken at any time during the final year of the license term or during a one-year period of grace after the date of expiration of the license sought to be renewed. The renewal examination will consist of the highest numbered examination element normally required for a new license of the class southt to be renewed,

> **plus the code test (if any) required for such new license. If the renewal examination is not successfully completed before expiration of the aforementioned one-year period of grace, the license will not be renewed on any basis.**
>
> **NOTE: By order dated and effective April 4, 1951, the Commission temporarily waived the requirement of prior service as a radio operator or examination for renewal in the case of any applicant for renewal of his commercial radio operator license. This order is applicable to commercial radio operator licenses which expired after June 30, 1950 until further order of the Commission.**

Duplicates. A license that has been lost or destroyed can be replaced as described in Section 13.71.

> **(a) An operator whose license or permit has been lost, mutilated, or destroyed shall immediately notify the Commission. If the authorization is of the diploma form, a properly executed application for duplicate should be submitted to the office of issue. If the authorization is of the card form (Restricted Radiotelephone Operator Permit), a properly executed application for replacement should be submitted to the Federal Communications Commission, Gettysburg, Pa., 17325. In either case the application shall embody a statement of the circumstances involved in the loss, mutilation, or destruction of the license or permit. If the authorization has been lost, the applicant must state that reasonable search has been made for it, and, further, that in the event it be found, either the original or the duplicate (or replacement) will be returned for cancellation. If the authorization is of the diploma form, the applicant should also submit documentary evidence of the service that has been obtained under the original authorization, or a statement embodying that information.**
>
> **(b) The holder of any license or permit whose name is legally changed may make application for a replacement document to indicate the new legal name by submitting a properly executed application accompanied by the license or permit affected. If the authorization is of the diploma form, the application should be submitted to the office where it was issued. If the authorization is of the card form (Restricted Radiotelephone Operator Permit) it should be submitted to the Federal Communications Commission, Gettysburg, Pa., 17325.**

Section 13.72 provides:

> **When a duplicate or replacement operator license or permit has been requested, or request has been made for renewal upon service or for an endorsement or a verification card, the operator shall exhibit in lieu of the original document a signed copy of the application which has been submitted by him.**

Verification Cards. A verification card may be obtained as set forth in Section 13.73:

> **The holder of an operator license or permit of the diploma form (as distinguished from such document of the card form) may, by filing a properly executed application accompanied by his license or permit, obtain a verification card (Form 758-F). This card may be carried on the person of the operator in lieu of the original license or permit when operating any station at which posting of an operator license is not required: Provided, That the license is readily accessible within a reasonable time for inspection upon demand by an authorized Government representative.**

Record of Service and Maintenance Duties. Section 13.75 provides the following:

> **In every case where a station log or service and maintenance records are required to be kept, and where service or maintenance duties are performed which may affect the proper operation of a station, the responsible operator shall sign and date an entry in the log of the station concerned, or in the station maintenance records if no log is required, giving:**
>
> **(a) Pertinent details of all service and maintenance work performed by him or under his supervision;**

(b) His name and address; and

(c) The class, serial number and expiration date of his license:

Provided, That the responsible operator shall not be subject to requirements of paragraphs (b) and (c) of this section in relation to a station, or stations of one licensee at a single location, at which he is regularly employed as an operator on a full time basis and at which his license is properly posted.

Service Record Endorsement. The following requirements are set forth in Sections 13.91 - 13.94 regarding the endorsement of the service record on an operator's license.

> **A station licensee, or his duly authorized agent, or the master of a vessel acting as the agent of a licensee, shall endorse the service record appearing on said operator license, showing the call letters and types of emission of the station operated, the nature and period of employment, and quality of performance of duty.**
>
> **If the operator has operated more than three stations in the aviation service, the service may be shown by giving the name of the aviation chain or company in lieu of listing the call letters of the several stations.**
>
> **Credit will be allowed only for satisfactory service obtained under conditions that required the employment of licensed operators, or when obtained at United States Government stations.**
>
> **The holder of a radiotelegraph first- or second-class operator license, or a temporary limited radiotelegraph second-class operator license desiring an endorsement to be placed thereon attesting to an aggregate of at least 6 months' satisfactory service as a qualified operator on a vessel of the United States or an applicant for a temporary limited radiotelegraph second-class operator license under §13.5(d)(3) may, in the event documentary evidence cannot be produced, submit to any office of the Commission a statement under oath accompanied by the license to be endorsed, embodying the following:**
>
> **(a) Names of ships at which employed;**
> **(b) Call letters of stations;**
> **(c) Types of emission used;**
> **(d) Type of service performed as follows:**
> **(1) Manual radiotelegraph operation only; and**
> **(2) Transmitter control only; or**
> **(3) Combination of (1) and (2) running concurrently;**
> **(e) Whether service was satisfactory or unsatisfactory;**
> **(f) Period of employment;**
> **(g) Name of master, employer, licensee, or his duly authorized agent.**

SUMMARY

This text gives you a general idea of the kind of material found in the Rules and Regulations. You should become thoroughly familiar with those that apply to your particular service.

The Rules and Regulations contain most of the information you will need to know about the licensing and operating requirements for radio stations and operators. These Rules and Regulations are made to put into effect the provisions of the Federal Communications Act, as amended. Therefore, both the Rules and the Communications Act often contain provisions that relate to the same subject. Consequently, it is useful to have a copy of this Act of Congress as well as the Rules that apply to your particular service. The Act has been printed separately, and can also be ordered from the Superintendent of Documents, Government Printing Office, Washington, D. C., 20402.

TYPE OF MODULATION OF MAIN CARRIER	TYPE OF TRANSMISSION	SYMBOL
Amplitude	With no modulation	A0
	Telegraphy without the use of a modulating audio frequency (by on-off keying)	A1
	Telegraphy by the on-off keying of an amplitude modulating audio frequency, or audio frequencies, or by the on-off keying of the modulated emission (special case: an unkeyed emission amplitude modulated).	A2
	Telephony	
	Double sideband	A3
	Single sideband, reduced carrier	A3A
	Single sideband, suppressed carrier	A3J
	Two independent sidebands	A3B
	Facsimile (with modulation of main carrier either directly or by a frequency modulated subcarrier).	A4
	Facsimile - single sideband, reduced carrier	A4A
	Television - vestigial sideband	A5C
	Multichannel voice-frequency telegraphy - single sideband, reduced carrier	A7A
	Cases not covered by the above, e.g., a combination of telephony and telegraphy - two independent sidebands	A9B
Frequency (or Phase)	Telegraphy by frequency shift keying without the use of a modulating audio frequency: one of two frequencies being emitted at any instant	F1
	Telegraphy by the on-off keying of a frequency modulating audio frequency or by the on-off keying of a frequency modulated emission (special case: an unkeyed emission, frequency modulated)	F2
	Telephony	F3
	Facsimile by direct frequency modulation of the carrier	F4
	Television	F5
	Four-frequency diplex telegraphy	F6
	Cases not covered by the above, in which the main carrier is frequency modulated.	F9

TYPE OF MODULATION OF MAIN CARRIER	TYPE OF TRANSMISSION	SYMBOL
Pulsed	A pulsed carrier without any modulation intended to carry information (e.g., radar)	P0
	Telegraphy by the on-off keying of a pulsed carrier without the use of a modulating audio frequency	P1D
	Telegraphy by the on-off keying of a modulating audio frequency or audio frequencies, or by the on-off keying of a modulated pulse carrier (special case: an unkeyed modulated pulsed carrier).	
	Audio frequency or audio frequencies modulating the amplitude of the pulses.	P2D
	Audio frequency or audio frequencies modulating the width (or duration) of the pulses.	P2E
	Audio frequency or audio frequencies modulating the phase (or position) of the pulses.	P2F
	Telephony	
	Amplitude modulated pulses	P3D
	Width (or duration) modulated pulses	P3E
	Phase (or position) modulated pulses	P3F
	Code modulated pulses (after sampling and quantization)	P3G
	Cases not covered by the above in which the main carrier is pulse modulated	P9

Table III. Classification of Typical Emissions.

GOOD RESOLUTIONS

When you make a good resolution, put it into effect at once. To postpone it is deadly. Anything that can be done next month or next year can be done *now* -- or at least a start can be made toward it.

Millions of people dream about doing fine, worthwhile things. But only a few hundred people ever get around to actually doing these things.

The few hundred may not be as smart as the others -- may not be as talented, as capable, or as well educated. But they *act* and achieve concrete results while the plans and good resolutions of the millions fade into nothing.

Remember this when you make plans -- when you make good resolutions. Put your plans and resolutions into effect at once. Get started!

MATH PROBLEMS

CXMX

STUDY SCHEDULE NO. CXMX

CPC1M768 **1968 EDITION** Printed in U. S. A.

This is the final lesson in your NRI course. No new concepts are introduced here. Instead, it is intended as a convenient review covering all types of questions you are likely to encounter in taking the FCC exam, which involve the use of mathematics. Using the various required formulas will not only serve to refresh your memory on certain points, but should serve as an excellent indicator to you of how thoroughly you have learned the material covered in preceding lessons.

This lesson also has another purpose; that is, as preparation for the examinations you will be required to take when applying for employment with many manufacturing and service organizations. This is often the first step in determining whether or not they can make use of your particular skills. If you fail the examination, there is little hope for employment with that concern.

These industry examinations also serve to point out exactly what we have told you throughout your training: Just to know the answer to a given question is not enough and is not an indication of skill. You must know the "hows" and "whys" of electronics to last long on any job. You may fool yourself by hurrying through lessons and learning just enough to answer the examination questions, but you won't fool an employer.

You have progressed too far now to permit any small difficulty to stand in your way. You can be justifiably proud of your accomplishments - a relatively small percentage of men have neither the ambition nor the courage to follow through to the end in a course of instruction such as you have completed.

Make this effort count. Don't hurry now, when success is so near. Remember, you can always study in haste and repent in leisure.

The lesson is divided into two parts. In the first part you will find 117 examination-type questions, generally arranged in an order of progressive difficulty.

When you have finished a problem, the correctness of your work can be verified by turning to the corresponding number in the second section of the lesson entitled "Answers."

It must be emphasized that this review is in no way intended as a "cram" device. Your training has been thorough and such practices are entirely unnecessary and undesirable. Although you may be able to pass a given exam by "cram" methods, and even obtain a job as a result of holding an FCC license, lack of real understanding becomes readily apparent to an employer and you would find yourself back where you started.

With this in mind, if you have difficulty with any problem, and if your understanding of the problem is still not perfectly clear after studying the answer, go back to the lesson text in which the material is covered and make a thorough review. For example, if you do not completely understand how a given formula is transposed, go back to the math book where the process is explained in detail. If you do not understand any part of the non-mathematical associated discussion, again go back to the original lesson text and review. The importance of this procedure cannot be over-emphasized.

When you have completed this lesson in the manner recommended and have sent your final exam to NRI for grading, make a final review of the rules and regulations contained in the Lessons 11CX and 12CX. If you do as we recommend, you will have no difficulty with the FCC exam.

Problems

1. State the three ordinary mathematical forms of Ohm's Law.

2. What is the resistance of a circuit if I = 5 amps and E = 30 volts?

3. If two resistors of 10 and 5 ohms are connected in series, what is the total resistance?

4. If two resistors of 10 and 15 ohms, respectively, are connected in parallel, what is their effective resistance?

5. A battery having an emf of 6 volts is connected in series with a 300-ohm resistor. What is the circuit current?

6. In a series dc circuit the current, as measured by an ammeter, is 0.05 ampere, and the resistance, as measured by an ohmmeter is 100 ohms. What is the applied emf?

7. Three resistors of 5, 10, and 20 ohms, are connected in parallel. What is their total effective resistance?

8. A 6-volt battery is to be charged at a 3-amp rate from a 115-volt line. What value of resistance should be connected in series with the battery?

9. The filament of a vacuum tube is rated at 250 ma and 5 volts. It is to be operated from a 6-volt battery. What is the value of the required series resistor?

10. The coil resistance of a relay is 600 ohms. The relay is designed to operate when 0.3 amp current passes through the coil. If operation is to be made from a 220-volt dc line, what value of resistance is needed in series with the coil?

11. Give the three basic formulas for calculating power in dc circuits.

12. What will be the heat dissipation, in watts, of a resistor of 50 ohms having a current of 0.2 amp passing through it?

13. What is the maximum rated current-carrying capacity of a resistor marked "5000 ohms 200 watts?"

14. If two 5-watt, 300-ohm resistors are connected in parallel, what are the power dissipation capabilities of the combination?

15. The input power to a transmitter is 500 watts. The radiated power from the antenna is 300 watts. What is the efficiency of the transmitter?

16. State the formula for determining (1) the quantity or charge of a capacitor; (2) the energy stored in a capacitor.

17. What is the formula used to determine the total capacitance of a group of capacitors connected in parallel?

18. What is the formula used to determine the total capacitance of a group of capacitors connected in series?

19. If capacitors of 5, 3, and 7 μf are connected in series, what is the total capacitance?

20. If capacitors of 10, 20, and 30 μf are connected in parallel, what is the total capacitance?

21. Given two identical mica capacitors of 0.2 μf capacitance each. One is charged to a potential of 116 volts and disconnected from the charging circuit. The charged capacitor is then connected in parallel with the uncharged capacitor. What voltage will appear across the two capacitors connected in parallel?

22. State the mathematical formula for the energy stored in the magnetic field surrounding an inductance carrying an electric current.

23. What is the formula for determining wavelength when the fre-

quency in kilocycles is known?

24. If the period of one complete cycle of a radio wave is 0.000001 second, what is the wavelength?

25. What is the effective value of a sine wave in relation to its peak value?

26. What is the seventh harmonic of 360 kc?

27. What factors must be known in order to determine the power factor of an alternating current circuit?

28. In a circuit consisting of an inductance having a reactance of 100 ohms and a resistance of 100 ohms, what will be the phase angle of the current with respect to the voltage?

29. State Ohm's Law for ac circuits.

30. Neglecting distributed capacitance, what is the reactance of a 6 millihenry choke coil at a frequency of 500 kc?

31. What is the reactance value of a capacitor of 0.02 μf at a frequency of 20 kc?

32. Given a series circuit consisting of a resistance of 4 ohms, an inductive reactance of 4 ohms, and a capacitive reactance of 1 ohm. The applied circuit alternating emf is 50 volts. What is the voltage drop across the inductance?

33. What is the impedance of a solenoid, if its resistance is 5 ohms and 0.3 amp flows through the winding when 110 volts at 60 cycles is applied to the solenoid?

34. State the formula for determining the resonant frequency of a circuit where the inductance and capacitance are known.

35. Given a series-resonant circuit consisting of a resistance of 6.5 ohms, and equal inductive and capacitive reactances of 175 ohms. What is the voltage drop across the inductance when the applied potential is 260 volts?

36. Given a series-resonant circuit consisting of a resistance of 6.5 ohms, and equal inductive and capacitive reactances of 175 ohms. What is the voltage drop across the resistance, assuming the applied circuit potential is 260 volts?

37. Explain how you would determine the value of cathode bias resistance necessary to provide correct grid bias for any particular amplifier.

38. Given the following vacuum tube constants, E_p = 1000 volts, I_p = 150 ma, I_g = 10 ma, and grid leak = 5000 ohms, what would be the value of dc grid-bias voltage?

39. What is the percentage regulation of a power supply with a no-load voltage output of 126.5 volts and a full-load voltage output of 115 volts?

40. If a 1500-kc radio wave is modulated by a 2000-cycle sine-wave tone, what frequencies are contained in the output wave?

41. State the formula for determining the percentage modulation in an AM system.

42. If a ship telephone station is assigned the frequency of 2738 kc and the maximum tolerance is 0.04 percent, what are the highest and lowest frequencies within the tolerance limits?

43. Define the term "decibel."

44. A ship radiotelephone transmitter operates on 2738 kc. At a certain point distant from the transmitter the 2738-kc signal has a measured field of 147 mv per meter. The second harmonic field at the same point is measured as 405 μv per meter. To the nearest whole unit in decibels, how much has the harmonic emission been attenuated below the 2738-kc fundamental?

45. If a superheterodyne receiver is tuned to a desired signal at 1000 kc, and its conversion oscillator is operating at 1300 kc, what would be

the frequency of an incoming signal which would possibly cause "image" reception?

46. How much energy is consumed in 20 hours by a radio receiver rated at 60 watts?

47. A 6-volt storage battery has an internal resistance of 0.01 ohm. What current will flow when a 3-watt, 6-volt lamp is connected?

48. What determines the synchronous speed of a synchronous motor?

49. A milliammeter with a full-scale deflection of 1 ma and a resistance of 25 ohms was used to measure an unknown current by shunting the meter with a four-ohm resistor. It then read 0.4 ma. What was the unknown current value?

50. If a 0-1 dc milliammeter is to be converted into a voltmeter with full-scale calibration 100 volts, what value of series resistance must be connected in series with the milliammeter?

51. If a heterodyne frequency meter, having a calibrated range of 1000 to 5000 kc, is used to measure the frequency of a transmitter operating on approximately 500 kc by measurement of the second harmonic of the transmitter, and the indicated measurement was 1008 kc, what is the actual frequency of the transmitter output?

52. If a frequency meter having an over-all error proportional to the frequency, is accurate to 10 cycles when set at 600 kc, what is its error in cycles when set at 1110 kc?

53. What is the total reactance of two inductors, connected in series, with zero mutual inductance?

54. If the mutual inductance between two coils is 0.1 henry, and the coils have inductances of 0.2 and 0.8 henry, respectively, what is the coefficient of coupling?

55. When two coils of equal inductance are connected in series with unity coefficient of coupling and their fields in phase, what is the total inductance of the two coils?

56. A potential of 110 volts is applied to a series circuit containing an inductive reactance of 25 ohms, a capacitive reactance of 10 ohms, and a resistance of 15 ohms. What is the phase relationship between the applied voltage and the current flowing in the circuit?

57. What is the reactance of a capacitor at the frequency of 1000 kc if the reactance is 600 ohms at 800 kc?

58. If an alternating current of 5 amp flows in a series circuit composed of 12 ohms resistance, 15 ohms inductive reactance, and 40 ohms capacitive reactance, what is the voltage drop across the circuit?

59. If a lamp, rated at 100 watts and 115 volts, is connected in series with an inductive reactance of 355 ohms and a capacitive reactance of 130 ohms across a voltage of 220 volts, what is the current value through the lamp?

60. If an ac series circuit has a resistance of 12 ohms, an inductive reactance of 7 ohms, and a capacitive reactance of 7 ohms, at the resonant frequency, what will be the total impedance at twice the resonant frequency?

61. A series circuit contains reactance, inductive reactance, and capacitive reactance. The resistance is 7 ohms, the inductive reactance is 8 ohms, and the capacitive reactance is unknown. What value of reactance must the capacitor have in order for the total circuit impedance to be 13 ohms?

62. If, in a given ac series circuit, the resistance, inductive reactance, and capacitive reactance are of equal magnitude of 11 ohms, and the frequency is reduced to 0.411 of its value of resonance, what is the re-

sultant impedance of the circuit at the new frequency?

63. If an alternating voltage of 115 volts is connected across a parallel circuit made up of a resistance of 30 ohms, an inductive reactance of 17 ohms, and a capacitive reactance of 19 ohms, what is the total current drain from the source?

64. A parallel circuit is made up of five branches, three of the branches being pure resistances of 7, 11, and 14 ohms, respectively. The fourth branch has an inductive reactance value of 500 ohms. The fifth branch has a capacitive reactance of 900 ohms. What is the total impedance of this network? If a voltage is impressed across this parallel network, which branch will dissipate the greatest amount of heat?

65. In a parallel circuit composed of an inductance of 150 microhenries and a capacitance of 160 micromicrofarads, what is the resonant frequency?

66. What value of capacitance must be shunted across a coil having an inductance of 56 microhenries in order that the circuit resonates at 5000 kc?

67. What is the stage amplification obtained with a single triode operating with the following constants: Plate voltage 250, plate current 20 milliamperes, plate impedance 5000 ohms, load impedance 10,000 ohms, grid bias 4.5 volts, and amplification factor 24?

68. If a preamplifier, having a 600 ohm output, is connected to a microphone so that the power output is -40 db, and assuming the mixer system to have a loss of 10 db, what must be the voltage amplification necessary in the line amplifier in order to feed 10 db into the transmitter line?

69. If a certain audio frequency amplifier has an over-all gain of 40 db, and the output is 6 watts, what is the input?

70. What is the power output of an audio amplifier if the voltage across the load resistance of 500 ohms is 40 volts?

71. If a transformer, having a turns ratio of 1:10, working into a load impedance of 2000 ohms, and out of a circuit having an impedance of 15 ohms, what value of resistance may be connected across the load to effect an impedance match?

72. What is the formula for determining the db loss or gain.

73. What unit has been adopted by leading program transmission organizations as a volume unit and to what power is this unit equivalent?

74. If a frequency doubler stage has an input frequency of 1000-kc, and the plate inductance is 60 microhenries, what value of capacitance is necessary for resonance, neglecting stray capacitances?

75. The dc input power to the final amplifier stage is exactly 1500 volts and 700 milliamperes. The antenna resistance is 8.2 ohms and the antenna current is 9 amperes. What is the plate efficiency of the final amplifier?

76. How is the inverse peak voltage to which the tubes of a full-wave rectifier will be subject, determined from the known secondary voltages of the power transformer? Explain.

77. If a power transformer has a primary voltage of 4400 volts, a secondary voltage of 220 volts, and an efficiency of 98%, when delivering 23 amperes of secondary current, what is the value of primary current?

78. Three single phase transformers, each with a ratio of 220 to 2200 volts, are connected across a 220-volt, three phase line, primaries in delta. If the secondaries are connected in Y, what is the sec-

ondary line voltage?

79. What is the predominant ripple frequency in the output of the single phase fullwave rectifier when the primary source of power is 110 volts at 60 cycles?

80. If a power supply has a regulation of 11% when the output voltage at full-load is 240 volts, what is the output voltage at no load?

81. If a power supply has an output voltage of 140 volts at no load, and the regulation at full load is 15%, what is the output voltage at full load?

82. A rectifier filter power supply is designed to furnish 500 volts at 60 milliamperes to one circuit, and 400 volts at 40 milliamperes to another circuit. The bleeder current in the voltage divider is to be 15 milliampere. What value of resistance should be placed between the 500 and 400-volt taps of the voltage divider?

83. A 600-kc X-cut crystal, calibrated at 50° C, and having a temperature coefficient of -20 parts per million per degree, will oscillate at what frequency when its temperature is 60°C?

84. A certain transmitter has an output of 100 watts. The efficiency to the final, modulated amplifier stage is 50%. Assuming that the modulator has an efficiency of 66%, what plate input to the modulator is necessary for 100% modulation of this transmitter? Assume that the modulator output is sinusoidal.

85. If you decrease the percentage of modulation from 100% to 50% by what percentage have you decreased the power in the side-bands?

86. If the power output of a modulator is decreased from 1000 watts to 10 watts, how is the power expressed in db?

87. Given a Class C amplifier with a plate voltage of 1000 volts, and a plate current of 150 milliamperes which is to be modulated by a Class A amplifier with a plate voltage of 2000 volts, plate current of 200 milliamperes and a plate impedance of 15,000 ohms. What is the proper turns ratio for the coupling (modulation) transformer?

88. If the transmission line current of an FM broadcast transmitter is 8.5 ampere without modulation, what is the transmission line current when the percentage of modulation is 90%?

89. If the conductors in a two-wire radio frequency transmission line are replaced by larger conductors, how is the surge impedance affected, assuming no charge in the center to center spacing of the conductor?

90. The power input to a 72-ohm concentric transmission line is 5000 watts. What is the RMS voltage between the inner conductor and sheath?

91. The power input to a 72-ohm concentric line is 5000 watts. What is the current flowing in it?

92. An antenna is being fed by a properly terminated two-wire transmission line. The current in the line at the input end is 3 amperes. The surge impedance of the line is 500 ohms. How much power is being supplied to the line?

93. A long transmission line delivers 10kw into an antenna; at the transmitter end, the line current is 5 amperes and at the coupling house, it is 4.8 amperes. Assuming the line to be properly terminated, and the losses in the coupling system negligible, what is the power loss in the line?

94. A 50kw transmitter employs six tubes in push-pull parallel in the final Class B linear stage, operating with a 50kw output and an efficiency of 33%. Assuming that all the heat radiation is transferred to the water cooling system, what amount of

power must be dissipated from each tube?

95. If the daytime transmission line current of a 10-kw transmitter is 12 amperes, and the transmitter is required to reduce to 5-kw at sunset, what is the new value of transmission line current?

96. If the power output of a broadcast station is quadrupled what effect will this have upon the field intensity at a given point?

97. What is the frequency swing of an FM broadcast transmitter when modulated 60%?

98. If an FM transmitter employs one doubler, one tripler, and one quadrupler, what is the carrier frequency swing when the oscillator frequency swing is 2-kc?

99. An FM broadcast transmitter operating on 98.1 megacycles has a reactance tube modulated oscillator operating on a frequency of 4905-kc. What is the oscillator frequency swing when the transmitter is modulated 100% by a 2000-cycle tone?

100. An FM broadcast transmitter is modulated 50% by a 7000-cycle test tone. When the frequency of the test tone is changed to 5000 cycles and the percentage of modulation is unchanged, what is the transmitter frequency swing?

101. An FM broadcast transmitter is modulated 40% by a 5000-cycle test tone. When the percentage of modulation is doubled, what is the frequency swing of the transmitter?

102. What is the approximate speed of a 220-volt, 60-cycle, 4-pole, 3-phase induction motor?

103. What is the ohms per-volt of a voltmeter constructed of a zero-1 dc milliammeter and a suitable resistor which makes the full-scale reading of the meter 500 volts?

104. A current squared meter has a scale divided into 50 equal divisions. When 45 milliamperes flows through the meter, the deflection is 45 divisions. What is the current flowing through the meter when the scale deflection is 25 divisions?

105. If a heterodyne frequency meter, having a straight line relation between frequency and dial reading, has a dial reading of 31.7 for a frequency of 1390-kc, and a dial reading of 44.5 for a frequency of 1400-kc, what is the frequency of the ninth harmonic of the frequency corresponding to a scale reading of 41.2?

106. If a broadcast station receives a frequency measurement report indicating that the station frequency was 45 cycles low at a certain time, and the transmitter log for the same time, shows the measured frequency to be 5 cycles high, what is the error of the station frequency monitor?

107. If the two towers of a 950-kc directional antenna are separated by 120 electrical degrees, what is the tower separation in feet?

108. What must be the height of a vertical radiator one-half wavelength high if the operating frequency is 1100-kc?

109. If the vertical antenna is 405 feet high and is operated at 1250-kc, what is the physical height, expressed in wavelength?

110. If the field intensity of 25 millivolts per-meter develops 2.7 volts in a certain antenna, what is its effective height?

111. If the power output of a broadcast station has been increased so that the field intensity at a given point is doubled, what increase has taken place in antenna current?

112. If the day input power to a certain broadcast station antenna having a resistance of 20 ohms is 2000 watts, what would be the night input power if the antenna current were cut in half?

113. If the antenna current of a

station is 9.7 amperes for 5 kilowatts, what is the current necessary for a power of 1-kilowatt?

114. What is the antenna current when a transmitter is delivering 900 watts into an antenna having a resistance of 16 ohms?

115. The ammeter connected at the base of a Marconi Antenna has a certain reading. If this reading is increased 2.77 times, what is the increase in output power?

116. An FM broadcast transmitter has 370 watts plate power input to the last radio frequency stage and an antenna field gain of 1.3. The efficiency of the last radio frequency stage is 65% and the efficiency of the antenna transmission line is 75%. What is the effective radiated power?

117. What is the effective radiated power of a television broadcast station if the output of the transmitter is 1000 watts, the antenna transmission line loss is 50 watts and the antenna power gain is 3?

Answers

1. $E = IR$, $R = \frac{E}{I}$ and $I = \frac{E}{R}$

2. Using Ohm's Law, $R = \frac{E}{I}$, by substitution,

$$R = \frac{30}{5} = 6 \text{ ohms.}$$

3. Resistors in series add. Thus, $R_t = R_1 + R_2 + \text{etc.}$ Substituting the values given, $R_t = 10 + 5 = 15$ ohms (R_t = total resistance).

4. For two resistors connected in parallel, the total effective resistance can be determined by using the formula

$$R_t = \frac{R_1 R_2}{R_1 + R_2}$$

where R_t is the total effective resistance and R_1 and R_2 represent the individual resistors. Substituting the values given,

$$R_t = \frac{10 \times 15}{10 + 15} = \frac{150}{25} = 6 \text{ ohms}$$

5. $I = \frac{E}{R} = \frac{6}{300} = 0.02$ amp = 20 ma.

6. $E = IR = 0.05 \times 100 = 5$ volts.

7. When more than two resistors are connected in parallel, the following formula is used to determine the total effective resistance.

$$R_t = \frac{1}{\frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \text{etc.}}$$

Substituting the values given,

$$R_t = \frac{1}{\frac{1}{5} + \frac{1}{10} + \frac{1}{20}}$$

$$= \frac{1}{0.2 + 0.1 + 0.05}$$

$$= \frac{1}{0.35}$$

$$= 2.86 \text{ ohms}$$

This problem could also be solved by finding a lowest common denominator in the fractional denominator in the first step. Thus,

$$R_t = \frac{1}{\frac{1}{5} + \frac{1}{10} + \frac{1}{20}}$$

$$= \frac{1}{\frac{4}{20} + \frac{2}{20} + \frac{1}{20}}$$

$$= \frac{1}{\frac{7}{20}}$$

Then, inverting and multiplying,

$$R_t = \frac{1 \times 20}{7} = \frac{26}{7} = 2.86 \text{ ohms}$$

8. Because the battery is the 6-volt type, the resistor must "drop" the remaining 109 volts available from the line. (115-6) From Ohm's Law we have the simple relation that

$$R = \frac{E}{I}$$

By substituting the values from our problem in this formula, we obtain

$$R = \frac{109}{3}$$

$$= 36.3 \text{ ohms}$$

9. This problem is very similar to No. 8. The supply voltage is 6 volts and we need 5 volts. The resistor must, therefore, drop 1 volt. By Ohm's Law,

$$R = \frac{E}{I}$$

$$= \frac{1}{0.25}$$

$$= 4 \text{ ohms}$$

10. During normal operation, the voltage drop across the coil is

$$E = IR = 0.3 \times 600 = 180 \text{ volts}$$

Thus, the series resistor must drop 220 - 180 = 40 volts. Again, by simple Ohm's Law,

$$R = \frac{E}{I}$$

$$= \frac{40}{0.3}$$

$$= 133.3 \text{ ohms}$$

11. $P = EI \quad P = I^2R \quad P = \frac{E^2}{R}$

12. In this problem we are given I and R. Thus, we use the formula

$$\begin{aligned} P &= I^2R \\ &= (0.2)^2 \times 50 \\ &= 0.04 \times 50 \\ &= 2 \text{ watts} \end{aligned}$$

13. Returning to the basic formula $P = I^2R$, in this problem we know P and R. The job is to find the value of I.

If we divide both sides of the basic formula by R, we obtain,

$$\frac{P}{R} = I^2$$

Then, to find I, we must eliminate the square. We can do this by taking the square root of both sides of the equation. When this is done,

$$I = \sqrt{\frac{P}{R}}$$

since the square root of a square is the quantity itself. Substituting the values originally given,

$$I = \sqrt{\frac{200}{5000}}$$

$$= \sqrt{0.04}$$

$$= 0.2 \text{ ampere}$$

14. Each resistor is able to handle five watts without overheating. This dissipation capability is unaffected by the method of connection. The two resistors, either in series or parallel, can, therefore, dissipate a total of 10 watts.

15. The efficiency of any device is equal to the useful output power divided by the input power. The trans-

mitter efficiency in this problem is therefore,

$$\frac{300}{500} = 0.6, \text{ or } 60\%$$

16. (1) The quantity of electricity is given by the formula

$$Q = CE$$

where Q is in coulombs, C is in farads, and E is in volts. (2) The energy stored in a capacitor is expressed by the formula

$$W = \frac{1}{2}E^2C$$

where W is expressed in joules. One joule is defined as the energy expended in one second by an electric current of one ampere through a resistance of one ohm.

17. $C_t = C_1 + C_2 + C_3$, etc.

18. $C_t = \dfrac{1}{\frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} + \text{etc.}}$

19. $C_t = \dfrac{1}{\frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3}}$

By substitution,

$$C_t = \frac{1}{\frac{1}{5} + \frac{1}{3} + \frac{1}{7}}$$

The LCD (lowest common denominator) for 5, 3, and 7 is 105. Thus,

$$C_t = \frac{1}{\frac{21}{105} + \frac{35}{105} + \frac{15}{105}}$$

$$= \frac{1}{\frac{71}{105}}$$

$$= \frac{105}{71}$$

$$= 1.48\ \mu f$$

20. $C_t = 10 + 20 + 30$
$= 60\ \mu f$

21. The formula Q = CE can be transposed to

$$E = \frac{Q}{C}$$

We can then see that when C is doubled, by the parallel connection, E is halved. The voltage across the two capacitors in parallel is, therefore, 58 volts.

22. $W = \frac{1}{2}LI^2$

where L = inductance in henries
I = current in amperes
W = energy in joules

23. $\lambda = \dfrac{300{,}000}{f}$ (kc)

where λ = wavelength in meters (Greek letter Lambda)

f = frequency

24. We must first determine frequency in cycles per second. The frequency is equal to the reciprocal of the period of one complete cycle. Thus,

$$f\ (\text{cps}) = \frac{1}{0.000001} = 1{,}000{,}000\ \text{cps}$$

Then, because 1,000,000 cps equals 1000 kc, we can use the formula previously given to find wavelength, that is,

$$\lambda = \frac{300{,}000}{1000} = 300\ \text{meters}$$

A more direct solution of the problem is to recall that electromagnetic waves travel 300,000,000 meters per second. In 0.000001 second, the wave must, therefore, travel

$$300{,}000{,}000 \times 0.000001 = 300 \text{ meters}$$

25. The effective (RMS) value of a sine wave is equal to 0.707 times the peak value. If the RMS value is applied to a resistance, it produces the same heating effect as an equal dc value.

26. A harmonic is defined as a multiple of the fundamental frequency, in this case, 360 kc. The 7th harmonic is, therefore, the 7th multiple of 360 kc,

$$7 \times 360 = 2520 \text{ kc}$$

27. The power factor can be determined when we know any of the following:

a. The ratio of true power (as measured by a wattmeter) to apparent power, as measured by a voltmeter and ammeter.

$$pf = \frac{P}{EI}$$

b. The ratio of resistance to impedance

$$pf = \frac{R}{Z}$$

c. The phase angle, Θ ($pf = \cos \Theta$)

d. The values of resistance and reactance. We then use these values to determine Z and then find the pf as in b.

28. When the reactance and resistance of a circuit are equal, the phase angle is 45°. If the reactance is greater than the resistance, the phase angle is some value between 45° and 90°. If the reactance is less than the resistance, the phase angle is some value between 0° and 45°.

29. $I = \frac{E}{Z} \quad Z = \frac{E}{I} \quad E = IZ$

where Z = circuit impedance in ohms.

30. The formula for determining inductive reactance X_L in ohms is

$$X_L = 2\pi fL$$

where 2π = a constant equal to approximately 6.28.

f = frequency in cycles per second

L = inductance in henries

Substituting the values given,

$$\begin{aligned} X_L &= 6.28 \times 5 \times 10^5 \times 6 \times 10^{-3} \\ &= 188.4 \times 10^2 \\ &= 18{,}840 \text{ ohms} \end{aligned}$$

31. The formula for finding capacitive reactance is

$$X_C = \frac{1}{2\pi fC}$$

where X_C = capacitive resistance in ohms

2π = a constant equal to approximately 6.28

f = frequency in cycles per second

C = capacitance in farads

Substituting the values,

$$\begin{aligned} X_C &= \frac{1}{6.28 \times 2 \times 10^{-8} \times 2 \times 10^4} \\ &= \frac{1}{25.12 \times 10^{-4}} \\ &= 398 \text{ ohms, approximately} \end{aligned}$$

32. The formula for determining

the voltage drop across the inductance is

$$E_L = IX_L$$

where E_L = voltage drop across inductance L

I = current in amperes through L

X_L = inductive reactance of L in ohms.

To use this formula, we must first determine circuit current. Because this is a series ac circuit the same current exists in all parts of the circuit and is equal to the ratio $E \div Z$. Impedance Z, in turn, is equal to

$$\begin{aligned} Z &= \sqrt{R^2 + (X_L - X_C)^2} \\ &= \sqrt{4^2 + (4 - 1)^2} \\ &= \sqrt{4^2 + 3^2} \\ &= \sqrt{16 + 9} \\ &= \sqrt{25} \\ &= 5 \text{ ohms} \end{aligned}$$

Then, $I = E \div Z = 50 \div 5 = 10$ amperes. Finally, we go back to the original formula given:

$$\begin{aligned} E_L &= IX_L \\ &= 10 \times 4 \\ &= 40 \text{ volts} \end{aligned}$$

33. In this case, Z is given by the basic relation $Z = E \div I$. Substituting given values in this equation:

$$Z = \frac{110}{0.3} = 367 \text{ ohms, approximately.}$$

34. $$f = \frac{1}{2\pi\sqrt{LC}}$$

where f = frequency in cycles per second

L = inductance in henries

C = capacitance in farads

35. The basic formula for impedance is $Z = \sqrt{R^2 + X^2}$. Obviously, if $X^2 = 0$, then $Z = R$, because the square root of a value squared is equal to the value itself. Thus, in the problem being considered, $Z = 6.5$ ohms, and by basic Ohm's Law, $I = E \div Z = 260 \div 6.5 = 40$ amperes. Then $E_L = IX_L = 40 \times 175 = 7000$ volts.

36. Because X_L and X_C are equal, the voltage drops developed across them cancel. Also, because we are dealing with a simple series circuit in which the sum of the voltage drops around the circuit is equal to the applied voltage, the entire 260 volts of applied emf must be dropped across the resistor.

37. The value of grid bias voltage is equal to

$$E_{CC} = IR_K$$

and,

$$R_K = E_{CC} \div I$$

where E_{CC} = desired grid bias voltage in volts

I = total current passing through cathode bias resistor in amps. R_K = resistance of cathode bias resistor in ohms.

Note: "I" may include plate and screen grid currents.

38. In this problem, notice that E_p and I_p are of no concern. The dc grid-bias voltage is determined entirely by grid current I_g and the value of the grid leak. Thus,

$$\begin{aligned} E_{CC} &= I_g R_g \\ &= 0.01 \times 5000 \\ &= 50 \text{ volts} \end{aligned}$$

39. The voltage regulation of a device is defined as the change in

voltage between full load and no load divided by the full-load voltage. To express regulation as a percentage regulation, as determined above, it is multiplied by 100. Thus, in our problem,

Percentage Regulation

$$= \left(\frac{126.5 - 115}{115}\right) 100$$

$$= \left(\frac{11.5}{115}\right) 100$$

$$= 0.1 \times 100$$

$$= 10\%$$

40. Assuming amplitude modulation is used, there will be the carrier frequency of 1500 kc and two sidebands, one 2 kc below the carrier and the other, 2 kc above the carrier. If FM is used, additional sidebands spaced at 2 kc intervals are also present. The number of such sidebands that need be considered depends on the modulation index.

41. Percentage modulation

$$= \left(\frac{E_{max} - E_{min}}{E_{max} + E_{min}}\right) 100$$

where E_{max} and E_{min} are the maximum and minimum values of the modulation envelope.

42. The first step is to determine the maximum permissible deviation from the assigned frequency,

$$0.0004 \times 2738 = 1.0952 \text{ kc}$$

Notice here that 0.04 percent is written as 0.0004 because percent means "by the hundred". Thus 0.04 means four hundredth parts of a quantity or number. The word "percent" or the symbol % thus does the job of two decimal places. The upper frequency limit is then

$$2738 + 1.0952 = 2739.0952 \text{ kc}$$

and the lower frequency limit is

$$2738 - 1.0952 = 2736.9048 \text{ kc}$$

43. The decibel is a unit used to express the ratio between two sound or electric power levels. The formula for calculating decibels (db) is

$$db = 10 \log_{10} \frac{P_1}{P_2}$$

where P_1 is generally the larger power. If amplification is involved, db becomes a plus (+) value, that is, simply db. If attenuation is involved, db is preceded by the negative (-) sign. Decibels can also be used to express the ratio between two voltages or two currents as follows:

$$db = 20 \log_{10} \frac{E_1}{E_2}$$

and

$$db = 20 \log_{10} \frac{I_1}{I_2}$$

In both of the above forms of the db equation, the two voltages or two currents involved must be measured at points of equal impedance.

In working with db in power problems, the following relations are useful to remember: an increase of 10 db increases power 10 times; an increase of 3db doubles the power, and a decrease of 3 db (-3 db) cuts power in half.

When working with voltages or currents, double the number of db involved to retain the same relationship. For example, an increase of 20 db increases E and I 10 times; an increase of 6 db doubles E and I; etc.

44. To have both the fundamental and harmonic field strength stated in the same units, we will first convert the signal strength, given in mv per meter, to µv per meter. This is accomplished simply by moving the decimal point three places to the right, so that 147 mv becomes 147,000 µv per meter. We now use the correct db formula using two voltages. Thus,

$$\text{db} = 20 \log_{10} \frac{147{,}000}{405}$$

$$= 20 \log_{10} 363$$

Because there are three places to the left of the decimal point, the characteristic for 363 is 2. From a table of logs we find the mantissa is 0.5599. Thus, the log of 363 is 2.5599, and

$$\begin{aligned}\text{db} &= 20\ (2.5599)\\ &= 51.2 \text{ approximately}\end{aligned}$$

If no log tables are available, we can estimate the answer from the relationships previously given. Multiplying 405 µv/m by 10 represents an increase of 20 db, and gives a value of 4050 µv/m. Multiplying again by ten gives us 40,500 µv/m and represents 40 db. If we double this value, it becomes 81,000 µv/m and represents 40 + 6 = 46 db. Doubling the voltage again gives a value of 162,000 µv/m and represents 46 + 6 = 52 db. This is somewhat higher than the 147,000 µv/m in our problem, but provides us with a reasonable estimate.

45. An image frequency lies as far above the oscillator frequency as the signal frequency does below the oscillator frequency. The difference between the desired signal and the oscillator frequency is called the "intermediate frequency." This intermediate frequency is equal to the difference between the image and oscillator frequencies. The image frequency is equal to the signal frequency plus twice the intermediate frequency.

In this problem, the i-f frequency is equal to 1300 - 1000 = 300 kc. The image frequency is then equal to 2(300) + 1000 = 1600 kc.

46. The watt hour is the unit used to measure work done in an electrical circuit. It is equal to the product of the circuit power in watts and time in hours. Thus, in this problem;

$$60 \times 20 = 1200 \text{ watt hours.}$$

This answer may also be expressed as 1.2 kilowatt hours.

47. By Ohm's Law, $I = E \div R$, where R is equal to the internal resistance of the battery plus the resistance of the light bulb. The resistance of the bulb is found by using the formula

$$\begin{aligned}R &= \frac{E^2}{P}\\ &= \frac{6^2}{3}\\ &= 12 \text{ ohms}\end{aligned}$$

The total resistance then is 12 + 0.01 = 12.01 ohms, and the circuit current is,

$$\begin{aligned}I &= E \div R\\ &= 6 \div 12.01\\ &= 0.4996 \text{ ampere or,}\end{aligned}$$

for practical purposes 0.5 ampere.

48. The number of poles and the frequency of the supply voltage. The speed in revolutions per minute is equal to 60 times the frequency di-

vided by the number of pairs of poles, that is

$$\text{rpm} = 60 \times f \div N$$

where N is the number of pairs of poles.

49. By Ohm's Law, the voltage drop is equal to IR. Thus,

$$E = IR = 0.0004 \times 25 = 0.01 \text{ volt}$$

Because the same voltage exists across all branches of a parallel circuit, the same 0.01 volt must act across the shunt so that the current through the shunt is,

$$I = E \div R = 0.01 \div 4 = 2.5 \text{ ma}$$

The unknown current value must, then, be the sum of the currents through the meter and through the shunt, that is,

$$0.4 + 2.5 = 2.9 \text{ ma}$$

50. The added value of resistance must be such that when 100 volts is applied across the meter, no more than 1 ma current passes through the meter. Thus,

$R = E \div I = 100 \div 0.001 = 100{,}000$ ohms.

51. The second harmonic is 1008 kc, the fundamental must be $1008 \div 2 = 504$ kc.

52. To find the error, which is proportional to frequency, we set up the following proportion:

$$\frac{10}{X} = \frac{600}{1110}$$

and by cross multiplication

$$600X = 11{,}110$$
$$X = 18.5 \text{ cps}$$

53. The basic formula that applies in this case is

$$L_t = L_1 + L_2 \pm 2M$$

where M is the mutual inductance, and L_1 and L_2 are the inductance of the two inductors. The formula indicates that if $M = 0$, then L_t is simply the sum of $L_1 + L_2$.

If the lines of force from one coil link the turns of the other, M is no longer zero, but assumes a definite value and must be considered in problems such as the above. If the fields aid each other, we use + 2M, and if the fields oppose each other, -2M.

54. The coefficient of coupling, designated k, is a measure of the degree of coupling between two circuits, and has a value ranging from 0 to 1. The two extremes indicate no coupling and maximum possible coupling, respectively. The formula for k is,

$$k = \frac{M}{\sqrt{L_1 L_2}}$$

when M is the mutual inductance in henries, L_1 and L_2 are the inductances of two coils in henries, and k is the coefficient of coupling, expressed as a pure number (dimensionless). Substituting the values given,

$$k = \frac{0.1}{\sqrt{0.2 \times 0.8}}$$
$$= \frac{0.1}{\sqrt{.16}}$$
$$= .1 \div .4$$
$$= 0.25$$

55. The mutual inductance between the two coils is found by simply transposing the formula given for k. This is accomplished by multiplying both sides of the equation by the square root of L_1 L_2. Thus,

$$M = k\sqrt{L_1 \; L_2}$$

Because k is given as unity (1), and L_1 is given as equal to L_2, the mutual inductance M is equal to the value of either L_1 or L_2. Thus, the total inductance is equal to four times the inductance of either coil. This can be seen in the equation

$$L_t = L_1 + L_2 + 2M$$

when M = L. Thus,

$$\begin{aligned} L_t &= L_1 + L_2 + 2L \\ &= 4L \end{aligned}$$

56. The phase angle is equal to the angle whose tangent is equal to $X \div R$. In the above problem the total reactance is $25 - 10 = 15$. Then the ratio $X \div R = 15 \div 15 = 1$. From a set of trigonometric tables, the angle is found to be 45°. Just remember, in any circuit where $X = R$, the phase angle is 45°. If the reactance is predominantly inductive, as in this problem, the 45° phase angle is said to be a "leading" phase angle. If capacitive reactance predominates, voltage lags current and the 45° phase angle is then "lagging". In either case, notice that "lead" or "lag" refers to the voltage in the circuit.

57. The reactance of a capacitor varies inversely with frequency; as frequency increases X_C decreases, and as frequency decreases, X_C increases. Thus, we can write,

$$\frac{600}{X} = \frac{1000}{800}$$

where $X = X_C$ at 1000 kc. Cross-multiplying,

$$\begin{aligned} 1000 \times &= (600 \times 800) \\ 1000 \times &= 480{,}000 \\ \times &= 480 \text{ ohms} \end{aligned}$$

58. The formula used in this solution of problems of this type is very similar to the formula for determining the impedance of an ac circuit. Mathematically,

$$E = E_R^2 + E_X^2$$

where E_X^2 is the algebraic sum of the voltages across the reactances. The voltage developed across the various elements are:

$$E_R = IR = 5 \times 12 = 60 \text{ volts}$$

$$E_L = IX_L = 5 \times 15 = 75 \text{ volts}$$

$$E_C = IX_C = 5 \times 40 = 200 \text{ volts}$$

Substituting these values in the previously given formula,

$$\begin{aligned} E &= (60)^2 + (200 - 75)^2 \\ &= (60)^2 + (125)^2 \\ &= 19{,}225 \\ &= 138.6 \text{ volts} \end{aligned}$$

59. Circuit current can only be determined after the lamp resistance and circuit impedance are known. The formula used for resistance is

$$R = \frac{E^2}{P} = \frac{(115)^2}{100} = 132.2 \text{ ohms}$$

This value is then used in the standard formula for impedance,

$$Z = \sqrt{R^2 + (X_L - X_C)^2}$$

$$= \sqrt{(132.2)^2 + (355 - 130)^2}$$

$$= \sqrt{(132.2)^2 + (225)^2}$$

$$= \sqrt{17477 + 50625}$$

$$= \sqrt{68102}$$

$$= 261 \text{ ohms}$$

As a final step,

$$I = \frac{E}{Z} = \frac{220}{261} = 0.843 \text{ ampere}$$

60. Inductive reactance is directly proportional to frequency and capacitive reactance is inversely proportional to frequency. Therefore, X_L is doubled, and X_C is halved when the frequency is doubled. Under these conditions,

$$Z = \sqrt{R^2 + (X_L - X_C)^2}$$

$$= \sqrt{(12)^2 + (14 - 3.5)^2}$$

$$= \sqrt{144 + 110.25}$$

$$= \sqrt{254.25}$$

$$= 15.9 \text{ ohms}$$

61. The standard formula for impedance is

$$Z = \sqrt{R^2 + X^2}$$

To find X, we first square both sides of the equation

$$Z^2 = R^2 + X^2$$

then subtract R^2 from both sides

$$Z^2 - R^2 = X^2$$

and finally take the square root of both sides

$$X = \sqrt{Z^2 - R^2}$$

where X = total circuit reactance.

Substituting the values given,

$$X = \sqrt{(13)^2 - (7)^2}$$

$$= \sqrt{169 - 49}$$

$$= \sqrt{120}$$

$$= 10.96 \text{ ohms}$$

The value of 10.96 ohms can represent either an inductive reactance (+) or a capacitive reactance (-), but we know we are looking for X_C so X is negative. Then, because

$$X = X_L - X_C = 10.96$$

and

$$= 8 - X_C$$

$$X_C = 18.96 \text{ ohms}$$

62. As noted before, X_L is directly proportional to frequency and X_C is inversely proportional to frequency. When the frequency (f) is reduced to 0.411 its value at resonance, therefore, is

$$X_L = 0.411 \times 11 = 4.52 \text{ ohms}$$

$$X_C = 11 \div 0.411 = 26.7 \text{ ohms}$$

and $Z = \sqrt{R^2 + (X_L - X_C)^2}$

$$= \sqrt{(11)^2 + (26.7 - 4.52)^2}$$

$$= \sqrt{(11)^2 + (22.2)^2}$$

$$= \sqrt{121 + 493}$$

$$= \sqrt{614}$$

$$= 24.8 \text{ ohms}$$

63. Because the same voltage acts across all branches of a parallel circuit

$$I_R = E \div R = 115 \div 30 = 3.83\text{A}$$

$$I_L = E \div X_L = 115 \div 17 = 6.76\text{A}$$

$$I_C = E \div X_C = 115 \div 19 = 6.05\text{A}$$

The total current drain is then equal to the vector sum of the branch currents, that is,

$$\begin{aligned} I_{total} &= \sqrt{I_R^2 + (I_L - I_C)^2} \\ &= \sqrt{(3.83)^2 + (6.76 - 6.05)^2} \\ &= \sqrt{15.27} \\ &= 3.91 \text{ amperes} \end{aligned}$$

64. If we assume an applied voltage of 100 volts,

$$I_1 = E \div R_1 = 100 \div 7 = 14.28 \text{ amps}$$

$$I_2 = E \div R_2 = 100 \div 11 = 9.09 \text{ amps}$$

$$I_3 = E \div R_3 = 100 \div 14 = 7.14 \text{ amps}$$

$$I_4 = E \div X_L = 100 \div 500 = 0.2 \text{ amps}$$

$$I_5 = E \div X_C = 100 \div 900 = 0.111 \text{ amp}$$

The currents through the three resistors are in phase and can be added directly. Thus,

$$\begin{aligned} I_R &= I_1 + I_2 + I_3 \\ &= 14.28 + 9.09 + 7.14 = 30.5 \text{ amps} \end{aligned}$$

Then, because $I_4 = I_L$ and $I_5 = I_C$,

$$\begin{aligned} I_{total} &= \sqrt{I_R^2 + (I_L - I_C)^2} \\ &= \sqrt{(30.5)^2 + (0.2 - 0.111)^2} \\ &= \sqrt{(30.5)^2 + (0.09)^2} \\ &= \sqrt{930 + .0081} \\ &= \sqrt{930} \\ &= 30.5 \text{ amperes} \end{aligned}$$

Knowing E and I, we can write

$$\begin{aligned} Z &= E \div I \\ &= 100 \div 30.5 \\ &= 3.28 \text{ ohms} \end{aligned}$$

Ideally, a capacitor or inductor dissipate no heat. The greatest heat is, therefore, dissipated in one of the resistive branches and is proportional to the power consumed, or to the product of EI. Because E is the same for all branches of a parallel circuit, I is the only value we need consider. The greatest current is in the 7-ohm resistor, and this branch must dissipate the most heat.

65. The resonant frequency of an LC circuit is found by using the formula

$$f = \frac{1}{2\pi\sqrt{LC}}$$

where 2π = constant, approximately 6.28. Thus, in the given problem,

$$\begin{aligned} f &= \frac{1}{6.28\sqrt{1.5 \times 10^{-4} \times 1.6 \times 10^{-10}}} \\ &= \frac{1}{6.28\sqrt{2.4 \times 10^{-14}}} \\ &= \frac{1}{6.28 \times 1.55 \times 10^{-7}} \\ &= \frac{1 \times 10^7}{9.73} \\ &= 1028 \text{ kc} \end{aligned}$$

66. To find the value of C, the formula used in problem 65 is transposed as follows:

First, squaring both sides to remove the radial sign,

$$f^2 = \frac{1}{(2\pi)^2 LC}$$

Then, multiplying both sides of the equation by C and dividing both sides by f^2,

$$C = \frac{1}{4\pi^2 Lf^2}$$

Substituting values given in the problem

$$C = \frac{1}{4(3.14)^2 \times 56 \times 10^{-6} \times (5 \times 10^6)^2}$$

$$= 18.1\ \mu\mu f$$

67. Stage amplification of a single triode is determined by using the formula

$$A = \frac{\mu R_L}{r_p + RL}$$

where A = stage gain

μ = amplification factor of triode

r_p = dynamic plate resistance of triode

R_L = plate load resistor

By substitution then,

$$A = \frac{2.4 \times 10^1 \times 1 \times 10^4}{5000 + 10{,}000}$$

$$= \frac{2.4 \times 10^5}{15{,}000}$$

$$= \frac{2.4 \times 10^5}{1.5 \times 10^4}$$

$$= \frac{2.4 \times 10^1}{1.5}$$

$$= 16$$

68. The total loss in db is

$$-40 + (-10) = -50 \text{ db}$$

Then, we can write

$$-50 + X = 10$$
$$X = 60$$

where X = required gain in db.

Using the basic formula for gain A,

$$db = 20 \log A$$

and substituting

$$60 = 20 \log A$$

$$\log A = \frac{60}{20}$$

$$\log A = 3$$
$$A = \text{antilog } 3$$

$$= 1000$$

69. The formula to use here is

$$db = 10 \log \frac{P_1}{P_2}$$

The output is, obviously P_1 and is, therefore, 6 watts. Thus, in our problem here we can write

$$40 = 10 \log \frac{6}{P_2}$$

$$\log \frac{6}{P_2} = \frac{40}{10}$$

$$\frac{6}{P_2} = \text{antilog } 4$$

$$\frac{6}{P_2} = 10{,}000$$

$$P_2 = \frac{6}{10{,}000}$$

$$= 0.0006 \text{ watts}$$

$$= 600\ \mu \text{ watts}$$

70. This problem is readily solved by using the formula

$$P = \frac{E^2}{R}$$

$$= \frac{40^2}{500}$$

$$= \frac{1600}{500}$$

$$= 3.2 \text{ watts}$$

71. A 15-ohm impedance is connected across the transformer primary. Using the formula

$$Z_S = Z_P \text{ (turns ratio)}^2$$

or

$$Z_S = Z_P \left(\frac{N_S}{N_P}\right)^2$$

where Z_S and Z_P = secondary and primary impedances, respectively, and N_P and N_S = number of primary and secondary turns, respectively, we first find the reflected impedance into the secondary.

$$Z_S = 15 \left(\frac{10}{1}\right)^2$$

$$= 15 \times 10^2$$

$$= 1500 \text{ ohms}$$

For a correct impedance match it is, therefore, necessary that $Z_S = 1500$ instead of 2000 ohms as given in the problem. Now we know that when two impedances are connected in parallel, the effective resistance R_E is equal to

$$R_E = \frac{R_1 R_2}{R_1 + R_2}$$

We already know R_E (1500 ohms) and R_1 (2000 ohms), so the problem is to find R_2. First, multiply both sides of the equation by $(R_1 + R_2)$,

$$R_E (R_1 + R_2) = R_1 R_2$$

Performing the indicated multiplication in the left side of the equation,

$$R_E R_1 + R_E R_2 = R_1 R_2$$

The quantity R_2 now appears on both sides of the equation, but we want it to appear only on one side, by itself, as the unknown. Thus, we must eliminate one of the R_2's. To do this, first subtract $R_E R_2$ from both sides of the equation so that

$$R_E R_1 = R_1 R_2 - R_E R_2$$

Next, factor R_2 in the right side of the equation,

$$R_E R_1 = R_2 (R_1 - R_E)$$

Then divide both sides by $R_1 - R_E$,

$$\frac{R_E R_1}{R_1 - R_E} = R_2$$

Substituting our known values

$$R_2 = \frac{1500 \quad (2000)}{2000 - 1500}$$

$$= \frac{(1.5 \times 10^3)(2 \times 10^3)}{500}$$

$$= \frac{3 \times 10^6}{5 \times 10^2}$$

$$= \frac{3 \times 10^4}{5}$$

$$= 0.6 \times 10^4$$

$$= 6000 \text{ ohms}$$

72. Power gain or loss

$$= 10 \log \frac{P_1}{P_2} \text{ db}$$

When voltages and currents are used in the equation, they must be measured at points of equal impedance and the numerical multiplier is 20 instead of 10.

Thus, voltage gain or loss

$$= 20 \log \frac{E_1}{E_2} \text{ db}$$

and, current gain or loss

$$= 20 \log \frac{I_1}{I_2} \text{ db}$$

73. The volume unit designated VU. The reference level, OVU, is 1 milliwatt in 600 ohms.

74. The formula for finding the resonant frequency f_r is,

$$f_r = \frac{1}{2\pi \sqrt{LC}}$$

and by transposition,

$$C = \frac{1}{4\pi^2 f_r^2 L}$$

Substituting given values,

$$C = \frac{1}{4 \times (3.14)^2 \times (2 \times 10^6)^2 \times 6 \times 10^{-6}}$$

$$= \frac{1}{4 \times 9.86 \times 4 \times 10^{12} \times 6 \times 10^{-5}}$$

$$= \frac{1}{946.56 \times 10^7}$$

$$= \frac{1 \times 10^{-7}}{947}$$

$$= 106 \ \mu\mu\text{f}$$

75. Plate efficiency expressed as a percentage

$$\left(\frac{P_o}{P_i}\right) 100$$

where P_o and P_i = output and input power, respectively.

In turn, $P_o = I^2 R$

$$= 9^2 \times 8.2$$

$$= 664 \text{ watts}$$

and $P_i = EI$

$$= 1.5 \times 10^3 \times 7 \times 10^{-1}$$

$$= 10.5 \times 10^2$$

$$= 1050 \text{ watts}$$

Then, plate efficiency $= \frac{664}{1050} \times 100$

$$= 63.2 \text{ percent}$$

76. The inverse peak voltage across the nonconducting tube is the rms value (peak-to-peak ac voltage) of the entire secondary winding times 1.414, less the drop in the conducting tube.

If the drop across the tube is not specified in a problem, the answer is found by simply multiplying the rms voltage value by 1.414.

77. With 98 percent efficiency, the power output of the secondary is

$$P_o = \frac{220 \times 23}{0.98}$$

$$= 5163 \text{ watts}$$

The same power must be delivered to the primary. Knowing the values of P and E,

$$I = P \div E$$
$$= 5163 \div 4400$$
$$= 1.173 \text{ amperes}$$

78. The secondary line voltage of a delta-Y connected three-phase system is determined by using the formula

$$E_s = E_p \times \text{turns ratio} \times 1.732$$

The turns ratio is the same as the voltage ratio, that is, 10:1, or simply 10. By substitution

$$E_s = 220 \times 10 \times 1.732$$
$$= 3810 \text{ volts}$$

In a Y connection, the output voltage is obviously greater than the voltage across a single line because two windings are in series between any two of the three windings. However, the voltages induced between any of the two windings are not entirely in phase, and this is why we use the factor 1.732 as a multiplier in the above equation, rather than 2.

79. In a single-phase, full-wave rectifier, the lowest and most predominant ripple frequency in the output is twice the applied frequency. Thus, the predominant ripple frequency is 2 × 60 = 120 cycles.

80. The output voltage at no load is equal to the full-load voltage, plus 11 percent of the full-load voltage. Thus,

$$0.11 \times 240 = 26.4 \text{ volts}$$

and no load voltage

$$= 240 + 26.4$$
$$= 266.4 \text{ volts}$$

81. The no-load output voltage E_{NL} is 15 percent greater than the full-load output voltage E_{FL}. Thus, the no-load voltage is equal to 115 percent of the full-load voltage, or

$$E_{NL} = \frac{140}{1.15}$$

$$= 121.7 \text{ volts}$$

In finding E_{NL}, we can also use the formula

$$\text{Regulation } (R) = \frac{E_{NL} - E_{FL}}{E_{FL}}$$

By transposition

$$R\,E_{FL} = E_{NL} - E_{FL}$$

$$R\,E_{FL} + E_{FL} = E_{NL}$$

$$E_{FL}\,(R + 1) = E_{NL}$$

and $$E_{FL} = \frac{E_{NL}}{R + 1}$$

By substitution

$$E_{FL} = \frac{140}{0.15 + 1}$$

$$= \frac{140}{1.15}$$

$$= 121.7 \text{ volts}$$

82. Two currents are present in the resistor section of this question, the 15-ma bleeder current, and the 40-ma taken by the 400-volt circuit. Total current through the resistor is, therefore,

$$40 + 15 = 55 \text{ ma}$$

The voltage drop across the same resistor is

$$500 - 400 = 100 \text{ volts}$$

By Ohm's Law,

$$R = E + I$$
$$= 100 + .055$$
$$= 1{,}818 \text{ ohms}$$

83. The crystal frequency decreases 20 cycles for every megacycle-operating frequency and for every 1°C temperature increase. In this problem the operating frequency is 0.6 mc and temperature increases

10°C. The total decrease in crystal frequency is

$$-20 \times 0.6 \times 10 = -120 \text{ cycles}$$

The new operating frequency is

$$\begin{aligned} 600{,}000 - 120 &= 599{,}880 \text{ cycles} \\ &= 599.88 \text{ kc} \end{aligned}$$

The characteristics of the crystal in this case are sometimes written as $-20 \div 10^6 \div °\text{C}$.

84. It is stated that the efficiency of the final stage is 50 percent. The dc power input to the stage must, therefore, be two times the output, that is, $100 \div 0.5 = 200$ watts. Under conditions of 100 percent modulation, the modulator must supply power equal to 50 percent of the dc power input to the final, that is, $200 \div 2 = 100$ watts. Then, because the efficiency of the modulator is only 66 percent, its input power must be $100 \div 0.66 = 151.5$ watts.

85. Assuming sinusoidal modulation, the power in the sidebands varies as the ratio of sideband power at 100 percent modulation squared to sideband power at the reduced percentage of modulation squared. Taking the values given, the new sideband power is in the ratio of

$$\frac{(100)^2}{(50)^2} = \frac{10{,}000}{2500} = \frac{4}{1}$$

This means P_{SB} is now one quarter (25 percent) of its value at 100 percent modulation.

86. For this problem we use the formula

$$\text{db power loss} = 10 \log_{10} \frac{P_1}{P_2}$$

where $P_1 = 1000$ watts

and $P_2 = 10$ watts

$$\begin{aligned} \text{db} &= 10 \log_{10} \frac{1000}{10} \\ &= 10 \log_{10} 100 \\ &= 10 \times 2 \\ &= 20 \text{ db} \end{aligned}$$

87. When a triode of moderate μ is used as a Class A amplifier, the load impedance should be about twice the dynamic plate resistance of the tube for reasonable power output and acceptable distortion (about 5 percent).

Assuming this condition is satisfied, the load impedance in our problem should be $2 \times 15{,}000 = 30{,}000$ ohms. The load on the modulator tube is equal to the dc plate impedance of the Class C modulated rf amplifier, in this problem,

$$\begin{aligned} \text{load on modulator} &= \frac{E_b}{I_b} = \frac{1000}{0.15} \\ &= 6667 \text{ ohms} \end{aligned}$$

We now have two widely different impedances of 30,000 and 6667 ohms, which must be matched by the modulation transformer.

To obtain this match, the turns ratio of the matching transformer should be equal to the square root of the ratio of the Class C stage impedance to the Class A stage impedance. Thus, the correct turns ratio (T.R.) is,

$$\begin{aligned} \text{T.R.} &= \frac{30{,}000}{6667} \\ &= 4.5 \\ &= 2.12 : 1 \end{aligned}$$

that is, 2.12 to 1.

88. The power output of an FM transmitter remains constant with or without modulation. Thus, the transmission line current remains at 8.5 amperes.

89. The formula for computing surge impedance Z_o is

$$Z_o = 276 \log_{10} \frac{2D}{d}$$

where D is the center-to-center spacing of the conductors and d is the diameter of the conductors.

Examination of the formula indicates that if d is increased while D remains unchanged, Z_o must decrease.

90. Assuming the line is nonresonant, we take the formula

$$P = \frac{E^2}{R}$$

and transpose to

$$E_{rms} = \sqrt{PR}$$

Then, by substitution,

$$\begin{aligned} E_{rms} &= \sqrt{72 \times 5000} \\ &= \sqrt{360{,}000} \\ &= 600 \text{ volts} \end{aligned}$$

If we wanted the peak voltage, we would multiply this rms value by 1.414.

91. Taking the basic formula

$$P = I^2R$$

and

$$I = \sqrt{P + R}$$

Substituting given values,

$$\begin{aligned} I &= \sqrt{\frac{5000}{72}} \\ &= \sqrt{69.5} \\ &= 8.34 \text{ amperes} \end{aligned}$$

92. Here we use the basic formula $P = I^2R$

$$\begin{aligned} P &= 3^2 \times 500 \\ &= 9 \times 500 \\ &= 4500 \text{ watts} \end{aligned}$$

93. We must first determine line impedance, which is equal to the input antenna impedance, assuming proper line termination. We do this by transposing the basic formula $P = I^2R$, so that

$$R = \frac{P}{I^2}$$

Substituting given values,

$$R = \frac{10{,}000}{(4.8)^2} = 434 \text{ ohms}$$

Knowing the value of R, the input power is

$$\begin{aligned} P_i &= I^2R \\ &= 5^2 \times 434 \\ &= 25 \times 434 \\ &= 10{,}840 \text{ watts} \end{aligned}$$

Then the line power loss is equal to $P_i - P_o$, that is,

$$\begin{aligned} \text{line power loss} &= 10{,}840 - 10{,}000 \\ &= 840 \text{ watts} \end{aligned}$$

94. We must first find the total power input which is equal to the power output divided by efficiency. Thus,

$$P_i = \frac{50{,}000}{0.33}$$

$$= 151{,}515 \text{ watts}$$

The total power dissipation for all six tubes is equal to

$$P_i - P_o = 151{,}515 - 50{,}000 = 101{,}515$$

Finally, the power dissipated by a single tube is equal to the total power dissipation divided by 6, that is, $101{,}515 \div 6 = 16{,}919$ watts.

95. The power is proportional to the square of the current as shown in the basic formula $P = I^2R$. Thus we can write

$$\frac{P_1}{P_2} = \frac{I_1{}^2}{I_2{}^2}$$

and by transposition

$$I_2 = I_1\sqrt{\frac{P_2}{P_1}}$$

Substituting given values,

$$I_2 = 12\sqrt{\frac{5}{10}}$$

$$= 12\sqrt{0.5}$$

$$= 12 \times 0.707$$

$$= 8.48 \text{ amperes}$$

96. The field intensity varies as the square root of radiated power. If power is increased four times, then field intensity doubles because $\sqrt{4} = 2$.

97. By definition, 100 percent modulation of an FM transmitter occurs when the frequency swing is ± 75 kc. At 60 percent modulation, the frequency swing then becomes

$$0.6 \times \pm 75 = \pm 45 \text{ kc}$$

98. Using a doubler, tripler, and quadrupler, the oscillator swing is multiplied

$$2 \times 3 \times 4 = 24 \text{ times}$$

Thus, the carrier frequency swing is

$$2 \text{ kc} \times 24 = 48 \text{ kc}$$

99. If the oscillator frequency is 4905 kc and the operating frequency is 98.1 mc, the multiplication between the oscillator and the final rf stage is

$$\frac{98.1}{4.905} = 20$$

At 100 percent modulator the output frequency swing is ±75 kc. This means the oscillator frequency swing at 100 percent modulation must be

$$\frac{1}{20} \times 75 \text{ kc} = \pm 3.75 \text{ kc}$$

100. The frequency of the test tone is of no importance in this problem. Since, at 100 percent modulation the frequency swing is ±75 kc, at 50 percent modulation it becomes

$$\frac{75 \text{ kc}}{2} = \pm 37.5 \text{ kc}$$

101. The new frequency swing is 80 percent of that which occurs at 100 percent modulation, that is,

$$0.8 \times 75 \text{ kc} = \pm 60 \text{ kc}$$

102. The voltage and number of phases need not be considered in this problem. The synchronous speed is equal to,

synchronous speed

$$= \frac{\text{line frequency} \times 60}{\text{No. pairs of poles}}$$

and by substitution,

synchronous speed

$$= \frac{60 \times 60}{2} = 1800 \text{ rpm}$$

In a synchronous motor, the emf generated by the rotor must be exactly the correct amount to produce a current that, in turn, produces a torque equal to the combined resisting torque of the load and rotor losses. This characteristic requires that the running speed be somewhat less, about 2 to 3 percent in the motor described, than the synchronous speed. This difference in speed is called "slip." Thus, the running speed of the motor in this problem would be

$$1800 \times 0.98 = 1764 \text{ rpm}$$

for 2 percent slip and

$$1800 \times 0.97 = 1746 \text{ rpm}$$

for 3 percent slip.

103. Regardless of the full-scale meter reading, the ohms per volt of a meter is equal to the reciprocal of full-scale current. Thus, in this problem,

$$\text{ohms per volt} = \frac{1}{0.001}$$

$$= 1000$$

104. The needle deflection is proportional to the square of measured current even though the scale is linear (has equal division). This permits us to set up the proportion

$$\frac{D_1}{D_2} = \frac{I_1{}^2}{I_2{}^2}$$

where D_1 = deflection of 25 divisions
D_2 = deflection of 45 divisions
I_2 = current for deflection D_2
I_1 = unknown current

By substitution

$$\frac{25}{45} = \frac{I_1{}^2}{(45)^2}$$

$$I_1{}^2 = \frac{25 \times (45)^2}{45}$$

$$I_1{}^2 = 25 \times 45$$

and $I_1 = \sqrt{25 \times 45}$

$$I_1 = \sqrt{1125}$$
$$= 33.5 \text{ ma}$$

105. When the frequency is changed 10 kc, from 1390 to 1400 kc, the dial reading changes 44.5 - 31.7 = 12.8 divisions. When the scale reading is 41.2 it is 9.5 divisions higher than the reading at 1390 kc, (41.2 - 31.7 = 9.5). Because 12.8 divisions represents 10 kc,

$$\frac{9.5}{12.8} \times 10 = 7.421 \text{ kc}$$

and the frequency at a dial reading of 41.2 is

$$1390 + 7.421 = 1397.421 \text{ kc}$$

The ninth harmonic of this frequency is

$$9 \times 1397.421 = 12576.789 \text{ kc}$$

106. The error in the monitor is the sum of the low reading report and the high reading recorded in the log, that is, 45 + 5 = 50 cps.

107. If 360° represents one wave-

length, the towers are separated by 1/3 wavelength (360/120). Converting the frequency in kc to wavelengths in meters

$$\lambda = \frac{300,000}{950}$$

$$= 316 \text{ meters}$$

The tower separation in meters is then

$$\frac{316}{3} = 105.3$$

To convert meters to feet, we multiply by 3.28. Thus, the tower separation in feet is

$$3.28 \times 105.3 = 345.4 \text{ feet}$$

108. The wavelength in meters is

$$= \frac{300,000}{1100}$$

$$= 272.7 \text{ meters}$$

One half wavelength at 1100 kc is, therefore,

$$\frac{272.7}{2} = 136.35 \text{ meters}$$

Multiplying by 3.28 we obtain the height of the half-wave vertical radiator in feet

$$3.28 \times 136.35 = 447 \text{ feet}$$

109. Changing height in feet to meters, we obtain

$$\frac{405}{3.28} = 123.44 \text{ meters}$$

Then, changing frequency in kc to meters,

$$= \frac{300,000}{1250}$$

$$= 240 \text{ meters}$$

Finally the ratio of the two measurements in meters is

$$\frac{123.44}{240} = 0.514 \text{ wavelengths}$$

110. The effective height is equal to the ratio of the total voltage developed, to the voltage developed per meter, that is,

$$\frac{2.7}{0.025} = 108 \text{ meters}$$

Converting to feet,

$$108 \times 3.28 = 354 \text{ feet}$$

111. Field intensity is directly proportional to antenna current and is a measure of voltage. When field density doubles, so does antenna current.

112. We know that $P = I^2R$. Inspecting this formula, it is apparent that when R is constant, if we cut I in half, P is reduced to $\frac{1}{4}$ its former value. Thus, the right input power is

$$\frac{1}{4} \times 2000 = 500 \text{ watts}$$

113. Power is proportional to the square of current, so we can write

$$\frac{P_1}{P_2} = \frac{{I_1}^2}{{I_2}^2}$$

By substitution

$$\frac{1}{5} = \frac{{I_1}^2}{(9.7)^2}$$

and transposing

$$I_1 = \frac{9.7}{\sqrt{5}}$$

$$= 4.33 \text{ amperes}$$

114. Here, we use the formula

$$I^2 = P/R \quad \text{and} \quad I = \sqrt{P/R}$$

substituting

$$I = \sqrt{\frac{900}{16}} = \frac{30}{4} = 7.5 \text{ amperes}$$

115. Output power is proportional to the square of the current. In this problem the increase in current is 2.77 times. Output power is, therefore,

$$(2.77)^2 = 7.67$$

times as great as its previous value.

116. The power output of the last rf stage is 370 × 0.65 = 241 watts. The power reaching the antenna is 241 × 0.75 = 180.4 watts. (Twenty-five percent is dissipated on line).

The antenna power gain is equal to the square of the antenna field gain, that is, $(1.3)^2 = 1.69$. Then, the effective radiated power is

$$1.69 \times 180.4 = 305 \text{ watts}$$

117. The power reaching the antenna is

$$1000 - 50 = 950 \text{ watts}$$

With an antenna power gain of 3, the effective radiated power is

$$3 \times 950 = 2850 \text{ watts}$$

SHOULD YOU DEPEND ON LUCK?

Accident--chance--luck--have very little bearing upon the production of any great result or true success in life. Of course, there have been many discoveries and accomplishments which may seem to be the result of "luck."

For instance: Newton "discovered" the law of gravity by watching an apple fall from a tree. Galileo "invented" the telescope after hearing of a toy constructed by a spectacle-maker. Brown "invented" the suspension bridge after watching a spider throw its web.

But these discoveries and inventions were made by men trained to take advantage of what they observed. Thousands of untrained men had seen the same things and paid no attention.

The new discoveries in radio--television--electronics will be made by men trained to take advantage of what they observe.

NATIONAL RADIO INSTITUTE • WASHINGTON, D. C.

FCC RULES AND REGULATIONS

C112X

STUDY SCHEDULE

☐ 1. Introduction . . . . Pages 1 - 2
Recommendations on how and what to study in order to pass your FCC exam are discussed in this section.

☐ 2. Basic Law – Element I . . . . Pages 2 - 5
This section gives 28 questions and answers on Element I.

☐ 3. Basic Operating Practice – Element II . . . . Pages 5 - 20
Fifty four general questions and answers and 68 Maritime questions and answers are covered in this section.

☐ 4. Basic and Advanced Radiotelephone for Elements III and IV. Pages 20 - 30
Here you study 55 questions and answers on Elements III and IV.

☐ 5. Glossary – FCC Words and Phrases . . . . Pages 31 - 85

CEC1M175 1975 EDITION Litho in U.S.A.

FCC Rules and Regulations

Although your final goal is a first-class radiotelephone license, the job is made somewhat easier by first acquiring a third-class radiotelephone permit. To do this, you must pass Elements I and II, which are essentially non-technical and made up largely of laws and regulations. To qualify for broadcast station operation Element IX must be passed. Once you have this permit, you will not have to be re-examined on Elements I and II when you take the examination for a first-class license.

The minimum passing grade on any Element is 75%.

The examination for Element I consists of 20 multiple-choice type questions.

The examination for Element II also consists of 20 multiple-choice type questions. This examination covers practices and procedures generally followed or required in radiocommunications. Two separate tests are offered. One is general and is intended for all persons seeking work in non-marine stations. This includes land, mobile, and aircraft stations. The general questions and answers are from 2.1 to 2.54. Marine questions are preceded by the letter "M".

The third part of this lesson contains "Rules and Regulations" type questions such as might be encountered in Elements III and IV. The examination for Element III consists of 100 questions and for Element IV, 50 questions. It is recommended that you study these questions after completing the material in the regular lesson dealing with television. Certain of these questions provide necessary information about transmitter frequency tolerances, permissible operating powers, methods of measurement acceptable by the FCC, etc. This material is not given in the regular lesson. Just remember, it costs you one to five points to miss a question on any examination, whether it is of a technical nature or related to Rules and Regulations.

A companion book on Rules and Regulations, C111X, should be consulted for more detailed information on many of the questions asked. We recognize that reading material of this type can be extremely tiresome, but it is an important part of your training and a job that must be done if you are to pass your FCC exam. It might be a good idea to underline or otherwise mark information which you will want to study again.

Lesson C111X also contains information related to amateur and citizen's band communications. It is not a required part of your study, but should be looked over at least partially whenever you have the opportunity. It may be that you will be employed by an organization that does a great deal of maintenance work on such equipment and this knowledge will then prove useful.

When you have completed the final examination in your course and, just before you go to take the FCC exam, it is suggested that you restudy the Rules and Regulations information contained both in this lesson and in Lesson C111X. This type of material is the most likely to be forgotten and can often cause the most trouble in passing the exam. More than one man has "sat" for his ticket with good preparation on technical material only to find that he failed due to a lack of knowledge about Rules and Regulations. Just remember, they all count and you cannot afford to give any points away.

It should be apparent by now why we think it is best to get your third class permit first, even though this means an extra trip to the FCC office and may cause you considerable inconvenience.

Basic Law - - Element I

1.1 Where and how is an operator license or permit obtained?

Ans. Licenses and permits are issued by the Federal Communications Commission to those citizens of the United States who have been found qualified to receive them. Applicants for a license or permit must appear before an FCC field engineer at a designated examining point and successfully complete a written examination and show other qualifications as required for the type of license or permit desired.

1.2 Who may apply for an FCC license?

Ans. Generally any citizen or other national of the United States. (The FCC may waive nationality requirements provided the alien holds an aircraft pilot certificate issued by the FAA and public interest is served.)

1.3 What is the usual license term for radio operators?

Ans. Five years from date of issuance.

1.4 When a licensee qualifies for a higher grade of FCC license or permit, what happens to the lesser grade license?

Ans. It will be cancelled upon issuance of the new license.

1.5 When may a license be renewed?

Ans. Any time during the final year of the license term or during a 1-year period of grace after expiration date of the license to be renewed.

1.6 Must a person designated to operate a radiotelephone station post his operator's license or permit, and if so, where?

Ans. Yes. The original license of each station operator must be posted at the place where he is on duty, or kept in his possession in the manner specified in the rules governing the particular class of station concerned.

1.7 If a licensee is notified that he has violated an FCC rule or provision of Communications Act of 1934, what must he do?

Ans. He must send a written reply within 10 days to the office of the Commission originating the official notice. If unavoidable circumstances make it impossible within that time, the reply must be made at the earliest practicable date and a satisfactory explanation given of the delay. The answer must be complete in itself and not abbreviated by reference to other correspondence or answers to other notices. It must contain a statement of action taken to correct the condition or omission. If the notice relates to violations due to physical or electrical characteristics of the transmitting apparatus, the reply shall state what steps, if any, have been taken to prevent future violations. If any new equipment is to be installed, the date of order, the name of the manufacturer, and the promised delivery date must be stated. If this installation requires a construction permit, the application file number or other identification must be given to help locate the application. If the notice relates to lack of attention to, or improper operation of, the transmitter, the name and license number of the operator in charge must be given.

1.8 What are the grounds for suspension of operator licenses?

Ans. Upon proof sufficient to satisfy the Commission that the licensee has: (1) violated any provision of any act, treaty, or convention binding on the United States, which the FCC is authorized to administer, or any regulation made by the FCC under any such act, treaty, or convention; (2) failed to carry out a lawful order of the master or person lawfully in charge of the ship or aircraft on which he is employed; (3) wilfully damaged, or permitted to be damaged, radio apparatus or installation; (4) transmitted superfluous radiocommunications or communications containing profane and/or obscene language or meaning; (5) transmitted false or deceptive signals, or call letters, not assigned by proper authority; (6) wilfully or maliciously interfered with any other radiocommunications or signals; or (7) obtained or attempted to obtain, or helped another person obtain, or attempt to obtain, an operator's license by fraudulent means.

1.9 If a licensee receives a notice of suspension of his license, what must he do?

Ans. Within 15 days of receipt of notice, or as soon as possible thereafter with a satisfactory explanation of the delay he must send an application for hearing to the FCC. The suspension order is held in abeyance until the hearing is concluded. At that time the FCC will affirm, modify, or revoke the order of suspension.

1.10 What must a person do whose operator license or permit has been lost, mutilated, or destroyed?

Ans. Immediately notify the Commission. A properly prepared and sworn application for a duplicate should then be submitted to the office of issue. This application should include a statement of the circumstances involved in the loss of the original license. It must also include a statement that a reasonable search has been made for the lost license, and if it is later found, it will be returned for cancellation. Documentary evidence of service obtained under the original license, or a statement under oath or affirmation embodying that information, must also be submitted.

1.11 Is it permissible to operate pending receipt of a duplicate operator license or permit after application has been made for reissue?

Ans. Yes. The operator should post a signed copy of the application for duplicate or renewal in place of the original document.

1.12 Is the holder of a radiotelephone third-class permit authorized to make technical adjustments to the transmitter he operates?

Ans. Only under the immediate supervision of a person holding the proper class of license required for the equipment involved. The licensed man is responsible for the proper functioning of the station equipment.

1.13 Should a radio station that is required to be operated by a licensed radio operator be a licensed radio station?

Ans. Yes. Any such station should be licensed.

1.14 Are communications bearing upon distress situations subject to the secrecy provisions of law?

Ans. No. Distress communications are exempt from these provisions.

1.15 When may an operator divulge the contents of an intercepted message?

Ans. Whenever the contents of any radiocommunication broadcast, transmitted by amateurs or others, is for the use of the general public, or relating to ships in distress.

1.16 What are the penalties for violating a provision of the Communications Act of 1934?

Ans. Any person upon conviction shall be punished for such offense for which no penalty (other than a forfeiture) is provided in this Act by a fine of not more than $10,000 or by imprisonment for a term not exceeding one year or both. Subsequent convictions provide the same penalty except for imprisonment term of two years.

1.17 What are the penalties for violating a provision of the Rules and Regulations of the FCC?

Ans. Any person upon conviction shall, in addition to any other penalties provided by law be punished by a fine of not more than $500 for each and every day during which such offense occurs.

1.18 Does the government have authority to impose fines for failure to comply with the Rules and Regulations governing the use of radio on compulsorily equipped ships?

Ans. Yes. Any person who knowingly violates any international radio treaty or convention to which the United States is a party may, upon conviction, be fined not more than $500 for each and every day during which such violation occurs. International treaties and conventions require certain ships to be compulsorily equipped with radio, and regulate the requirements and use of this equipment.

1.19 What government agency inspects radio stations in the U. S.?

Ans. The Federal Communications Commission has authority to inspect all radio stations required to be licensed, to ascertain if station construction, installation, and operation meet the requirements of the Commission Rules and Regulations.

1.20 Who keeps the station logs?

Ans. The station employee (or contract operator) competent to do so and having knowledge of facts required.

1.21 Who corrects errors in the station logs?

Ans. The operator on duty or other person who made the error. All corrections must be approved by the person responsible for keeping the log.

1.22 How may errors in the station logs be corrected?

Ans. By striking out the erroneous portion, or by making a corrective explanation on the log or attachment to it.

1.23 Is it prohibited by law to transmit false or fraudulent signals of distress?

Ans. Yes. International convention and the Communications Act of 1934 forbid false distress signals.

1.24 Under what conditions may messages be rebroadcasted?

Ans. Only when authority is obtained from the originating station.

1.25 What messages and signals may not be transmitted?

Ans. Unnecessary, unidentified, superfluous, obscene, indecent, profane, false or deceptive messages and signals. Unassigned call letters or signals may not be transmitted.

1.26 May an operator deliberately interfere with any radiocommunication or signal?

Ans. No.

1.27 What is meant by "harmful interference"?

Ans. Any emission, radiation or induction which endangers the functioning of a radionavigation service or of other safety services, or seriously degrades, obstructs, or repeatedly interrupts a radiocommunication service.

1.28 What type of communication has top priority in the mobile service?

Ans. All distress communications including alarm signals and distress traffic.

Basic Operating Practice
Element II

2.1 If a radiotelephone operator desires to make a brief test of a transmitter, what would be a good choice of words to use in the test?

Ans. The official call sign of the testing station, then the word "testing" followed by the count "1, 2, 3, 4 . . ." or by test phrases or sentences not in conflict with normal operating signals. The test signals shall have a duration not exceeding 10 seconds.

2.2 Why is it important to avoid unnecessary calls by radiocommunications?

Ans. To help prevent interference, to allow others the opportunity to use the air waves, and to improve station operating efficiency.

2.3 Is it required that a person listen in on a channel before transmitting?

Ans. Yes. Failure to listen in on a channel before transmitting can cause serious interference and should be avoided.

2.4 Why is it desirable to listen in on a channel before transmitting?

Ans. To make sure that interference will not be caused in communications already in progress.

2.5 Why should a trial of the radiotelephone installation be made every day?

Ans. To insure that it is in proper operating condition, not only for normal use, but also for emergency use.

2.6 How can a radiotelephone installation be tested?

Ans. See Question 2.1. In testing a radiotelephone transmitter, the operator should clearly indicate that he is testing, and station identification must be given. Tests should be made as brief as possible.

2.7 Before placing the transmitter apparatus of a radio station in operation for a test, what precautions must be taken?

Ans. The radio operator shall ascertain by careful listening that the test emissions will not be likely to interfere with any other communications.

2.8 What is the correct form for transmitting a distress call by radiotelephone?

Ans. The correct form for transmitting a distress call by radiotelephone is: (1) announce the distress signal Mayday three times, and (2) the words, "this is," followed by the identification of the mobile station in distress, the whole repeated three times. This distress call, when sent by radiotelephony, is generally preceded by the signal ... - - - ... (SOS) produced by a whistle or other suitable means.

2.9 Why is it a good policy to be brief in radiotelephone conversation?

Ans. To aid in preventing interference and give others an opportunity to use the airwaves.

2.10 What may happen to the received signal when an operator has shouted into a microphone?

Ans. Shouting into the microphone overloads the audio amplifier and overmodulates the transmitter. This causes so much distortion the signals may become unintelligible at the receiving end. Also, the width of the radiated band is increased, possibly causing interference with other services. The operator should make every effort to train his voice for most effective radiocommunication. His voice should be loud enough to be distinctly heard by the receiving operator, but not so loud as to become distorted and difficult to understand. Normally the microphone is held 2 to 6 inches from the operator's lips.

2.11 How should a microphone be treated when used in noisy locations?

Ans. The operator cups his hands over the microphone to exclude extraneous noise.

2.12 Why should the operator use well-known words and phrases?

Ans. To insure accuracy and save time from undue repetition of words.

2.13 What is the operator's responsibility upon hearing the word "SECURITY" repeated three times?

Ans. The word "SECURITY" is the safety signal. Upon hearing it three times the operator must continue to listen on the frequency on which it is being transmitted until he is satisfied that the message is of no interest to him. In addition, he must not make any transmission likely to interfere with the message.

2.14 What must the operator do if he is told that he is interfering with a distress call?

Ans. He must discontinue the cause of interference at once. The distress call has absolute priority over all other transmissions. All stations that hear it must immediately cease any transmission capable of interfering with the distress traffic and must listen on the frequency used for the emission of the distress call.

2.15 What are the meanings of these words: clear, out, over, roger, words twice, repeat, and break?

Ans. "Clear" means the sending station has completed all messages for the receiving station and is ending its transmission. "Out" means "This conversation is ended and no response is expected." "Over" means "My transmission is ended, and I expect a response from you." "Roger" means "I have received all of your last transmission." "Words twice" means "Give every phrase twice." "Say again" means "Repeat." "Break" means a separation between portions of a message.

2.16 Can a radio operator always consider his conversation completely confidential and not heard by other persons?

Ans. No. Radio signals normally travel outward from the transmitter in all directions, and can easily be intercepted by unauthorized persons.

2.17 In calling a station, how many times does the calling station generally repeat the call sign or name of the called station in each calling transmission?

Ans. Generally, not more than three times, followed by the letters of the calling station not more than three times.

2.18 Would you listen on a shared channel before transmitting? Why?

Ans. Yes, to make sure that you do not interfere with communications in progress.

2.19 Under normal conditions would a transmission on a calling frequency be proper if the receiver for that frequency were inoperative?

Ans. No. Calls other than emergency calls should not be made until the receiver is repaired.

2.20 What is the difference between calling and working frequencies?

Ans. Calling frequencies are those used for initial contact of another station, or stations, for some particular purpose. Once initial contact is made, all stations concerned shift to another designated frequency, known as the working frequency, for completion of further communications. For example, in the ship service, an initial call may be made on 500 kc. After contact is made, operation may be shifted to 410 kc.

2.21 Why is the station's call sign transmitted?

Ans. To avoid unnecessary repetition of call letters or names, and to enable monitoring stations to clearly identify all calls.

2.22 Should a test of the transmitting equipment be made each day?

Ans. Yes. Regular tests may reveal defects which, if corrected immediately, may prevent delays when communications are necessary. If, however, the equipment is used during the day for regular communications purposes, its general operating condition is known, and special tests are unnecessary.

2.23 What precautions should be observed in testing a station on the air?

Ans. The operator should clearly indicate that he is testing. Tests should be as brief as possible. He should be certain that the test message will not interfere with other communications in progress at the same time.

2.24 Should messages bearing upon safety, including weather information, be given priority over business messages?

Ans. Yes. Communications preceded by the safety signal have priority over all communications except those related to distress and preceded by the urgency signal.

2.25 If a station is required by law to listen in on a calling of distress frequency, when may the listening be discontinued?

Ans. The listening may be discontinued whenever the station is being used for transmission on that channel, or for communication on other radio channels.

In the event a distress, urgent, or safety call is heard, the operator must continue to listen until it is evident that the distress, urgency, or safety message does not concern his station.

2.26 Why should radio transmitters be "off" when signals are not being transmitted?

Ans. The operator of a radiotelephone station should not press the push-to-talk button except when he intends to speak into the microphone. Radiation from a transmitter may cause interference even when voice is not transmitted.

2.27 Why is it beneficial for the transmitter radio station to be in constant readiness for making a call?

Ans. So that it is available as needed, either for routine or emergency use.

2.28 If a station is required to maintain effective listening on a distress frequency, why is it desirable for the equipment to return automatically to reception on the distress frequency immediately after completing use of the equipment on another frequency?

Ans. To eliminate the possibility of the operator forgetting to switch back to the distress frequency channel.

2.29 Why is rapid frequency change of the transmitter and receiver desirable?

Ans. To permit the operator to quickly shift from a calling to a working frequency.

2.30 What would you do if you were told that your voice was distorting?

Ans. Lower my voice to see if the distortion is eliminated. If not, check the transmitter for improper operation.

2.31 Under what conditions may a station employ a calling frequency as contrasted to a working frequency?

Ans. When separate calling and working frequencies have been designated by the FCC, or by international convention, for the particular service involved.

2.32 Should a calling station repeat the call sign or name of the called station in each calling transmission more than three times?

Ans. No. Repetition of the call sign or name more than three times during any one calling is prohibited. The call may be repeated, however, after a one minute delay, if no response is obtained to the first call.

2.33 Why should stations using a shared frequency have an interval between calls?

Ans. To allow other stations sharing the frequency an opportunity to make calls.

2.34 Under what conditions may it be desirable to repeat important words?

Ans. When conditions of reception are such that words are not clearly intelligible, or when requested by the receiving operator.

2.35 What is the operator's responsibility upon hearing a distress call in a mobile service?

Ans. Cease all transmissions and continue to listen until he is certain the distress message in no way concerns his station.

2.36 Is it good practice to listen on the working frequency to be later used before making an initial call on the calling frequency?

Ans. Yes, to make sure that the desired communication can be handled on the working frequency. Unnecessary interference to other parties wishing to use the calling frequency is thereby avoided.

2.37 Why is it important to avoid unnecessary calls?

Ans. Unnecessary calls are forbidden by international law because they may cause interference with other stations wishing to use the air lanes.

2.38 State why station identification should be clearly made by a radio station.

Ans. To avoid unnecessary repetition of call letters or names, and to enable monitoring stations to identify all calls.

2.39 When routine radiocommunications are unreliable due to static or fading, should the operator continue transmitting or wait for more favorable conditions?

Ans. When radiocommunications at a station are unreliable or are disrupted due to static or fading, the operator should wait for more favorable conditions. Continued calling can cause severe interference with other stations.

2.40 What is the order of priority for communications?

Ans. (1) Distress calls, distress messages, and distress traffic; (2) communications preceded by an urgent signal; (3) communications preceded by the safety signal; (4) communications related to radio direction finding bearing; (5) communications related to the navigation and safe movement of aircraft; (6) communications related to the navigation, movements, and need of ships for an official meteorological service; (7) government communications for which priority rights have been claimed; (8) service communications related to the working of the radiocommunications service, or to communications previously transmitted; and (9) all other communications.

2.41 What is the priority of the urgency signal?

Ans. The urgency signal is second in the order of priority. Distress signals are first and safety signals third.

2.42 What are the distress, urgency, and safety signals?

Ans. The distress signal is the word MAYDAY. The urgency signal is the word PAN. The safety signal is the word SECURITY. All are repeated three times before the call.

2.43 In radiocommunications what does the transmission of the "distress," "urgency," and "safety" signals signify, respectively?

Ans. "MAYDAY" indicates that the ship, aircraft, or other vehicle sending the distress signals is threatened by serious and imminent danger, and requests immediate assistance. "PAN" indicates the calling station has an urgent message to transmit concerning the safety of a ship, aircraft, or other vehicle, or person on board or within sight. "SECURITY" indicates the station is about to transmit a message concerning the safety of navigation or important meterological warnings.

2.44 What information must be contained in a distress message?

Ans. (1) The distress call, (2) the name of the ship, aircraft, or vehicle in distress, (3) position of the latter, (4) the nature of the distress, (5) assistance, and (6) any other information which might facilitate matters.

2.45 Under what conditions may a mobile radio station send a distress message for another mobile station in distress?

Ans. (1) When the station in distress cannot itself transmit the message, (2) the master or person responsible for the ship, aircraft, or other vehicle carrying the station which intervenes believes additional help is needed, and (3) when directed to do so by the station in charge of distress traffic.

2.46 In the case of a mobile radio station in distress, what station is responsible for the control of distress message traffic?

Ans. The mobile station in distress, or the mobile station which, under the provision of the Commission Rules and Regulations, sends the distress call. These stations may, however, delegate the control of distress traffic to another station.

2.47 What does the distress call consist of?

Ans. The word MAYDAY repeated three times, and the words "this is," followed by the call of the mobile station in distress, repeated three times. The distress call may be preceded by the Morse Code signal ... --- ... (SOS) produced by a whistle or some other means.

2.48 What should an operator do when he leaves a transmitter unattended?

Ans. The transmitter should be left inoperable or inaccessible to unauthorized persons. The operator continues to bear responsibility for proper operation of the station.

2.49 Where does an operator find specifications for obstruction marking and lighting (where required) for the antenna towers of a particular radio station?

Ans. Part 17 of the Rules and Regulations of the FCC. If he wishes to determine the specifications for a particular station he should examine the station authorization issued by FCC.

2.50 What should an operator do if he hears profanity being used at his station?

Ans. He should discontinue broadcast immediately. Warn the offender. Take such other action as necessary to prevent recurrence. Prepare explanation in event suspension notice is received.

2.51 How does the licensed operator of a station normally exhibit his authority to operate the station?

Ans. By posting a valid operator license or permit at the transmitter control point.

2.52 When may an operator use his station without regard to certain provisions of his station license?

Ans. During a period of emergency in which normal communications facilities are disrupted as a result of hurricane, flood, earthquake or similar disaster.

2.53 Who bears the responsibility if an operator permits an unlicensed person to speak over his station?

Ans. The operator bears the responsibility for proper operation at all times.

2.54 What is meant by a "phonetic" alphabet in radiotelephone communications?

Ans. It is an alphabet or word list used to identify letters or words that may sound like other letters or words of different meaning. For example "group" may sound like "scoop," or "bridge" may sound like "ridge." It consists of 26 words, each word representing a letter of the alphabet. If the letters "GROUP" are represented in a phonetic alphabet as George, Roger, Oboe, Uncle and Peter, the word "group" is transmitted as "GROUP," G as in George, R as in Roger, O as in Oboe, U as in Uncle, P as in Peter.

MARITIME QUESTIONS AND ANSWERS

2.1M In making a ship-to-ship contact, except in an emergency involving safety, how long may a ship station continue calling in each instance?

Ans. Calling a particular station, either by voice or by automatic means, shall not continue for a period of more than 30 seconds.

2.2M Except in an emergency involving safety, if a ship radiotelephone station does not receive a reply after calling, how long must it wait before calling again?

Ans. At least two minutes.

2.3M What types of communications may be transmitted by ship stations on the ship-to-ship frequencies between 2000 and 3000 kc?

Ans. Frequencies between 2000 and 3000 kc can be used for distress, safety, or urgent signals, initial calls and answers, and normal radio traffic on working frequencies.

2.4M In regions of heavy traffic, how long may the ship-to-ship radiotelephone frequencies between 2000 and 3000 kc be used for any one exchange of communication (other than distress or emergency)?

Ans. Any one exchange shall not exceed three minutes in duration.

2.5M How is a ship radiotelephone station required to be identified in connection with its operation?

Ans. All radiotelephone emissions from a ship station shall be clearly identified by transmitting in the English language the official call sign assigned to that station by the Commission. If no call sign has been assigned the complete name of the ship and name of licensee shall be sent. The required station identification shall be made: (1) at the beginning and upon the completion of each transmission made for any other purpose, (2) at intervals not exceeding fifteen minutes whenever transmission is sustained for a period exceeding fifteen minutes.

2.6M Do public coast stations normally charge for forwarding messages reporting dangers to navigation?

Ans. No public coast station shall charge for the transmission, receipt, or reply of information concerning dangers to navigation originating on a ship of the United States or a foreign country.

2.7M How does the licensed operator of a ship radiotelephone station exhibit his authority to operate the station?

Ans. The operator must post his original license in a conspicuous place at the principal location on board ship at which the station is operated. If, however, the station is portable, or is a marine utility station, the operator can keep the required license, or a duly issued verification card attesting to the existence of the license, on his person.

2.8M If a radiotelephone installation is provided on board ship for safety purposes, in accordance with a treaty, and it becomes defective, what action must the licensed operator take?

Ans. The ship master must be notified promptly. If the ship is being navigated outside of port, the licensed operator shall make every effort to return the equipment to normal operating conditions as quickly as possible. If operating on the Great Lakes, and the equipment cannot be repaired sooner, it must be placed in operating condition at the next port of arrival. In addition, the master of the vessel must send a written report to the Federal Communications Commission in Washington, D. C., giving full particulars of the matter. The report must include the date the master became aware of the deficiency, a description of the steps taken to correct it, and a statement to the effect that the equipment has been, or will be, placed in operation before the ship again leaves port.

2.9M Who signs the radio log of a ship radiotelephone station certifying the entries made therein?

Ans. The licensed operator who is responsible for the operation of radiotelephone apparatus. The use of initials or signs in lieu of the operator's signature is not authorized.

2.10M What are the requirements for keeping watch on 2182 kc? If a radio operator is required to "stand watch" on international distress frequency, when may he stop listening?

Ans. Ship stations shall during its hours of service maintain an efficient watch for the reception of A3 and A3H emissions on 2182 kc frequency whenever such station is not being used for transmission on that frequency or for communication on other frequencies.

The watch period on an international distress frequency, when the ship station is in Region 1 or 3 shall be, insofar as possible, maintained at least twice each hour for 3 minutes commencing at X h.00 and X h.30, GMT.

2.11M Who may operate the radiotelephone set aboard the vessel?

Ans. Operation of all transmitting apparatus in any radio station in the maritime mobile service of the United States must normally be carried on only by a person holding an operator's license of the required class. However, at a ship station, the licensee or master may permit an unlicensed person to speak into the microphone.

2.12M Is it necessary for all vessels having knowledge of distress traffic to follow the traffic even if they do not take any part in it?

Ans. Any station of the mobile service having knowledge of distress traffic must follow such traffic, even if it does not take part in it. While following such distress traffic, however, if the mobile station is able to continue its normal service, it may do so, provided the distress traffic is well established, and provided it does not transmit on frequencies used for the distress traffic, and does not interfere with the distress traffic.

2.13M What is the proper form to use in acknowledging a distress message?

Ans. To acknowledge receipt of a distress message, use the following form: (1) call sign of the mobile station in distress repeated three times; (2) the letters DE in Morse Code or the words "This is," followed by (3) call sign of the station repeated three times; (4) the three-lettered group RRR in Morse Code, or the spoken word "received" repeated three times; and (5) distress signal.

2.14M What information is required to be sent following acknowledgement of a distress message?

Ans. The following information, in the order shown, must be transmitted as soon as possible by the mobile station acknowledging receipt: (1) its name, (2) its position, (3) the speed at which it is proceeding toward the ship, aircraft, or other vehicle in distress. Before sending the message, the station must insure that it will not interfere with the emissions of other stations better situated to render immediate assistance to the station in distress.

2.15M Is it necessary that the authority of the master or person responsible for the vessel be obtained prior to sending information required following acknowledgement of a distress call?

Ans. Yes. The information can only be sent on the order of the master or person responsible for the ship, aircraft, or other vehicle.

2.16M Is it desirable that care be taken to insure that an acknowledgment to a distress message will not interfere with other acknowledgments from vessels that are better able to assist?

Ans. Yes. Mobile stations that receive a distress message from another mobile station which, beyond any possible doubt, is not in their vicinity, must allow a short interval of time before acknowledging receipt of the message, to permit stations nearer the station in distress to answer and acknowledge receipt without interference.

2.17M Is a vessel which hears a distress message, but is not in a position to assist, required to take all steps to attract the attention of stations which might be in a position to assist?

Ans. Yes. Any mobile station not in a position to assist, after hearing a distress message which has not been properly acknowledged, must take all possible steps to attract the attention of mobile stations which are in a position to render assistance. For this purpose, with the approval of the person lawfully responsible for the station, the distress message may be repeated. All necessary steps are also taken to notify authorities who may be able to help.

2.18M Is it necessary to make a trial of the ship radiotelephone installation every day?

Ans. Yes, unless normal daily use of the equipment demonstrates that it is in proper operating condition for an emergency.

2.19M How can the radiotelephone installation be tested each day?

Ans. By making a test communication to demonstrate that the equipment is in proper operating condition for an emergency.

2.20M Does the Geneva 1959 Treaty give other countries the authority to inspect U. S. vessels?

Ans. Yes. The license must be produced for examination upon request of the government of the country being visited by the mobile station. The operator of the mobile station will cooperate in this examination.

2.21M What is the difference between calling and working frequencies?

Ans. Calling frequency is transmission from a station solely for getting the attention of another station(s) for a particular purpose. Working frequency is for all radiocommunications except calling.

2.22M How would you contact another vessel prior to communicating with it for routine communication purposes?

Ans. Example: Suppose Station KENT wishes to contact Station WASH. KENT would call as follows: "WASH, WASH, WASH, this is KENT, KENT, KENT, over." The repetition of the call station and the calling station as shown is not absolutely required and should never be repeated more than three times.

2.23M Why are call signs sent? Why should they be sent clearly and distinctly?

Ans. To enable other stations to identify calls easily.

2.24M In the mobile service, why

should messages be as brief as possible?

Ans. To allow other stations on the same frequency to make calls.

2.25M What procedure would you use in contacting the U. S. Coast Guard?

Ans. Example: "Baltimore Lifeboat Station, this is KENT, over."

2.26M Is it permissible to use 2182 kc for establishing contact prior to communicating on an appropriate public correspondence channel?

Ans. Yes; 2182 kc is the international radiotelephone calling frequency for the maritime mobile service.

2.27M Is it the general practice for a ship to use 2182 kc for establishing contact prior to communicating with a coast station on an appropriate public correspondence channel?

Ans. Yes.

2.28M Is it permissible to communicate with coast stations or any other stations on 2182 kc except for safety purposes?

Ans. Yes. See Question 2.26M.

2.29M Give a typical procedure you might use to call a vessel when its identity is not known.

Ans. In this case, the inquiry symbol CQ is used in place of the call sign of the station called. Example: "CQ, CQ, CQ, this is KENT, KENT, KENT, calling tanker at position 35 degrees north, 81 degrees west, over."

2.30M What do distress, safety and urgency signals indicate?

Ans. (1) Distress signal indicates that a mobile station is threatened by grave and imminent danger and requests immediate assistance. (2) Safety signal indicates that the station is about to transmit a message concerning the safety of navigation or giving meteorological warnings. (3) Urgency signal indicates that the calling station has a very urgent message to transmit concerning the safety of a ship, aircraft or other vehicle or the safety of a person.

2.31M What are the international urgency, safety and distress signals?

Ans. (1) Urgency signal is PAN. (2) Safety signal is SECURITY. (3) Distress signal is MAYDAY.

2.32M In the case of a mobile radio station in distress, what station is responsible for the control of distress message traffic?

Ans. It is the responsibility of the mobile station in distress or the station which had sent the message. These stations may delegate control to another station.

2.33M What daily attention should be given to the antenna tower lights at a radio station?

Ans. A daily check of the tower lights must be made not later than one hour after sunset. Inspection may be made either by visually observing the tower lights or by observing an automatic indicator, to insure that all tower lights are functioning properly as required.

2.34M What should be done in case of failure of the antenna tower lights at a radio station?

Ans. Report immediately by telephone or telegraph to the nearest airways communications station or office of the Federal Aviation Agency any observed failure of any code or rotating beacon light if such failure is not corrected within thirty minutes after observation thereof. Further, notify the above station or office immediately upon resumption of the required illumination. Data concerning the failure of tower lights must also be recorded in the station log. Include in the log entry the nature of the failure, the date and time the failure was observed, and the date, time, and nature of the adjustments, repairs, or replacements made. In the event of failure of rotating or beacon lights, the time of notifying the Federal Aviation Agency must also be entered.

2.35M How should a radio identification be made at a coast station using radiotelephony?

Ans. All radiotelephone emissions of a public coast station shall be clearly identified by voice transmission in the English language, either by the official call sign assigned to that station by the Commission or by the approximate geographic location of the station as approved in such case by the Commission. Alternatively, the official call sign may be clearly transmitted by tone-modulated telegraphy in the Morse Code, either by a duly licensed radiotelegraph operator or by means of an automatic device approved by the Commission.

2.36M If a licensed operator at the controls of a coast station observes or hears obscene language being transmitted through the facilities of a station, what action should be taken?

Ans. The station should immediately be removed from the air or steps taken to insure against further transmission of the obscene language. Details of the unlawful transmission must be entered in the station log, and a report sent to the FCC.

2.37M If a coast station hears a distress call from a mobile station, what action, if any, should the operator on duty take?

Ans. The operator must immediately cease any transmission capable of interfering with the distress traffic and listen on the frequency used for the emission of the distress call. After the distress message is sent, receipt should be acknowledged.

2.38M Under what circumstances should a public coast station employing radiotelephony use a calling frequency in establishing a communications circuit with a ship or aircraft?

Ans. (1) For distress signals and traffic, (2) urgency signals, and very urgent messages concerning safety of a ship, aircraft, or other vehicle, or safety of a person on board or within sight of such vehicles, (3) safety messages, (4) occasional messages of general interest to ship mobile stations, (5) normal calls, replies, and brief operating signals, (6) brief test signals, to determine if the station transmitting equipment is in good operating condition.

2.39M When may a coast station NOT charge for messages it is requested to handle?

Ans. Whenever tariffs for the requested service are not on file with the Commission. No charge will be made (1) for transmission of distress messages and replies thereto, involving safety of life and property at sea; (2) for transmission, receipt or relay of information about dangers to navigation, and (3) any services related to preparation for national defense.

2.40M In regions of heavy traffic why should an interval be left between radiotelephone calls? Why should a radio operator listen before transmitting on a shared channel?

Ans. Each authorized channel is available for use on a shared rather than an exclusive basis. Cooperation on use of assigned frequency reduces interference. Listen first, and if interference is likely, then wait until existing communication is ended. Intervals between calls permit calls to be made by another station using the same frequency.

2.41M How long may a radio operator in the mobile service continue attempting to contact a station which does not answer?

Ans. An interval of 2 minutes must elapse before calling a station again. After three attempts without response the interval will be 15 minutes. Should harmful interference to other communications not be indicated then the calls may be made as before, with a pause of 3 instead of 15 minutes. In all cases calling may continue for no longer than 30 seconds. These provisions do not apply to emergency calls involving safety.

2.42M What is meant by "safety communication" in the maritime service?

Ans. Safety communication is the transmission or reception of distress, alarm, urgent, or safety signals, or any form of radiocommunication which, if delayed in transmission or reception, may adversely affect the safety of life or property; an occasional test transmission or reception is necessary for determining if the radio equipment is in good working condition for purposes of safety.

2.43M Describe completely what actions should be taken by a radio operator who hears a safety message?

Ans. All stations hearing the safety signal shall listen to the safety message until they are satisfied that the message is of no concern to them. They shall not make any transmission likely to interfere with the message.

2.44M What are the requirements with respect to log-keeping at a coast station using radiotelephony?

Ans. Public coast stations using telephony shall maintain an accurate log during their hours of service. Each log sheet shall be numbered in sequence, be dated, and shall include the official call sign of the station and the signature of the licensed operator on duty. The entry "on duty," followed by his signature, shall be made by the operator at the beginning of a duty period. The entry "off duty," followed by his signature, shall be made by the operator ending a duty period. All log entries shall be currently completed and, unless otherwise stated, shall be made by the licensed operator on duty. The use of initials in lieu of any operator's signature is not authorized. The time of each entry shall be shown opposite the entry and, except for the following, shall be expressed in Greenwich Mean Time (GMT). (1) In the Great Lakes region, the time shall be expressed in Eastern Standard Time counted from 00:00 to 24:00 o'clock, beginning at midnight. (2) For public coast stations which communicate exclusively with vessels on inland waters of the United States, the time shall be expressed in local standard time. The first entry in each hour shall consist of four figures; additional entries in the same hour may be expressed in two figures by omitting the hour designation. The abbreviation GMT (or other kind used) shall be marked at the head of the column in which the time is entered.

2.45M What is the importance of the frequency 2182 kc?

Ans. This is the international distress frequency. It shall be used for this purpose by ship, aircraft and survival craft stations using frequencies in the authorized bands between 1605 and 4000 kc when requesting assistance from the maritime services.

2.46M What information must be contained in distress messages? What procedures should be followed by a radio operator in sending a distress message? What is a good choice of words to be used in sending a distress message?

Ans. The distress message consists of: (1) the distress signal MAYDAY; (2) name of mobile station in distress; (3) its position; (4) nature of distress; (5) kind of assistance desired; (6) any other information which might facilitate rescue.

The distress procedure consists of: (1) alarm signal (when possible); (2) distress call; (3) distress message. Transmissions shall be made slowly and distinctly with each word clearly pronounced to ease receipt of message. After sending the distress message, the mobile station may be requested to send suitable signs followed by its call sign or name to permit direction-finding stations to determine its position. As necessary, this request may be repeated at frequent intervals. The alarm signal, when possible, distress call and distress message shall be repeated at intervals until an answer is received. If no answer is received on the distress frequency, any other frequency may be used to attract attention.

2.47M Describe completely what actions should be taken by a radio operator who hears a distress message.

Ans. When a distress message is received from a mobile station which is, beyond any possible doubt, in his vicinity, he shall immediately acknowledge receipt. If reliable communication with one or more coast stations is practicable, ship stations may defer acknowledgment for a short interval so that a coast station may acknowledge receipt. When the distressed mobile station is, without doubt, not in the vicinity, then a short interval will be allowed to elapse before acknowledging receipt of message, in order to permit stations nearer the mobile station in distress to acknowledge receipt without interference.

Acknowledgment of receipt of a distress message takes this form: (1) Call sign or other identification of the station sending the distress message, spoken three times; (2) the words THIS IS; (3) call sign or other identification of the station acknowledging receipt, spoken three times; (4) the word RECEIVED; the distress signal MAYDAY.

Every mobile station which acknowledges receipt of a distress message shall, on the order of the master or person responsible for the ship, aircraft or other vehicle carrying such mobile station, transmit as soon as possible the following information in the order shown: (1) Its name; (2) its position; (3) the speed at which it is proceeding towards, and approximate time it will take to reach, the mobile station in distress.

Before acknowledging, the station shall ensure that it will not interfere with the emissions of other stations better situated to render immediate assistance to the station in distress.

2.48M Under what conditions may a coast station intervene in a distress situation?

Ans. Any station or mobile service, which is not in a position itself to render assistance, but which has heard a distress message that has not been acknowledged, must take all possible steps to attract the attention of stations which are in a position to render service. With the approval of the person lawfully in charge of the station, the distress call or the distress message may be repeated, using full power, on the distress frequency or on another frequency which may be used in case of distress.

2.49M To what extent may a coast station using radiotelephony communicate with stations other than ship stations?

Ans. Coast stations may communicate with other land stations to facilitate the transmission or reception of safety communications to and from a ship or aircraft station. They may also communicate with marine fixed stations on a frequency below 4000 kc, provided no harmful interference or intolerable delay is caused in communication with mobile stations as a result of such communication.

2.50M What is indicated by the use of the word "break" in a radiotelephone conversation?

Ans. The word "break" indicates a separation between portions of a message.

2.51M What is indicated by the use of the word "Roger" as a reply to a radiotelephone communication?

Ans. "Roger" means "I have received all of your last transmission."

2.52M What is indicated by the expression "words twice" when transmitted by radiotelephone?

Ans. "Words twice" is used to ask a station to send every phrase twice, or to inform a station every word will be sent twice.

2.53M What is indicated by the use of the words "read back" when transmitted by radiotelephone?

Ans. The words "read back" are used to request that the message be read back to the sending operator for verification.

2.54M Why are test transmissions sent? How often should they be sent? What is the proper way to send a test message? How often should the station's call sign be sent?

Ans. Tests may reveal defects or faults which, if corrected immediately, may prevent delays when communications are necessary. Before testing, listen to make sure there will be no interference with transmissions in progress. The call sign of the testing station, followed by the word "test" shall be announced on the radio channel being used for the test, as a warning that test emissions are about to be made on that frequency. The test must be delayed if there is interference or when "wait" is heard.

The operator announces the word "Testing" followed by "1, 2, 3, 4 ..." or by test phrases, sentences or test signals not in conflict with normal operating signals. The signals shall not last longer than 10 seconds. At the end of the test, announcement is made of the call sign, name of ship and its general location at time of test. One minute should elapse before retest on 2182 kc in heavy traffic, 5 minutes is waiting period. The call sign is sent at the beginning and end of test.

2.55M For what purpose is the frequency 121.5 megacycles authorized to be used by an aircraft radio station?

Ans. This is a universal simplex emergency and distress frequency for air-ground communications.

2.56M In lieu of using a call sign, how may a private aircraft telephone station be identified in the course of operation?

Ans. By use of the official aircraft registration number. The full number must be given for the initial call of a continuous series of communications or, name of owner of aircraft followed by last two characters of registration; type of aircraft may be substituted for name or owner, provided practice is initiated by ground station operator.

2.57M What types of communications or messages is an aircraft radiotelephone station authorized to transmit?

Ans. Communications limited to those necessary for safe aircraft operations.

2.58M When must an aircraft radio station and maintenance record be made available for inspection?

Ans. Upon request of an authorized representative of the FCC made to the licensee or his representative.

2.59M How is the communications range of an aircraft radio station at a very high frequency dependent upon the altitude of the aircraft?

Ans. The higher the aircraft, the greater the communications range, because very high frequency radiations travel in essentially straight lines, which limits reception to the line-of-sight distance. The higher the aircraft radio station, the greater the distance to the horizon and the greater the communications range.

2.60M Why should an aircraft station avoid making unnecessary "on the air" tests?

Ans. To avoid interference with communications in progress and to permit other stations with necessary business to use the airways.

2.61M What is the normal calling procedure of a private aircraft for contacting a control tower?

Ans. Example: "Washington control tower, this is Beechcraft N123456, Over."

2.62M How should an air carrier aircraft radiotelephone station normally be identified in operation in lieu of using the call sign?

Ans. The official aircraft registration number or company flight identification may be used, provided proper records are kept to permit ready identification of a given aircraft.

2.63M What is meant by a phonetic alphabet in radiotelephone communications?

Ans. A phonetic alphabet is a word list with each letter represented by an easily understood word. This alphabet is used to make sure a message is received correctly. For example, the word "robe" may be transmitted as Roger (r), oboe (o), baker (b), easy (e). The possibility of the word then being misunderstood is minimized.

2.64M What radio channel or channels are used by ships for communicating by radiotelephone with the U. S. Coast Guard?

Ans. Normally 2182 kc. In the Great Lakes, distress calls may be made on 2670 kc.

2.65M How often should station identification be made at a base or land radiotelephone station?

Ans. At the end of each transmission or exchange of transmissions, or once every 30 minutes of the operating period, as the licensee may prefer.

2.66M What entries must be made in the logs or records of radio stations required to have antenna tower lights?

Ans. The time each day the lights are turned on and off if manually controlled, the time a daily check for proper operation is made if an automatic alarm system is not provided, and results of periodic inspections required at least once every three months. This includes general condition of the system and any adjustments, replacements, or repairs made and the date.

If the tower lights fail, the log must show the nature of the failure, the time observed, the date, time, and nature of repairs, and the time the FAA was notified (for failures not corrected within 30 minutes). The results of the periodic inspection required every three months must be entered in the log, showing the date of the inspection and the condition of all tower lights and associated equipment. Any adjustments, replacements, or repairs to insure compliance with the lighting requirements must also be shown.

2.67M What attention should be given periodically to the antenna tower lights and associated apparatus at a radio station?

Ans. The lights must be checked at least once every 24 hours, either by direct observation or through a properly operating indicator system that will indicate any failure. Inspection must also be made at least once every three months to insure that all automatic or mechanical control devices, indicators, and alarm systems associated with the tower lighting is in proper operating order.

2.68M What precaution should be taken in a radio station which is left unattended in a public place?

Ans. The station should be locked up and other necessary precautions taken to prevent unauthorized use of the equipment. This may include temporary disablement of the equipment by tube removal, crystal removal, etc.

Basic and Advanced Radiotelephone for Elements III and IV

3.1 What is the frequency range associated with the following general subdivisions?

ULF	Below 30 kc	VHF	30-300 mc
LF	30-300 kc	UHF	300-3000 mc
MF	300-3000 kc	SHF	3-30 gc
HF	3-30 mc	EHF	30-300 gc

3.2 What is meant by the following emission designations? (Answer combined with question).

Symbol	Modulation	Type of transmission	Other characteristics
A3	**Amplitude**	**Telephony**	**Double sideband**
A3A	**Amplitude**	**Telephony**	**Single sideband, reduced carrier**
A5C	**Amplitude**	**Television**	**Vestigial sideband**
F3	**Frequency or phase**	**Telephony**	———
F5	**Frequency or phase**	**Television**	———
P3D	**Pulse**	**Telephony**	**Amplitude modulated**

3.3 What is the basic difference between type approval and type acceptance of transmitting equipment?

Ans. Type approval is based on tests made by FCC. Type acceptance is based on test data submitted by manufacturer or licensee and accepted by FCC.

3.4 May stations in the Public Safety Radio Services be operated for short periods of time without a station authorization issued by FCC?

Ans. No. Even in emergencies involving safety of life or property, authorization must be obtained.

3.5 What notification must be forwarded to the Engineer in Charge of the FCC district office prior to testing a new radio transmitter in the Public Safety Radio Service which has been obtained under a construction permit issued by FCC?

Ans. At least two days before test date, send written notice giving name of permittee, station location, call sign and frequencies to be used in testing.

3.6 Where may standard forms applicable to the Public Safety Radio Services be obtained?

Ans. From any engineering field office or FCC, Washington, D. C. 20554.

3.7 In general, what type of changes in authorized stations must be approved by FCC? What type does not require FCC approval?

Ans. Approval is necessary whenever any operation would be inconsistent with terms of authorization. Proposed changes which are consistent do not require approval.

3.8 The carrier frequency of a transmitter in the Public Safety Radio Service must be maintained within what percentage of the licensed value? Assume the station is operating at 160 mc with a licensed power of 50 watts.

Ans. .0005 per cent.

3.9 What is the authorized bandwidth and frequency deviation of Public Safety stations operating at about 30 mc? At about 160 mc?

Ans. At either 30 mc or 160 mc, authorized bandwidth is 20 kc with 5 kc frequency deviation.

3.10 What is the maximum percentage modulation allowed by FCC rules for stations in the Public Safety Radio Services which utilize amplitude modulation?

Ans. Not more than 100% on negative peaks.

3.11 Outline the transmitter measurements required by FCC rules for stations in the Public Safety Radio Service.

Ans. Each transmitter operating with a plate input power to the final radio frequency stage in excess of 3 watts must be measured at stated intervals. Objectives are to assure that (1) carrier frequency is maintained within prescribed tolerance, (2) maximum voltage specified in the station authorization is not exceeded, and (3) that modulation does not exceed specified limits.

3.12 What are the general requirements for transmitting the identification announcements for stations in the Public Safety Radio Service?

Ans. The assigned signal at each transmission, or each 30 minutes, as licensee prefers. Mobile units operating above 30 mc may use another identifier plus name of government unit.

3.13 When a radio operator makes transmitter measurements required by FCC rules for a station in the Public Safety Radio Service, what information should be transcribed into the station's records?

Ans. Results and dates of required measurements and name of person making measurements.

3.14 What are FCC general requirements regarding the records which are required to be kept by stations in the Public Safety Radio Service?

Ans. Kept in an orderly manner and in detail so that required facts are readily available. Key letters and abbreviations may be used provided meaning is set forth in the record. Each entry shall be signed by a qualified person who has actual knowledge of the recorded facts. No entries shall be erased, obliterated or destroyed within the retention period. Correction may be made by person originating the entry who shall strike out the erroneous portion, initial correction made and show date of correction. Records will be retained by licensee for at least one year.

3.15 If a standard broadcast station is licensed to operate at a frequency of 1260 kc, what are the minimum and maximum frequencies at which it may operate and still be within the proper limits established by the FCC rules?

Ans. The operating frequencies shall be maintained within 20 cycles. Therefore, 1259.98 kc and 1260.02 kc are frequency limits.

3.16 What is an STL system?

Ans. It is a fixed station using telephony for transmission of aural program material between the studio and the transmitter of a broadcasting station, other than an international broadcasting station, for simultaneous or delayed broadcast.

3.17 What is a proof-of-performance? How does a proof-of-performance differ from annual equipment performance measurements required by FCC rules? What must be included in the annual equipment performance measurements?

Ans. Proof-of-performance is a set schedule of tests made throughout the year for purposes of locating trouble areas, making measurements and keeping station at top efficiency. It is more inclusive and frequent than the annual measurements required by FCC. Required annual measurements are: (1) data and curves showing over-all audio frequency response from 30 to 7500 cps for approximately 25, 50, 85, and 100 (if obtainable) percent modulation; (2) data and curves showing audio frequency for harmonic content for 25, 50, 85, and 100 per cent modulation for fundamental frequencies of 50, 100, 400, 1000, 5000, and 7500 cps; (3) data showing percentage carrier shift for 25, 50, 85, and 100 per cent modulation with 400 cps tone; (4) carrier hum and extraneous noise generated within the equipment and measured as the level below 100 per cent modulation throughout the audio spectrum or by bands; and (5) measurements or evidence that spurious radiations including radio frequency harmonics are suppressed or are not causing objectionable interference.

3.18 What are the specifications of a plate current meter in the last radio stage of a transmitter?

Ans. Length of scale not less than 2.3 inches; accuracy at least 2% of full-scale reading; maximum rating shall not read off-scale during modulation; scale must have at least 40 divisions; full scale reading shall not be greater than five times the minimum normal indication.

3.19 Under what conditions may remote reading antenna ammeters be used to indicate antenna current?

Ans. When the transmission line current meter is used at transmitter.

3.20 (a) What is the maximum temperature variation at the normal operating temperature when using X or Y cut crystals? (b) When using low temperature coefficient crystals?

Ans. (a) Not greater than ± 0.1°C; (b) ± 1.0°C.

3.21 Who keeps the keys to the fence which surrounds the antenna base at a standard broadcast station? Where are the keys usually kept?

Ans. In possession of the operator on duty at the transmitter.

3.22 Changes to the broadcast transmitter of what general nature require FCC approval? What types of changes or alterations do not require approval?

Ans. No change in the last radio stage, the number of vacuum tubes, nor change to vacuum tubes of different power rating or class of operation, nor change in system or modulation without authority of the FCC. Other changes which do not affect the maximum power rating or operating power of the transmitter or the operation or precision of the frequency control equipment may be made at any time without authority of the FCC.

3.23 What is the FCC requirement regarding maintenance of operating power?

Ans. As practicable, but not above 5% nor below 10% of licensed power.

3.24 What is frequency tolerance at standard broadcast stations?

Ans. ± 20 cycles of assigned frequency.

3.25 What are the FCC requirements concerning stations which operate their transmitters by remote control?

Ans. Operation by remote control shall be subject to the following conditions: (1) the equipment at the operating and transmitting positions shall be so installed and protected that it is not accessible to or capable of operation by persons other than those duly authorized by the licensee; (2) the control circuits from the operating positions to the transmitter shall provide positive on and off control and shall be such that open circuits, short circuits, grounds or other line faults will not actuate the transmitter and any fault causing loss of such control will automatically place the transmitter in an inoperative position; (3) a malfunction of any part of the remote control equipment and associated line circuits resulting in improper control or inaccurate meter readings shall be cause for the immediate cessation of operation by remote control; (4) control and monitoring equipment shall be installed so as to allow the licensed operator at the remote control point to perform all the functions in a manner required by the FCC's rules; (5) the indications at the remote control point of the antenna current meter or, for directional antennas, the common point current meter and remote base current meters shall be read and entered in the operating log each half hour; (6) the indications at the transmitter, if a directional antenna station, of the common point current, base currents, phase monitor sample loop currents and phase indications shall be read and entered in the operating log once each day for each pattern. These readings must be made within two hours after the commencement of operation for each pattern.

All stations, whether operating by remote control or direct control, shall be equipped so as to be able to follow the prescribed procedure for Emergency Broadcast Service in event of national emergency.

3.26 At what place must the station license be posted? Where must the licenses of the operator be posted?

Ans. Station license: In a conspicuous place at the principal control point of the transmitter; a photocopy at each other control point is also required. Operator license: Original license or FCC Form 759 of each operator at his place of duty.

3.27 What are the operator requirements for AM broadcast stations?

Ans. Third Class permit with Broadcast Endorsement, provided that a First Class licensed operator is on call, except in the case of certain stations employing directional antennas, in which case a First Class operator must be on duty at all times during directional operation.

3.28 During what period of time preceding the date of filing for a renewal of the station license should such measurements be made?

Ans. During a four-month period before filing renewal applications.

3.29 (a) Explain how operating power is computed using direct measurement; (b) Using indirect measurement; (c) Under what conditions at a standard broadcast station may the indirect method be used?

Ans. (a) Resistance is determined by taking measurements at 5, 10, 15 and 20 kc on each side of operating frequency. These readings are plotted and a smooth curve developed. Where the operating frequency cuts the curve is the antenna resistance. Operating power is the square of the antenna current times the resistance. (b) Computed from the plate input power of the last radio stage and is the product of $E_p \times I_p \times F$. F is a factor based on method of modulation, maximum rated carrier power and class of amplifier. (c) Emergency, where antenna system has been damaged; pending completion of changes in antenna system or any change affecting antenna system.

3.30 What is the FCC requirement as to maintenance of percentage of modulation?

Ans. As high as possible along with good quality of transmission and broadcast practice. It must not exceed 100% on negative peaks of frequent recurrence, nor should it be less than 85% on peaks of frequent recurrence except as necessary to avoid objectionable loudness.

3.31 (a) What should be done if the station's modulation monitor becomes defective? (b) If the frequency monitor becomes defective?

Ans. (a) The station may be operated up to 60 days without FCC authority, pending repair or replacement. During this time modulation will be monitored with cathode ray oscilloscope, or other means. Engineer in Charge will be notified immediately of defect and whenever additional time is needed to correct. Entries in maintenance log showing date and time, when removed and restored to service; (b) same requirements as in (a) except frequency of station shall be measured by an external source at least each 7 days and results entered in maintenance log.

3.32 Under what conditions may a standard broadcast station use its facilities for communications directly with individuals or other stations? What notice shall be given when a station is operating during a local emergency?

Ans. When there is a severe emergency and communications are to dispatch aid, assist in rescue, promote safety of life and property, and reduce hardship. Notify the FCC in Washington, D. C., Engineer in Charge of District, of use to which station is being put, at the start and end of operations.

3.33 How many times and when must the station's operating log be signed by an operator who goes on duty at 10 a.m. and off duty at 6 p.m.?

Ans. Usually twice; upon going on and coming off duty.

3.34 (a) What entries shall be made in the operating log? (b) In the station's maintenance log?

Ans. (a) All readings pertaining to transmitting apparatus. (b) All readings, tests, and results of equipment installation and grounds inspections.

3.35 How long must the station's logs be kept?

Ans. Two years. However, logs with entries about a disaster, investigation by the FCC, will be kept until the FCC authorizes their destruction. Logs involving claims or complaints shall be kept until settled or when statute time limit runs out.

3.36 What information (logs and records) must be made available to an authorized FCC employee?

Ans. All logs, equipment performance records, copy of most recent antenna resistance or common-point impedance measurements submitted to the FCC and copy of most recent field intensity measurements to establish performance of directional antennas.

3.37 What specific equipment performance measurements must be made at all FM broadcast stations on an annual basis?

Ans. Audio frequency response, audio frequency harmonic distortion, output noise level (frequency modulation), and output noise level (amplitude modulation).

3.38 During what time period may an FM broadcast station transmit signals for testing and maintenance purposes?

Ans. Between 1:00 a.m. and 6:00 a.m.

3.39 What are the operator license requirements for FM broadcast stations?

Ans. One or more operators holding a Third Class permit, endorsed for broadcast operation (Element IX). However, a First Class licensed operator must be on call.

3.40 By what methods may operating power at FM broadcast stations be computed?

Ans. By direct or indirect method.

3.41 What is the allowable frequency tolerance at FM broadcast stations?

Ans. The center frequency shall be maintained within 2000 cycles of the assigned frequency.

3.42 What is SCA? What are some possible uses of SCA?

Ans. SCA means Subsidiary Communications Authorization. It permits limited types of secondary services on a multiplex basis. Possible uses are: (1) Transmissions of interest to segments of public wishing to subscribe thereto, and (2) transmissions of signals directly related to operation of FM broadcast stations.

3.43 What items must be included in an SCA operating log?

Ans. The times subcarrier generator is turned on and off; and times modulation is applied to, and removed from subcarrier. Daily entries are made excluding subcarrier interruptions of 5 minutes or less.

3.44 What are the transmission standards of subsidiary communications multiplex operations?

Ans. FM of SCA subcarriers shall be used; instantaneous frequency shall be within 20 to 75 kc -- range for stereophonic broadcast is 53 to 75 kc; sum of modulation of main carrier by SCA subcarriers shall not exceed 30% -- 10% for stereophonic broadcast; FM of main carrier caused by SCA subcarrier shall, in frequency range 50 to 15,000 cycles, be at least 60 db below 100% modulation.

3.45 What are the licensed operator requirements for a TV broadcast station? An FM broadcast station? A 5-kilowatt, nighttime directional standard broadcast station?

Ans. For a TV broadcast station, one or more licensed radiotelephone First Class operators must be on duty where the transmitting equipment is located, and in actual charge thereof when the equipment is in operation.

At an FM broadcast station, one or more operators holding a Third Class permit, endorsed for broadcast operation, must be on duty, provided that a First Class licensed operator is on call.

Adjustment of transmitting equipment by lower-class operators, except when under the immediate supervision of a radiotelephone First Class operator, shall be limited to the following; (1) putting the transmitter on and off the air in a routine manner; (2) making external adjustments required as a result of variations of primary power supply; (3) making external adjustments required to insure proper modulation.

Should the transmitting equipment be observed to be operating improperly, an operator holding a license other than First Class must shut down the equipment and call a radiotelephone First Class operator to make the necessary repairs and adjustments. Every FM station with power over 25 kw must have at least one

First Class licensed operator in full-time employment, whose primary duties are to insure proper equipment operation.

For an AM broadcast using a highly critical or unstable directional antenna, a First Class licensed operator is required on duty during directional operation. In less critical installations, a Third Class operator may be employed, but only if a First Class operator is on call.

3.46 What is the frequency tolerance for television stations?

Ans. (a) The carrier frequency of the visual transmitter shall be maintained within ± 1000 cycles of the authorized carrier frequency. (b) The center frequency of the aural transmitter shall be maintained 4.5 megacycles ± 1000 cycles, above the visual carrier frequency.

3.47 What items must be included in a television station's operating log? What items must be included in a television station's maintenance log?

Ans. The following entries shall be made in the operating log by the properly licensed operator in actual charge of the transmitting apparatus only: (a) An entry of the time the station begins to supply power to the antenna and the time it stops. (b) An entry of each interruption of the carrier wave, where restoration is not automatic, its cause and duration followed by the signature of the person restoring operation (if licensed operator other than the licensed operator on duty). (c) An entry, at the beginning of operation and at intervals not exceeding one-half hour, of the following (actual readings observed prior to making any adjustments to the equipment) and, when appropriate, an indication of corrections made to restore parameters to normal operating values: (1) Operating constants of last radio stage of aural transmitter (total plate voltage and plate current). (2) Transmission line meter readings for both transmitters. (d) Any other entries required by the instrument of authorization or the provisions of this part. (e) The entries required for tower light inspections.

The following entries shall be made in the maintenance log: (a) An entry each week of the time and result of test of auxiliary transmitters. (b) A notation each week of the calibration check of automatic recording devices. (c) An entry describing the method used and the results obtained in determining the operating frequency of the transmitter: (1) Whenever the required frequency check is made. (2) Whenever the required frequency measurement is made. (d) An entry of the date and time of removal from and restoration to service of any of the following equipment in the event it becomes defective: (1) Visual modulation monitoring equipment or aural modulation monitor. (2) Final stage plate voltmeters of aural and visual transmitters. (3) Final stage plate ammeters of aural and visual transmitters. (4) Visual and aural transmitter transmission line radio frequency voltage, current, or power meter. (e) Record of tower light inspections. (f) Entries shall be made so as to describe fully any operation for testing and maintenance purposes.

3.48 (a) How is operating power determined for the visual transmitter at a television broadcast station? (b) For the aural transmitter?

Ans. (a) Average power output shall be measured while operating into a dummy load of substantially zero reactance and a resistance equal to the transmission line characteristic impedance. During this measurement the transmitter shall be modulated only by a standard synchronizing signal with blanking level set at 75 per cent of peak amplitude as observed in an output monitor, and with this blanking level amplitude maintained throughout the time interval between synchronizing pulses. The peak power output shall be the power so measured in the dummy load multiplied by the factor 1.68. During this measurement the direct plate voltage and current of the last radio stage and the transmission line meter shall be read and compared with similar readings taken with the dummy load replaced by the antenna. These readings shall be in substantial agreement. (b) Determined by either the direct or indirect method: (1) Using the direct method, the power shall be measured at the output terminals of the transmitter while operating into a dummy load of substantially zero reactance and a resistance equal to the transmission line characteristic impedance. The transmitter shall be unmodulated during this measurement. During this measurement the direct plate voltage and current of the last radio stage and the transmission line meter shall be read and compared with similar readings taken with the dummy load replaced by the antenna. These readings shall be in substantial agreement. (2) Using the indirect method, the operating power is the product of the plate voltage (E_p) and the plate current (I_p) of the last radio stage, and an efficiency factor, F, as follows:

$$\text{Operating power} = E_p \times I_p \times F$$

3.49 Describe the Emergency Action Notification Attention Signal.

Ans. It consists of two 5-second carrier breaks and 15 seconds of 1000 cps tone. It is followed by the warning or other message.

3.50 Under normal conditions all standard FM and TV broadcast stations must make what provisions for receiving Emergency Action Notifications and Terminations?

Ans. Licensees are required to install, maintain, and operate radio receiving equipment for such messages.

3.51 What type of station identification shall be given during an Emergency Action Condition?

Ans. No broadcast of call letters; only State and Operational Area identifications will be given.

3.52 Must stations operate in accordance with Section 73.57 (about maintenance of operating power) of the FCC Rules during an Emergency Action Condition?

Ans. No, not while operating under NDEA.

3.53 How often and at what times must EBS tests be sent?

Ans. Once each week on an unscheduled basis between 8:30 a.m. and local sunset.

SPECIAL BROADCAST SERVICES

3.54 What is the uppermost power limitation imposed on remote pickup broadcast stations? STL (studio transmitter link) stations? Intercity relay broadcast stations?

Ans. Not more than 5% above the maximum authorized power for all these stations.

3.55 What records of operation must be maintained for each licensed remote pickup broadcast station?

Ans. Hours of operation; program transmitted; frequency check; remarks about transmission; entry giving points of program origination and receiver location; where an antenna structure(s) is required to be illuminated.

3.56 What is the basic difference between STL and Intercity Relay broadcast stations?

Ans. STL stations can transmit program material only between the studio and transmitter location of a broadcast station; the Intercity Relay station is authorized to transmit between broadcast stations.

3.57 What type of antenna must be used with STL and Intercity Relay broadcast stations?

Ans. Directional.

3.58 What is the frequency tolerance provided by FCC Rules for an STL (studio transmitter link) and Intercity Relay broadcast station?

Ans. ± 0.005 per cent of the assigned frequency.

ANTENNAS

3.59 Under what two general conditions must antenna structures be painted and lighted?

Ans. When higher than 200 feet above ground or when aeronautical study is required.

3.60 What color(s) should antenna structures be painted? Where can paint samples be obtained?

Ans. With alternate bands of aviation surface orange and white. Specifications for paint can be obtained from General Services Administration, Washington, D.C. 20407.

3.61 If a tower is required to be lighted and the lights are controlled by a light-sensitive device and the device malfunctions, when should the tower lights be on?

Ans. Sunset to sunrise.

3.62 As a general rule, a light-sensitive device used to control tower lights should face which direction?

Ans. North.

3.63 If the operation of a station's tower lights are not continuously monitored by an alarm device, how often should the lights be visually checked?

Ans. At least once each 24 hours.

3.64 How often should automatic control devices and alarm circuits associated with antenna tower lights be checked for proper operation?

Ans. Not less than once every three months.

3.65 What items regarding the operation of antenna tower lighting should be included in the station's maintenance log?

Ans. The licensee of any radio station which has an antenna structure requiring illumination shall make the following entries in the station record of the inspections: (a) The time the tower lights are turned on and off each day if manually controlled. (b) The time the daily check of proper operation of the tower lights was made, if automatic alarm system is not provided. (c) In the event of any observed or otherwise known extinguishment or improper functioning of a tower light: (1) Nature of such extinguishment or improper functioning. (2) Date and time the extinguishment or improper functioning was observed, or otherwise noted. (3) Date, time, and nature of the adjustments, repairs or replacements made. (4) Identification of Flight Service Station (Federal Aviation Administration) notified of the extinguishment of improper functioning of any code or rotating beacon light or top light not corrected within 30 minutes, and the date and time such notice was given. (5) Date and time notice was given to the Flight Service Station (Federal Aviation Administration) that the required illumination was resumed. (d) Upon completion of the periodic inspection required at least once each 3 months: (1) The date of the inspection and the condition of all tower lights and associated tower lighting control devices, indicators and alarm systems. (2) Any adjustments, replacements, or repairs made to insure compliance with the lighting requirements and the date such adjustments, replacements or repairs were made.

3.66 Generally speaking, how often should the antenna tower be painted?

Ans. As necessary to maintain good visibility.

3.67 Is it necessary to have replacement lamps for the station's antenna tower lights?

Ans. A sufficient supply of spare lamps shall be maintained for immediate replacement at all times.

3.68 Generally speaking, how soon, after a defect in the antenna tower lights is noted, should the defect be corrected?

Ans. As soon as possible.

3.69 What action should be taken if the tower lights at a station malfunction and cannot be repaired immediately?

Ans. Report immediately by telephone or telegraph to the nearest airways communications station or office of the Federal Aviation Agency any observed failure of any code or rotating beacon light if such failure is not corrected within thirty minutes after observation thereof. Further, notify the above station or office immediately upon resumption of the required illumination. Data concerning the failure of tower lights must also be recorded in the station log. Include in the log entry the nature of the failure, the date and time the failure was observed, and the date, time, and nature of the adjustments, repairs, or replacements made. In the event of failure of rotating or beacon lights, the time of notifying the Federal Aviation Agency must also be entered.

Glossary - - FCC Words and Phrases

CONTENTS

HOW TO USE THIS GLOSSARY

When the Service is shown separately, use the section first. Whenever the word or phrase is not shown, use Section I - General Definitions next.

These groupings by Service are arranged for your convenient reference when studying for the exam. Necessarily, all definitions are not shown because some of them are very simple or familiar.

An asterisk (*) with a word means an often asked definition in examination. Know these words very well.

I General Definitions

Active satellite. An earth satellite carrying a station intended to transmit or retransmit radiocommunication signals.

Alaska Communication System or ACS. The telecommunication system within Alaska and between Alaska and other areas which is operated by the United States Army Signal Corps.

Alaska-public fixed station. A fixed station in Alaska, which is open to public correspondence and is licensed by the Commission for radiocommunication between specified fixed points in Alaska exclusively.

Antenna power gain. The square of the ratio of the root-mean-square free space field intensity produced at one mile in the horizontal plane, in millivolts per meter for one kilowatt antenna input power to 137.6 mv/m. This ratio should be expressed in decibels (db). (If specified for a particular direction, antenna power gain is based on the field strength in that direction only.)

Antenna power input. The radio frequency peak or RMS power, as the case may be, supplied to the antenna from the antenna transmission line and its associated impedance matching network.

Antenna structures. The term "antenna structure" includes the radiating system, its supporting structures, and any surmounting appurtenances.

Assigned frequency. The frequency coinciding with the center of an authorized bandwidth of emission shall be specified as the assigned frequency.

Aural broadcast intercity relay station. A fixed station utilizing telephony for the transmission of aural program material between broadcasting stations other than international broadcasting stations, for simultaneous or delayed broadcast.

Aural broadcast STL (studio transmitter link) station. A fixed station utilizing telephony for the transmission of aural program material between a studio and the transmitter of a broadcasting station other than an international broadcasting station, for simultaneous or delayed broadcast.

***Authorized bandwidth.** The authorized bandwidth is the occupied bandwidth authorized to be used by a station.

Authorized carrier frequency. A specific carrier frequency authorized for use by a station, from which the actual or suppressed carrier frequency is permitted to deviate, solely because of frequency instability, by an amount not to exceed the frequency tolerance.

Authorized frequency. The frequency assigned to a station by the Commission and specified in the instrument of authorization.

Authorized power. The power assigned to a radio station by the Commission and specified in the instrument of authorization. The authorized power does not necessarily correspond to the power used by the Commission for purposes of its Master Frequency Record (MFR) and notification to the International Telecommunication Union.

***Bandwidth occupied by an emission.** The width of the frequency band (normally specified in kilocycles) containing those frequencies upon which a total of 99 percent of the radiated power appears, extended to include any discrete frequency upon which the power is at least 0.25 percent of the total radiated power.

Baseband. In the process of modulation, the baseband is the frequency band occupied by the aggregate of the modulating signals when first used to modulate a carrier.

***Base station.** A land station in the land mobile service carrying on a service with land mobile stations.

Broadcasting service. A radiocommunication service in which the transmissions are intended for direct reception by the general public. This service may include sound transmissions, television transmissions or other types of transmissions.

Broadcasting station. A station in the broadcasting service.

***Carrier.** In a frequency stabilized system, the sinusoidal component of a modulated wave whose frequency is independent of the modulating wave; or the output of a transmitter when the modulating wave is made zero; or a wave generated at a point in the transmitting system and subsequently modulated by the signal; or a wave generated locally at the receiving terminal which, when combined with the side bands in a suitable detector, produces the modulating wave.

***Carrier frequency.** The frequency of the carrier.

Carrier power. The average power supplied to the antenna transmission line by a transmitter during one radio frequency cycle under conditions of no modulation. This definition does not apply to pulse modulated emissions.

Citizens radio service. A radiocommunication service of fixed, land, and mobile stations intended for personal or business radiocommunications, radio signalling, control of remote objects or devices by means of radio, and other purposes not specifically prohibited.

***Coast station.** A land station in the maritime mobile service.

"Common carrier" or "carrier". "Common carrier" or "carrier" means any person engaged as a common carrier for hire, in interstate or foreign communication by wire or radio or in interstate or foreign radio transmission of energy, except where reference is made to common carriers not subject to the Communications Act of 1934, as amended; but a person engaged in radio broadcasting shall not, insofar as such person is so engaged, be deemed a common carrier.

Common carrier fixed station. A fixed station open to public correspondence.

Common carrier land station. A land station open to public correspondence.

Common carrier mobile station. A mobile station open to public correspondence.

Communication common carrier. Any person engaged in rendering communication service for hire to the public.

Communication-satellite earth station. An earth station in the communication-satellite service.

Communication-satellite service. A space service: (a) between earth stations, when using active or passive satellites for the exchange of communications of the fixed or mobile service, or (b) between an earth station and stations on active satellites for the exchange of communications of the mobile service, with a view to their re-transmission to or from stations in the mobile service.

Communication-satellite space station. A space station in the communication-satellite service, on an earth satellite.

Community antenna relay service. A fixed service, the stations of which are used for the transmission of television and related audio signals, and signals of standard and FM broadcasting stations, to a terminal point from which the signals are distributed to the public by cable.

Community antenna relay station. A fixed station in the community antenna relay service.

Control point. A control point is an operating position which is under the control and supervision of the licensee, at which a person immediately responsible for the proper operation of the transmitter is stationed, and at which adequate means are available to aurally monitor all transmissions and to render the transmitter inoperative.

Control station. A fixed station whose transmissions are used to control automatically the emissions or operations of another radio station at a specified location, or to transmit automatically to an alarm center telemetering information relative to the operation of such station.

Deep space. Space at distances from the earth equal to or greater than the distance between the earth and the moon.

Developmental broadcast station. A station licensed experimentally to carry on development and research primarily in radiotelephony for the advancement of the broadcast services.

Disaster communications service. A service of fixed, land, and mobile stations licensed or authorized to provide essential communications incident to or in connection with disaster or other incidents which involve loss of communications facilities normally available or which require the temporary establishment of communications facilities beyond those normally available.

Dispatch point. A dispatch point is any position from which messages may be transmitted under the supervision of the person at a control point.

Domestic fixed public service. A fixed service, the stations of which are open to public correspondence, for radiocommunications originating and terminating solely at points all of which lie within: (a) the State of Alaska, or (b) the State of Hawaii, or (c) the contiguous 48 states and the District of Columbia, or (d) a single possession of the United States. Generally, in cases where service is afforded on frequencies above 72 mc/s, radiocommunications between the contiguous 48 States (including the District of Columbia) and Canada or Mexico, or radiocommunications between the State of Alaska and Canada, are deemed to be in the domestic fixed public service.

Domestic fixed public station. A fixed station in the domestic fixed public service.

Domestic public radiocommunication services. The land mobile and domestic fixed public services the stations of which are open to public correspondence.

Duplex operation. Operating method in which transmission is possible simultaneously in both directions.

***Earth station.** A station in the space service located either on the earth's surface, including on board a ship, or on board an aircraft.

Environmental communications. Communications in the maritime mobile service for the broadcast of information pertaining to the environmental conditions, in which vessels operate, i.e., weather, sea conditions, time signals of a grade adequate for practical navigation, notices to mariners and hazards to navigation.

Experimental station. A station utilizing radio waves in experiments with a view to the development of science or technique. This definition does not include amateur stations.

Experimental television broadcast station. A station licensed for experimental transmission of transient visual images of moving or fixed objects for simultaneous reception and reproduction by the general public.

Facsimile. A system of telecommunication for the transmission of fixed images, with or without halftones, with a view to their reproduction in a permanent form.

Facsimile broadcasting station. A station licensed to transmit images of still objects for record reception by the general public.

Fixed earth station. An earth station intended to be used at a specified fixed point.

Fixed public control service. A fixed service carried on for the purpose of transmitting intelligence between transmitting or receiving stations in the public radiocommunication services and the message centers or control points associated therewith.

Fixed relay station. An operational fixed station established for the automatic retransmission of radiocommunications received from either one or more fixed stations or from a combination of fixed and mobile stations and directed to a specified location.

Fixed service. A service of radiocommunication between specified fixed points.

***Fixed station.** A station in the fixed service.

FM broadcasting station. A broadcasting station utilizing telephony by means of frequency modulation, and when authorized under a Subsidiary Communications Authorization (SCA), utilizing F9 emissions.

Frequency modulation (FM). A system of modulation where the instantaneous radio frequency varies in proportion to the instantaneous amplitude of the modulating signal (amplitude of modulating signal to be measured after pre-emphasis, if used) and the instantaneous radio frequency is independent of the frequency of the modulating signal.

Frequency tolerance. The extent to which an actual or suppressed carrier frequency is permitted to depart, solely because of frequency instability, from the authorized carrier frequency. The frequency tolerance is expressed in parts in 10^6 or in cycles per second.

Gc/s (gigacycle per second). A gigacycle per second (gc/s) means one thousand megacycles.

Great Lakes Agreement. The Agreement for the Promotion of Safety on the Great Lakes by Means of Radio and the regulations referred to therein, made by and between the Governments of the United States and Canada, which came into force on November 13, 1954.

***Harmful interference.** Any emission, radiation or induction which endangers the functioning of a radionavigation service or of other safety services or seriously degrades, obstructs, or repeatedly interrupts a radiocommunication service.

Hertz. A unit of frequency equivalent to one cycle per second. The terms Hertz (Hz) and cycle(s) per second (c/s) are synonymous and may be used interchangeably.

Hours of service. The period of time during each calendar day when a station is used, in conformity with the terms of the station authorization, for the rendition of its normal service.

Industrial radio services. Any service of radiocommunication essential to, operated by, and for the sole use of, those enterprises which for purposes of safety or other necessity require radiocommunication in order to function efficiently, the radio transmitting facilities of which are defined as fixed, land, mobile or radiolocation stations.

Industrial, scientific and medical equipment (ISM equipment). Devices which use radio waves for industrial, scientific, medical, or any other purposes including the transfer of energy by radio and which are neither used nor intended to be used for radiocommunication.

Instructional television fixed station. A fixed station operated by an educational organization and used primarily for the transmission of visual and aural instructional, cultural and other types of educational material to one or more fixed receiving locations.

ITFS response station. A fixed station operated at an authorized location to provide voice communication to an associated instructional television fixed station.

International broadcasting station. A broadcasting station employing frequencies allocated to the broadcasting service between 5950 kc/s and 26100 kc/s, whose transmissions are intended to be received directly by the general public in foreign countries.

International control station. A fixed station in the fixed public control service associated directly with the international fixed public radiocommunication service.

International fixed public radio service. A fixed service, the stations of which are open to public correspondence and which, in general, is intended to provide radiocommunication between any one of the contiguous 48 states (including the District of Columbia) and the State of Alaska, or the State of Hawaii, or any U. S. possession or any foreign point; or between any U. S. possession and any other point; or between the State of Alaska and any other point; or between the State of Hawaii and any other point. In addition, radiocommunications within the contiguous 48 states (including the District of Columbia) in connection with the relaying of international traffic between stations which provide the above service, are also deemed to be in the international fixed public radiocommunication service; provided, however, that communications solely between Alaska, or any one of the contiguous 48 states (including the District of Columbia), and either Canada or Mexico are not deemed to be in the international fixed public radiocommunication service when such radiocommunications are transmitted on frequencies above 72 mc/s.

International fixed public station. A fixed station in the international fixed public radio service.

International Radio Regulations. The Radio Regulations in force annexed to the International Telecommunication Convention, Geneva, 1959, as between the Government of the United States and other Contracting Governments; and such preceding international radio regulations as remain in force between the Government of the United States and other Contracting Governments.

Interzone station. A fixed station in the public safety (police) radio service using radiotelegraphy (A1 emission) for communication with zone stations within the zone and with interzone stations in other zones.

Ionospheric scatter. The propagation of radio waves by scattering as a result of irregularities or discontinuities in the ionization of the ionosphere.

Kc/s (kilocycle per second). A kilocycle per second (kc/s) means one thousand cycles per second.

***Land mobile service.** A mobile service between base stations and land mobile stations, or between land mobile stations.

Land mobile station. A mobile station in the land mobile service capable of surface movement within the geographical limits of a country or continent.

***Land station.** A station in the mobile service not intended to be used while in motion.

Land transportation radio service. Any private service of radiocommunication essential to the conduct of certain land transportation activities and operated for the use of persons engaged in those activities, the transmitting facilities of which are defined as fixed, land, mobile or radiolocation stations.

Loran station. A long distance radionavigation land station transmitting synchronized pulses. Hyperbolic lines of position are determined by the measurement of the difference in the time of arrival of these pulses.

Man-made structure. Any construction other than a tower, mast or pole.

Marine radiobeacon station. A radionavigation land station, the emissions of which are intended to enable a ship station to determine its bearing or its direction in relation to the marine radiobeacon station.

Maritime mobile service. A mobile service between coast stations and ship stations, or between ship stations, in which survival craft stations may also participate.

Maritime radionavigation service. A radionavigation service intended for the benefit of ships.

Mc/s (megacycle per second). A megacycle per second (mc/s) means one thousand kilocycles.

Mean power of radio transmitter. The power supplied to the antenna during normal operation, averaged over a time sufficiently long compared to the period corresponding to the lowest frequency encountered in actual modulation.

Meteorological aids service. A radiocommunication service used for meteorological, including hydrological, observations and exploration.

Meteorological-satellite earth station. An earth station in the meteorological-satellite service.

Meteorological-satellite service. A space service in which the results of meteorological observations, made by instruments on earth satellites, are transmitted to earth stations by space stations on these satellites.

Meteorological-satellite space station. A space station in the meteorological-satellite service, on an earth satellite.

Mobile earth station. An earth station intended to be used while in motion or during halts at unspecified points.

Mobile, except television pickup, station. Any mobile station other than a television pickup station.

Mobile relay station. A base station established for the automatic retransmission of mobile service communications which originate on the transmitting frequency of the mobile stations and which are retransmitted on the receiving frequency of the mobile stations.

***Mobile service.** A service of radiocommunication between mobile and land stations, or between mobile stations.

Mobile station. A station in the mobile service intended to be used while in motion or during halts at unspecified points.

Modulation. The process of producing a wave some characteristic of which varies as a function of the instantaneous value of another wave, called the modulating wave.

NARBA and the U.S./Mexican Agreement. "NARBA" means the North American Regional Broadcasting Agreement signed at Washington, D. C., November 15, 1950, which entered into force April 19, 1960 and to which the signatory countries are The Bahama Islands and Jamaica, Canada, Cuba, the Dominican Republic, and the United States of America. U.S./Mexican Agreement means the Agreement between the United States of America and the United Mexican States concerning radio broadcasting in the standard broadcast band signed at Mexico, D.F., January 29, 1957 which entered into force June 9, 1961.

Occupied Bandwidth. The frequency bandwidth such that, below its lower and above its upper frequency limits, the mean powers radiated are each equal to 0.5 percent of the total mean power radiated by a given emission.

Operational land station. A land station, excluding aeronautical stations, not open to public correspondence, operated by and for the sole use of those agencies operating their own radiocommunication facilities in the public safety, industrial, land transportation, marine or aviation services.

Operational mobile station. A mobile station, excluding aircraft stations, not open to public correspondence, operated by and for the sole use of those agencies operating their own communication facilities in the public safety, industrial, land transportation, marine or aviation services.

Passive satellite. An earth satellite intended to transmit radiocommunication signals by reflection.

Peak envelope power. The average power supplied to the antenna transmission line by a transmitter during one radio frequency cycle at the highest crest of the modulation envelope, taken under conditions of normal operation.

Peak power of a radio transmitter. The mean power supplied to the antenna during one radio frequency cycle at the highest crest of the modulation envelope, taken under conditions of normal operation.

Permittee. A person who holds a valid station construction permit.

Person. An individual, partnership, association, joint stock company, trust, or corporation.

Point of communication. This term, when applied to an Alaska-public fixed station, means a specified fixed station or specified geographic location with which such station is authorized to communicate.

Port operations. Communications in or near a port, or in locks or waterways, between coast stations and ship stations, or between ship stations, in which messages are restricted to those relating to the movement and safety of ships and, in emergency, to the safety of persons.

***Primary standard of frequency.** The primary standard of frequency for radio frequency measurements shall be the national standard of frequency maintained by the National Bureau of Standards, Department of Commerce, Washington, D. C. The operating frequency of all radio stations will be determined by comparison with this standard or the standard signals of station WWV of the National Bureau of Standards.

Public correspondence. Any telecommunication which the offices and stations must, by reason of their being at the disposal of the public, accept for transmission.

Public safety radio service. Any service of radiocommunication essential either to the discharge of non-Federal governmental functions or the alleviation of an emergency endangering life or property, the radio transmitting facilities of which are defined as fixed, land, mobile, or radiolocation stations.

Racon. A radionavigation system transmitting, automatically or in response to a predetermined received signal, a pulsed radio signal with specific characteristics.

Racon station. A radionavigation land station which employs a racon.

Radar. A radiodetermination system based on comparison of reference signals with radio signals reflected, or retransmitted, from the position to be determined.

Radio. A general term applied to the use of radio waves.

Radio astronomy. Astronomy based on the reception of radio waves of cosmic origin.

Radio astronomy service. A service involving the use of radio astronomy.

Radio astronomy station. A station in the radio astronomy service.

Radiobeacon station. A station in the radionavigation service, the emissions of which are intended to enable a mobile station to determine its bearing or direction in relation to the radiobeacon station.

Radiocommunication. Telecommunication by means of radio waves.

Radiodetermination. The determination of position, or the obtaining of information relating to position, by means of the propagation properties of radio waves.

Radiodetermination service. A service involving the use of radiodetermination.

Radiodetermination station. A station in the radiodetermination service.

Radio direction-finding. Radiodetermination using the reception of radio waves for the purpose of determining the direction of a station or object.

Radio direction-finding station. A radiodetermination station using radio direction-finding.

Radio district. The territory within each radio district.

Radiolocation. Radiodetermination used for purposes other than those of radionavigation.

Radiolocation land station. A station in the radiolocation service not intended to be used while in motion.

Radiolocation mobile station. A station in the radiolocation service intended to be used while in motion or during halts at unspecified points.

Radiolocation service. A radiodetermination service involving the use of radiolocation.

Radionavigation. Radiodetermination used for the purposes of navigation, including obstruction warning.

Radionavigation land station. A station in the radionavigation service not intended to be used while in motion.

Radionavigation mobile station. A station in the radionavigation service intended to be used while in motion or during halts at unspecified points.

Radionavigation-satellite earth station. An earth station in the radionavigation-satellite service.

Radionavigation-satellite service. A service using space stations on earth satellites for the purpose of radionavigation, including, in certain cases, transmission or re-transmission of supplementary information necessary for the operation of the radionavigation system.

Radionavigation-satellite space station. A space station in the radionavigation-satellite service, on an earth satellite.

Radionavigation service. A radiodetermination service involving the use of radionavigation.

Radionavigation station. A station in the radionavigation service.

Radio range station. A radionavigation land station in the aeronautical radionavigation service providing radial equisignal zones.

Radiosonde. An automatic radio transmitter in the meteorological aids service usually carried on an aircraft, free balloon, kite or parachute, and which transmits meteorological data.

Radio service. An administrative subdivision of the field of radiocommunication. In an engineering sense, the subdivisions may be made according to the method of operation, as, for example, mobile service and fixed service. In a regulatory sense, the subdivisions may be descriptive of particular groups of licensees.

Radio waves (or Hertzian waves). Electromagnetic waves of frequencies lower than 3,000 gc/s (3,000,000 mc/s), propagated in space without artificial guide.

Region 1, Region 2, and Region 3. Those geographic areas defined as "Region 1", "Region 2", and "Region 3" in Article 5 of the International Radio Regulations, Geneva, 1959.

Remote pickup broadcast base station. A base station licensed for communicating with remote pickup broadcast mobile stations.

Remote pickup broadcast mobile station. A land mobile station licensed for the transmission of program material and related communications from the scene of events which occur outside a studio to broadcasting station, and for communicating with other remote pickup broadcast base and mobile stations.

Repeater station. An operational fixed station established for the automatic retransmission of radio communications received from any station in the Mobile Service.

Safety Convention. The International Convention for the Safety of Life at Sea, London, 1960, including the Regulations annexed thereto.

Safety service. A radiocommunication service used permanently or temporarily for the safeguarding of human life and property.

Selective calling. A means of calling in which signals are transmitted in accordance with a prearranged code for the purpose of operating a particular automatic attention device in use at the selected station whose attention is sought.

Ship station. A mobile station in the maritime mobile service located on board a vessel, other than a survival craft, which is not permanently moored.

Ship station license. A license authorizing the operation of a ship station, a survival craft station associated with a ship, or a ship radionavigation station.

Signaling. Intermittent or periodic transmission (excluding radiotelephony or any type of Morse code) of intelligence by means of prearranged tones, impulses, or combinations thereof, designed to actuate a mechanism at the point of reception.

Simplex operation. Operating method in which transmission is made possible alternately in each direction, for example, by means of manual control.

Spacecraft. Any type of space vehicle including an earth satellite or a deep-space probe, whether manned or unmanned.

Space research earth station. An earth station in the space research service.

Space research service. A space service in which spacecraft or other objects in space are used for scientific or technological research purposes.

Space research space station. A space station in the space research service.

Space telecommand. The use of radiocommunication for the transmission of signals to a space station to initiate, modify or terminate functions of the equipment on a space object, including the space station.

Space telemetering. The use of telemetering for the transmission from a space station of results of measurements made in a spacecraft, including those relating to the functioning of the spacecraft.

Space tracking. Determination of the orbit, velocity or instantaneous position of an object in space by means of radio determination, excluding primary radar, for the purpose of following the movement of the object.

Space service. A radiocommunication service: (a) between earth stations and space stations, or (b) between space stations, or (c) between earth stations when the signals are retransmitted by space stations, or transmitted by reflection from objects in space, excluding reflection or scattering by the ionosphere or within the earth's atmosphere.

Spurious emission. Emission on a frequency or frequencies which are outside the necessary band, and the level of which may be reduced without affecting the corresponding transmission of information. Spurious emissions include harmonic emissions, parasitic emissions, and intermodulation products, but exclude emissions in the immediate vicinity of the necessary band, which are a result of the modulation process for the transmission of information.

Standard broadcasting station. A broadcasting station operated on a frequency in the band 535-1605 kilocycles.

Standard frequency service. A radiocommunication service for scientific, technical and other purposes, providing the transmission of specified frequencies of stated high precision, intended for general reception.

Stationary satellite. A satellite, the circular orbit of which lies in the plane of the earth's equator and which turns about the polar axis of the earth in the same direction and with the same period as those of the earth's rotation.

Station. One or more transmitters or receivers or a combination of transmitters and receivers, including the accessory equipment, necessary at one location for carrying on a radiocommunication service. Each station shall be classified by the service in which it operates permanently or temporarily.

***Station authorization.** Any construction permit, license, or special temporary authorization issued by the Commission.

Survival craft station. A mobile station in the maritime or aeronautical mobile service intended solely for survival purposes and located on any lifeboat, liferaft or other survival equipment.

Telecommunication. Any transmission, emission or reception of signs, signals, writing, images, and sounds, or intelligence of any nature by wire, radio, optical or other electromagnetic systems.

Telegraphy. A system of telecommunication which is concerned in any process providing transmission and reproduction at a distance of documentary matter, such as written or printed matter or fixed images, or the reproduction at a distance of any kind of information in such form. The foregoing definition appears in the International Telecommunication Convention, but, for the purposes of the Commission's rules, telegraphy shall mean, unless otherwise specified, "A system of telecommunication for the transmission of written matter by the use of a signal code."

Telemetering. The use of telecommunication for automatically indicating or recording measurements at a distance from the measuring instrument.

Telemetering fixed station. A fixed station, the emissions of which are used for telemetering.

Telemetering land station. A land station, the emissions of which are used for telemetering.

Telemetering mobile station. A mobile station, the emissions of which are used for telemetering.

Telephony. A system of telecommunication set up for the transmission of speech or, in some cases, other sounds.

Television. A system of telecommunication for transmission of transient images of fixed or moving objects.

Television broadcasting station. A broadcasting station utilizing both television and telephony to provide combination and simultaneous visual and aural programs intended to be received directly by the general public.

Terrestrial service. Any radio service defined in this Part, other than a space service or the radio astronomy service.

Terrestrial station. A station in a terrestrial service.

Tropospheric scatter. The propagation of radio waves by scattering as a result of irregularities or discontinuities in the physical properties of the troposphere.

Zone station. A fixed station in the public safety (police) radio service using radiotelegraph (A1 emission) for communication with other similar stations in the same zone and with an interzone station.

II Experimental Radio Services (other than broadcast)

Experimental Service. A service in which Hertzian waves are employed for purposes of experimentation in the radio art or for purposes of providing essential communications for research projects which could not be conducted without the benefit of such communications.

Experimental Service (Research). An Experimental Service (1) for research in the radio art not related to the development of an established or proposed new service, or (2) for providing essential communications for research projects which could not be conducted without the benefit of such communications.

Experimental Service (Developmental). An Experimental Radio Service for the development of equipment, engineering or operational data, or techniques for an existing or proposed radio service.

III Radio Frequency Devices

Community antenna television system. A restricted radiation device designed and used for the purpose of distributing television signals by means of conducted or guided radio frequency currents to a multiplicity of receivers outside the confines of a single building. Note: The television signals that are distributed are modulated radio frequency signals and may be: (a) Broadcast signals that have been received and amplified, (b) Broadcast signals that have been received and converted to another frequency, (c) Any other modulated radio frequency signals fed into the system.

Incidental radiation device. A device that radiates radio frequency energy during the course of its operation although the device is not intentionally designed to generate radio frequency energy.

Low power communication device. A low power communication device is a restricted radiation device, exclusive of those employing conducted or guided radio frequency techniques, used for the transmission of signs, signals, (including control signals), writing, images and sounds or intelligence of any nature by radiation of electromagnetic energy. Examples: Wireless microphone, phonograph oscillator, radio controlled garage door opener and radio controlled models.

Restricted radiation device. A device in which the generation of radio frequency energy is intentionally incorporated into the design and in which the radio frequency energy is conducted along wires or is radiated, exclusive of transmitters which require licensing under other parts of this chapter and exclusive of devices in which the radio frequency energy is used to produce physical, chemical, or biological effects in materials and which are regulated under the Rules.

Television broadcast receiver. Apparatus designed to receive television pictures broadcast simultaneously with sound.

IV Industrial, Scientific and Medical Equipment

Industrial heating equipment. Any apparatus which utilizes a radio frequency oscillator or any other type of radio frequency generator and transmits radio frequency energy used for or in connection with industrial heating operations utilized in a manufacturing or production process.

Industrial, scientific and medical equipment (ISM equipment). Devices which use radio waves for industrial, scientific, medical or any other purposes including the transfer of energy by radio and which are neither used nor intended to be used for radiocommunication.

ISM frequency. A frequency assigned for the use of ISM equipment. A specified tolerance is associated with each ISM frequency.

Medical diathermy equipment. Any apparatus (other than surgical diathermy apparatus designed for intermittent operation with low power) which utilizes a radio frequency oscillator or any other type of radio frequency generator and transmits radio frequency energy used for therapeutic purposes.

Miscellaneous equipment. Any apparatus other than that defined in or excepted above in which radio frequency energy is applied to materials to produce physical, biological, or chemical effects such as heating, ionization of gases, mechanical vibrations, hair removal and acceleration of charged particles, which do not involve communications or the use of radio receiving equipment.

Ultrasonic equipment. Any apparatus which generates radio frequency energy and utilizes that energy to excite or drive an electromechanical transducer for the production of sonic or ultrasonic mechanical energy for industrial, scientific, medical or other noncommunication purposes.

V Broadcast Services

A. STANDARD BROADCAST STATIONS

1. General Definitions

Auxiliary transmitter. A transmitter maintained only for transmitting the regular programs of a station in case of failure of the main transmitter.

*Broadcast day. Period of time between local sunrise and 12 midnight local standard time.

*Daytime. Period of time between local sunrise and local sunset.

Dominant station. A Class I station operating on a clear channel.

*Experimental period. That time between 12 midnight and local sunrise. This period may be used for experimental purposes in testing and maintaining apparatus by the licensee of any standard broadcast station on its assigned frequency and with its authorized power, provided no interference is caused to other stations maintaining a regular operating schedule within such period. No station licensed for "daytime" or "specified hours" of operation may broadcast any regular or scheduled program during this period.

*Nighttime. Time between local sunset and 12 midnight local standard time.

Portable transmitter. A transmitter so constructed that it may be moved about conveniently from place to place, and is in fact so moved about from time to time, but not ordinarily used while in motion. In the standard broadcast band, such a transmitter is used in making field intensity measurements for locating a transmitter site for a standard broadcast station. A portable broadcast station will not be licensed in the standard broadcast band for regular transmission of programs intended to be received by the public.

Secondary station. Any station except a Class I station operating on a clear channel.

Service areas. (a) Primary service area of a broadcast station means the area in which the groundwave is not subject to objectionable interference or objectionable fading. (b) Secondary service area of a broadcast station means the area served by the skywave and not subject to objectionable interference. The signal is subject to intermittent variations in intensity. (c) Intermittent service area of a broadcast station means the area receiving service from the groundwave but beyond the primary service area and subject to some interference and fading.

***Standard broadcast band.** The band of frequencies extending from 535 to 1605 kilocycles.

***Standard broadcast channel.** The band of frequencies occupied by the carrier and two sidebands of a broadcast signal with the carrier frequency at the center. Channels shall be designated by their assigned carrier frequencies. The 107 carrier frequencies assigned to standard broadcast stations shall begin at 540 kilocycles and be in successive steps of 10 kilocycles.

***Standard broadcast station.** A broadcasting station licensed for the transmission of radiotelephone emissions primarily intended to be received by the general public and operated on a channel in the band 535-1605 kilocycles.

***Sunrise and sunset.** For each particular location and during any particular month, the time of sunrise and sunset as specified in the instrument of authorization.

2. Technical Definitions

***Antenna current.** The radio frequency current in the antenna with no modulation.

***Antenna power.** Antenna input power or antenna power means the product of the square of the antenna current and the antenna resistance at the point where the current is measured.

***Antenna resistance.** Total resistance of the transmitting antenna system at the operating frequency and at the point at which the antenna current is measured.

Blanketing. Form of interference which is caused by the presence of a broadcast signal of 1 v/m or greater intensity in the area adjacent to the antenna of the transmitting station. The 1 v/m contour is referred to as the blanket contour and the area within this contour is referred to as the blanket area.

Combined audio harmonics. Arithmetical sum of the amplitudes of all the separate harmonic components. Root sum square harmonic readings may be accepted under conditions prescribed by the Commission.

Effective field. Effective field or effective field intensity is the root-mean-square (RMS) value of the inverse distance fields at a distance of 1 mile from the antenna in all directions in the horizontal plane.

***Grid modulation.** Modulation produced by introduction of the modulating wave into any of the grid circuits of any tube in which the carrier frequency wave is present.

***High level modulation.** Modulation produced in the plate circuit of the last radio stage of the system.

***Last radio stage.** Oscillator or radio-frequency-power amplifier stage which supplies power to the antenna.

***Low level modulation.** Modulation produced in an earlier stage than the final.

Maximum percentage of modulation. Greatest percentage of modulation that may be obtained by a transmitter without producing in its output harmonics of the modulating frequency in excess of those permitted by these regulations.

Maximum rated carrier power. Maximum power at which the transmitter can be operated satisfactorily. It is determined by the design of the transmitter and the type and number of vacuum tubes used in the last radio stage.

***Modulated stage.** The radio frequency stage to which the modulator is coupled and in which the continuous wave (carrier wave) is modulated in accordance with the system of modulation and the characteristics of the modulating wave.

***Modulator stage.** The last amplifier stage of the modulating wave which modulates a radio frequency stage.

***Operating power.** Power that is actually supplied to the radio station antenna.

***Percentage modulation (amplitude).** The ratio of half the difference between the maximum and minimum amplitudes of the amplitude modulated wave to the average amplitude expressed in percentage.

***Plate modulation.** Modulation produced by introduction of the modulating wave into the plate circuit of any tube in which the carrier frequency wave is present.

***Plate input power.** The product of the direct plate voltage applied to the tubes in the last radio stage and the total direct current flowing to the plates of these tubes, measured without modulation.

B. FM STATIONS

1. Frequency Modulation

Antenna height above average terrain. The average of the antenna heights above the terrain from 2 to 10 miles from the antenna for the eight directions spaced evenly for each 45 degrees of azimuth starting with True North. (In general, a different antenna height will be determined in each direction from the antenna. The average of these various heights is considered the antenna height above the average terrain. In some cases less than eight directions may be used.) Where circular or elliptical polarization is employed, the antenna height above average terrain shall be based upon the height of the radiation center of the antenna which transmits the horizontal component of radiation.

***Antenna power gain.** The square of the ratio of the root-mean-square free space field strength produced at 1 mile in the horizontal plane, in millivolts per meter for 1 kilowatt antenna input power to 137.6 mv/m. This ratio should be expressed in decibels (db). (If specified for a particular direction, antenna power gain is based on the field strength in that direction only.)

***Center frequency.** (1) The average frequency of the emitted wave when modulated by a sinusoidal signal. (2) The frequency of the emitted wave without modulation.

***Effective radiated power.** The product of the antenna power (transmitter output power less transmission line loss) times (1) the antenna power gain, or (2) the antenna field gain squared. Where circular or elliptical polarization is employed, the term effective radiated power is applied separately to the horizontal and vertical components of radiation. For allocation purposes, the effective radiated power authorized is the horizontally polarized component of radiation only.

***FM broadcast band.** The band of frequencies extending from 88 to 108 megacycles per second, which includes those assigned to noncommercial educational broadcasting.

***FM broadcast channel.** A band of frequencies 200 kc/s wide and designated by its center frequency. Channels for FM broadcast stations begin at 88.1 mc/s and continue in successive steps of 200 kc/s to and including 107.9 mc/s.

***FM broadcast station.** A station employing frequency modulation in the FM broadcast band and licensed primarily for the transmission of radiotelephone emissions intended to be received by the general public.

***Field strength.** The electric field strength in the horizontal plane.

Free space field strength. The field strength that would exist at a point in the absence of waves reflected from the earth or other reflecting objects.

***Frequency Modulation.** A system of modulation where the instantaneous radio frequency varies in proportion to the instantaneous amplitude of the modulating signal (amplitude of modulating signal to be measured after pre-emphasis, if used) and the instantaneous radio frequency is independent of the frequency of the modulating signal.

***Frequency swing.** The instantaneous departure of the frequency of the emitted wave from the center frequency resulting from modulation.

***Multiplex transmission.** The simultaneous transmission of two or more signals within a single channel. Multiplex transmission as applied to FM broadcast stations means the transmission of facsimile or other signals in addition to the regular broadcast signals.

***Percentage modulation.** The ratio of the actual frequency swing to the frequency swing defined as 100 percent modulation, expressed in percentage. For FM broadcast stations, a frequency swing of ± 75 kilocycles is defined as 100 percent modulation.

2. Stereophonic Broadcasting

***Cross-talk.** An undesired signal occurring in one channel caused by an electrical signal in another channel.

FM stereophonic broadcast. The transmission of a stereophonic program by a single FM broadcast station utilizing the main channel and a stereophonic subchannel.

***Left (or right) signal.** The electrical output of a microphone or combination of microphones placed so as to convey the intensity, time, and location of sounds originating predominantly to the listener's left (or right) of the center of the performing area.

***Left (or right) stereophonic channel.** The left (or right) signal as electrically reproduced in reception of FM stereophonic broadcasts.

***Main channel.** The band of frequencies from 50 to 15,000 cycles per second which frequency-modulate the main carrier.

***Pilot subcarrier.** A subcarrier serving as a control signal for use in the reception of FM stereophonic broadcasts.

***Stereophonic separation.** The ratio of the electrical signal caused in the right (or left) stereophonic channel to the electrical signal caused in the left (or right) stereophonic channel by the transmission of only a right (or left) signal.

***Stereophonic subcarrier.** A subcarrier having a frequency which is the second harmonic of the pilot subcarrier frequency and which is employed in FM stereophonic broadcasting.

***Stereophonic subchannel.** The band of frequencies from 23 to 53 kilocycles per second containing the stereophonic subcarrier and its associated sidebands.

3. Facsimile

Available line. The portion of the total length of scanning line that can be used specifically for picture signals.

Index of cooperation. The product of the number of lines per inch, the available line length in inches, and the reciprocal of the line-use ratio (e.g., 105 × 8.2 × 8/7 = 984).

Line-use ratio. The ratio of the available line to the total length of scanning line.

Optical density. The logarithm (to the base 10) of the ratio of incident to transmitted or reflected light.

Rectilinear scanning. The process of scanning an area in a predetermined sequence of narrow straight parallel strips.

C. TELEVISION BROADCAST STATIONS

Amplitude Modulation (AM). A system of modulation in which the envelope of the transmitted wave contains a component similar to the waveform of the signal to be transmitted.

Antenna height above average terrain. The average of the antenna heights above the terrain from two to ten miles from the antenna for the eight directions spaced evenly for each 45 degrees of azimuth starting with True North. (In general, a different antenna height will be determined in each direction from the antenna. The average of these various heights is considered the antenna height above the average terrain. In some cases less than 8 directions may be used.

Antenna power gain. The square of the ratio of the root-mean-square free space field intensity produced at one mile in the horizontal plane, in millivolts per meter for one kilowatt antenna input power to 137.6 mv/m. This ratio should be expressed in decibels (db). (If specified for a particular direction, antenna power gain is based on the field strength in that direction only.)

***Aspect ratio.** The ratio of picture width to picture height as transmitted. The standard now used is 4 to 3.

***Aural transmitter.** The radio equipment for the transmission of the aural signal only.

***Aural center frequency.** (1) The average frequency of the emitted wave when modulated by a sinusoidal signal; (2) the frequency of the emitted wave without modulation.

***Blanking level.** The level of the signal during the blanking interval, except the interval during the scanning synchronizing pulse and the chrominance subcarrier synchronizing burst.

***Chrominance.** The colorimetric difference between any color and a reference color of equal luminance, the reference color having a specific chromaticity.

***Chrominance subcarrier.** The carrier which is modulated by the chrominance information.

***Color transmission.** The transmission of color television signals which can be reproduced with different values of hue, saturation, and luminance.

***Effective radiated power.** The product of the antenna input power and the antenna power gain. This product should be expressed in kilowatts and in decibels above one kilowatt (dbk). (If specified for a particular direction, effective radiated power is based on the antenna power gain in that direction only. The licensed effective radiated power is based on the average antenna power gain for each horizontal plane direction.)

***Field.** Scanning through the picture area once in the chosen scanning pattern. In the line interlaced scanning pattern of two to one, the scanning of the alternate lines of the picture area once.

***Frame.** Scanning all of the picture area once. In the line interlaced scanning pattern of two to one, a frame consists of two fields.

***Free space field intensity.** The field intensity that would exist at a point in the absence of waves reflected from the earth or other reflecting objects.

***Frequency swing.** The instantaneous departure of the frequency of the emitted wave from the center frequency resulting from modulation.

***Interlaced scanning.** A scanning process in which successively scanned lines are spaced an integral number of line widths, and in which the adjacent lines are scanned during successive cycles of the field frequency.

***Luminance.** Luminous flux emitted, reflected, or transmitted per unit solid angle per unit projected area of the source.

***Monochrome transmission.** The transmission of television signals which can be reproduced in gradations of a single color only.

***Negative transmission.** Where a decrease in initial light intensity causes an increase in the transmitted power.

Noise figure of a television broadcast receiver. The ratio of (1) the total noise power delivered by the receiver into its output termination when the noise temperature of its input termination is standard (290°K) at all frequencies, to (2) the portion thereof engendered by the input termination. Note: For a television broadcast receiver, portion (2) includes only that noise from the input termination which appears in the output via the principal frequency transformation and does not include spurious contributions such as those from image frequency transformation.

Peak picture sensitivity for television broadcast receiver. The lowest input signal which results in standard picture test output when the receiver is tuned for maximum picture output. Note: Standard picture test output for symmetrical sine wave modulation shall be 20 volts peak-to-peak between the control elements of the picture tube.

***Peak power.** The power over a radio frequency cycle corresponding in amplitude to synchronizing peaks.

Percentage modulation. As applied to frequency modulation, the ratio of the actual frequency swing to the frequency swing defined as 100 percent modulation, expressed in percentage. For the aural transmitter of television broadcast stations, a frequency swing of ± 25 kilocycles is defined as 100 percent modulation.

Polarization. The direction of the electric field as radiated from the transmitting antenna.

***Reference black level.** The level corresponding to the specified maximum excursion of the luminance signal in the black direction.

***Reference white level of the luminance signal.** The level corresponding to the specified maximum excursion of the luminance signal in the white direction.

***Scanning.** The process of analyzing successively, according to a predetermined method, the light values of picture elements constituting the total picture area.

***Scanning line.** A single continuous narrow strip of the picture area containing highlights, shadows, and halftones, determined by the process of scanning.

***Standard television signal.** A signal which conforms to the television transmission standards.

***Synchronization.** The maintenance of one operation in step with another.

***Television broadcast band.** The frequencies in the band extending from 54 to 890 megacycles which are assignable to television broadcast stations. These frequencies are 54 to 72 megacycles (channels 2 through 4), 76 to 88 megacycles (channels 5 and 6), 174 to 216 megacycles (channels 7 through 13), and 470 to 890 megacycles (channels 14 through 83).

Television broadcast station. A station in the television broadcast band transmitting simultaneous visual and aural signals intended to be received by the general public.

Television broadcast booster station. A station in the broadcasting service operated for the sole purpose of retransmitting the signals of a television broadcast station by amplifying and reradiating such signals which have been received directly through space, without significantly altering any characteristic of the incoming signal other than its amplitude.

Television broadcast translator station. A station in the broadcasting service operated for the purpose of retransmitting the signals of a television broadcast station, another television broadcast translator station, or a television translator relay station, by means of direct frequency conversion and amplification of the incoming signals without significantly altering any characteristic of the incoming signal other than its frequency and amplitude, for the purpose of providing television reception to the general public.

***Television channel.** A band of frequencies 6 megacycles wide in the television broadcast band and designated either by number or by the extreme lower and upper frequencies.

Television intercity relay station. A fixed station used for intercity transmission of television program material and related communications for use by television broadcast stations.

Television pickup station. A land mobile station used for the transmission of television program material and related communications from the scenes of events occurring at points removed from television broadcast station studios to television broadcast stations.

Television STL station (studio-transmitter link). A fixed station used for the transmission of television program material and related communications from the studio to the transmitter of a television broadcast station.

***Television transmission standards.** The standards which determine the characteristics of a television signal as radiated by a television broadcast station.

Television transmitter. The radio transmitter or transmitters for the transmission of both visual and aural signals.

Television translator relay station. A fixed station used for relaying the signals of television broadcast stations to television broadcast translator stations.

UHF translator. A television broadcast translator station operating on a UHF television broadcast channel.

UHF translator signal booster. A station in the broadcasting service operated for the sole purpose of retransmitting the signals of a UHF translator station by amplifying and reradiating such signals which have been received directly through space, without significantly altering any characteristic of the incoming signal other than its amplitude.

VHF translator. A television broadcast translator station operating on a VHF television broadcast channel.

***Vestigial sideband transmission.** A system of transmission wherein one of the generated sidebands is partially attenuated at the transmitter and radiated only in part.

Visual carrier frequency. The frequency of the carrier which is modulated by the picture information.

Visual transmitter. The radio equipment for the transmission of the visual signal only.

***Visual transmitter power.** The peak power output when transmitting a standard television signal.

D. INTERNATIONAL BROADCAST STATIONS

Autumnal equinox season. That period of any calendar year starting at 0000 EST on 1 August and ending at 2400 EST on 31 October.

Contract operation. Any nongovernment operation of an international broadcast station pursuant to a contract with an agency of the United States Government and subject to Governmental control as to program content, target areas to be covered, and time of broadcast.

Day. Any twenty-four hour period beginning 0000 EST and ending 2400 EST.

Delivered median field intensity or field intensity. The field intensity incident upon the target area expressed in microvolts per meter, or decibels above one microvolt per meter, which is exceeded by the hourly median value on 50 percent of the days of the reference month.

Frequency-hour. One frequency used for one hour.

International broadcast station. A broadcasting station employing frequencies allocated to the broadcasting service between 5950 and 26100 kc, whose transmissions are intended to be received directly by the general public in foreign countries.

Maximum usable frequency (MUF). The highest frequency which is returned to the surface of the earth for a particular path and time of day on 50 percent of the days of the reference month.

Optimum working frequency (OWF). The frequency which is returned to the surface of the earth for a particular path and time of day on 90 percent of the days of the reference month.

Primary station. The television broadcast station radiating the signals which are retransmitted by a television broadcast booster station or translator station.

Private operation. Any nongovernment operation of an International Broadcast station which is not contract operation.

Reference month. The middle month of any season in "Daily Frequency Hour Availability Table."

Summer season. That period of any calendar year starting at 0000 EST on 1 May and ending at 2400 EST on 31 July.

Sunspot number. The predicted 12 month running average of the number of sunspots for any month as indicated in the National Bureau of Standards CRPL Series D publications.

Target area. Geographic area in which the reception of particular programs is specifically intended and in which adequate broadcast coverage is contemplated.

Vernal equinox season. That period of any calendar year starting at 0000 EST on 1 February and ending at 2400 EST on 30 April.

Winter season. That period of any calendar year starting at 0000 EST on 1 November and ending at 2400 EST on 31 January.

E. EMERGENCY ACTION NOTIFICATION SYSTEM AND THE EMERGENCY BROADCAST SYSTEM

Emergency Action Notification System. The System by which all licensees and regulated services of the Federal Communications Commission, and the general public, are notified (with or without an Attack Warning) of the existence of an Emergency Action Condition resulting from a grave national crisis or war. The Emergency Action Notification System and the Emergency Broadcast System Implementation System consist only of the following approved facilities, systems, and arrangements:

(a) First Method. From the President of the United States via the White House Communications Agency to the Associated Press (AP) and United Press International (UPI); thence via automatic selective switching and teletype Emergency Action Notification to all standard, FM, and television broadcast and other stations subscribing to the AP and UPI Radio Wire Teletype Networks.

(b) Second Method. From the President of the United States via the White House Communications Agency to specified control points of the nationwide commercial Radio and Television Broadcast Networks, the American Telephone and Telegraph Co. and other specified points via a dedicated teletypewriter network; thence to all affiliates via any available internal commercial radio and television network alerting facilities.

(c) Third Method. Off-the-air monitoring of specified standard, FM, and television broadcast stations by standard, FM, and television broadcast stations and other licensees and regulated services for receipt of the Emergency Action Notification. All broadcast licensees are required to install, maintain, and operate radio receiving equipment for receipt of the Emergency Action Notification.

(d) Fourth Method. Off-the-air monitoring of standard, FM, and television broadcast stations by the general public who are listening or viewing or whose radio or television receivers are equipped for actuation by the Attention Signal to receive the Emergency Action Notification.

Attention Signal. The signaling arrangement transmitted by all standard, FM, and television broadcast stations for the purpose of actuating muted standard, FM, and television receivers.

***Emergency Action Notification.** Notice (with or without an Attack Warning) to all licensees and regulated services of the Federal Communications Commission and to the general public of the existence of an Emergency Action Condition. The Emergency Action Notification is released upon direction of the President of the United States and is disseminated only via the Emergency Action Notification System.

***Emergency Action Condition.** The Emergency Action Condition is the period of time between the transmission of an Emergency Action Notification and the transmission of the Emergency Action Condition Termination.

***Emergency Action Condition Termination.** The Emergency Action Condition Termination is the notice to all licensees and regulated services of the Federal Communications Commission and to the general public of the termination of an Emergency Action Condition. The Emergency Action Condition Termination is released upon direction of the President of the United States and is disseminated only via the Emergency Action Notification System.

Emergency Broadcast System (EBS). System of facilities and personnel of nongovernment broadcast stations and other authorized facilities licensed or regulated by the Federal Communications Commission, including approved and authorized integral facilities or systems, arrangements, procedures, and interconnecting facilities, which have been authorized by the Commission to operate in a controlled manner during a grave national crisis or war.

***Basic Emergency Broadcast System (EBS) Plan.** Plan containing, among other things, approved basic concepts and designated national-level systems, arrangements, procedures, and interconnecting facilities to satisfy the White House Statement of Requirements for Presidential Messages and National Programing and News. Provision is made therein for the development, designation, and approval of facilities, mutually compatible operational arrangements, procedures, and interconnecting facilities to satisfy the Department of Defense (Office of Civil Defense) statement of requirements for the dissemination of emergency information and instructions by Regional, State, and Operational Area (Local) authorities in addition to Presidential Messages and National Programing and News, as set forth above.

NIAC Order. Service order previously filed with the American Telephone and

Telegraph Co. providing for approved arrangements for program origination reconfiguration of the major commercial Radio and Television (aural) Broadcast Networks (except UPI Audio) voluntarily participating in the Emergency Broadcast System (EBS). Broadcast networks presently participating are American Broadcasting Co. (ABC), Columbia Broadcasting System (CBS), Mutual Broadcasting System (MBS), National Broadcasting Co. (NBC), Intermountain Network (IMN), and the United Press International Audio (UPI). Any NIAC Order must meet White House requirements and may be activated only when requested by the White House Communications Agency in accordance with approved established procedures.

National Defense Emergency Authorization (NDEA). Authorization issued by the Federal Communications Commission only to the licensees of broadcast stations to permit controlled operation of such stations, as well as associated auxiliary broadcast stations on a voluntary organized basis during an Emergency Action Condition, also consistent with the Basic Emergency Broadcast System (EBS) Plan, including the annexes and supplements to that plan. A broadcast station licensee will be issued a National Defense Emergency Authorization only in accordance with the Criteria for Eligibility set forth in the Basic Emergency Broadcast System (EBS) Plan, which will remain valid concurrently with the term of the broadcast station license, so long as the station licensee continues to comply with the Criteria for Eligibility.

Primary Station National Defense Emergency Authorization (NDEA). Authorization issued to one or more broadcast station licensees in an Operational Area assigning such licensees the responsibility for broadcasting a common emergency program for the initial period of, or for the duration of, and Emergency Action Condition. Broadcasts by such stations are intended for direct public reception in an Operational Area, as specified in an approved Detailed State Emergency Broadcast System (EBS) Operational Plan.

Alternate Station National Defense Emergency Authorization (NDEA). Authorization issued to one or more broadcast licensees in an Operational Area assigning such licensees as specified alternates. An Alternate station will assume broadcasting responsibility in accordance with the Detailed State Emergency Broadcast System (EBS) Operational Plan.

Primary Relay National Defense Emergency Authorization (NDEA). Authorization issued to one or more broadcast licensees in an Operational Area assigning such licensees the function of emergency program distribution or relay service of emergency programing to stations holding Primary or Alternate Station National Defense Emergency Authorizations, in accordance with an approved Detailed State Emergency Broadcast System (EBS) Operational Plan. A Relay station will not generally broadcast emergency program material intended for direct public reception.

Alternate Relay National Defense Emergency Authorization (NDEA). Authorization issued to one or more broadcast licensees in an Operational Area assigning such licensees as specified alternates to stations holding Primary Relay National Defense Emergency Authorizations. In the event a Primary Relay station is unable to assume its initial operational functions, or discontinues such operation for any reason, an alternate Relay station will assume those operational functions, in accordance with the "alternate" designations (1st, 2d, 3d, 4th, etc.) contained in an approved Detailed State Emergency Broadcast System (EBS) Operational Plan.

Non-NDEA Station. A broadcast station which is not voluntarily participating in the Emergency Broadcast System (EBS) and does not hold a National Defense Emergency Authorization. Such stations are required to discontinue operations for the duration of an Emergency Action Condition.

Detailed Regional Emergency Broadcast System (EBS) Operational Plan. Plan providing for a regional emergency programing origination capability at the Federal Regional Center in coordination with the State Industry Advisory Committees and integrated into the Detailed State Emergency Broadcast System (EBS) Operational Plans within the Federal Region as a coordinated Regional/State operation.

Detailed State Emergency Broadcast System (EBS) Operational Plan. Plan containing the designation of facilities, approved detailed mutually compatible operational arrangements, procedures, instructions, and interconnecting facilities to satisfy the requirements of the President and the Federal Government, as well as State and Operational Area (Local) authorities for communicating with the general public during the Emergency Action Condition. Such a plan includes approved and authorized detailed emergency operational communications facilities, systems, procedures, and interconnecting systems.

Operational Area. Geographical area which may encompass a number of contiguous communities, as mutually determined by the State Industry Advisory Committee and State authorities, and as delineated in the approved Detailed State Emergency Broadcast System, (EBS) Operational Plan.

Common Program Control Broadcast Station. A Primary NDEA broadcast station in each Operational Area assigned the responsibility for coordinating the operations for the broadcasting of the common program for the Operational Area.

F. REMOTE PICKUP BROADCAST STATIONS

Associated broadcasting station. The broadcasting station with which a remote pickup broadcast base or mobile station is licensed as an auxiliary and with which it is principally used.

Attended operation. Operation of a station by a qualified operator on duty at the place where the transmitting apparatus is located with the transmitter in plain view of the operator.

Automatic mobile relay station. A remote pickup broadcast base station actuated by automatic means and used to relay communications between base and mobile stations, between mobile stations, and from mobile stations licensed under the rules of this subpart, to broadcast stations.

Operational communications. Communications related to the technical operation of a broadcasting station and its auxiliaries, other than the transmission of program material and cues and orders directly concerned therewith.

Remote control operation. Operation of a station by a qualified operator at a control position from which the transmitter is not visible but which control position is equipped with suitable control and telemetering circuits so that the essential functions which could be performed at the transmitter can also be performed from the control point.

Remote pickup broadcast base station. A base station licensed for communicating with remote pickup broadcast mobile stations.

Remote pickup broadcast mobile station. A land mobile station licensed for the transmission of program material and related communications from the scene of events, which occur outside a studio, to broadcasting stations and for communicating with other remote pickup broadcast base and mobile stations. (As used in this part, land mobile station includes hand-carried, pack-carried, and other portable transmitters.)

Studio. Any room or series of rooms equipped for the regular production of broadcast programs of various kinds. A broadcasting booth at a stadium, convention hall, church, or other similar place is not considered to be a studio.

VI Maritime Services (Land and Shipboard Stations)

A. GENERAL

Categories of ships. (1) Where use of the term "passenger ship" or "cargo ship" occurs in reference to the provisions of Part II of Title III of the Communications Act, such use of the term shall be construed as follows: A ship is a passenger ship if it carries or is licensed or certificated to carry more than twelve passengers. A cargo ship is any ship not a passenger ship. (2) Where use of the term "passenger ship" or "cargo ship" occurs in reference to the radio provisions of the Safety Convention or in reference to frequency assignment, such use of the term shall be construed as follows: A ship is a passenger ship if it carries more than twelve passengers. A cargo ship is any ship not a passenger ship. (3) A "commercial transport vessel" is any ship or vessel which is used primarily in commerce (i) for transporting persons or goods to or from any harbor(s) or port(s) or between places within a harbor or port area, or (ii) in connection with the construction, change in construction, servicing, maintenance, repair, loading, unloading, movement, piloting, or salvaging of any other ship or vessel. (4) The term "passenger carrying vessel," as used in this part solely in reference to requirements of the Great Lakes Agreement, means any vessel transporting persons for hire.

Day. (1) Where the word "day" is applied to the use of a specific frequency assignment or to a specific authorized transmitter-power, such use of the word "day" shall be construed to mean transmission on such frequency assignment or with such authorized transmitter-power during that period of time included between one hour after local sunrise and one hour before local sunset. (2) Where the word "day" occurs in reference to watch requirements, or to the provisions of §83.449, such use of the word "day" shall be construed to mean the calendar day, from midnight to midnight, local ship's time.

Destination. In reference to the Great Lakes Agreement this term means a port which a vessel enters for the purpose of initiating or completing the specific activity which characterizes the vessel. For example, with respect to vessels carrying passengers or goods, a port at which a vessel, either partially or completely, loads or unloads passengers or goods, would constitute its destination.

Great Lakes. This term, as used in this part solely in reference to the Great Lakes Agreement, means all of the Great Lakes, their connecting and tributary waters, and the St. Lawrence River as far east as the lower exit of the Lachine Canal and the Victoria Bridge at Montreal, but shall not include tributary rivers which are not also connecting rivers, and shall not include the Niagara River (including the Black Rock Canal).

Installed. As used in this part with respect to the requirements of radio apparatus authorized under the provisions of this part for use on board ship or in stations subject to this part, the term "installed" means installed on board the particular ship or in the particular station to which the pertinent rule or regulation, involving the use of this term, is applied.

Mile. As used in this part, the term "mile" means a statute mile or 5,280 feet.

Safety Convention Certificates. (1) Nuclear Passenger Ship Safety Certificate. A certificate issued after inspection and survey to a nuclear passenger ship which complies with the relevant requirements of the Safety Convention. **(2) Passenger Ship Safety Certificate.** A certificate issued after inspection and survey to a passenger ship which complies with the relevant requirements of the Safety Convention. **(3) Nuclear Cargo Ship Safety Certificate.** A certificate issued after inspection and survey to a nuclear cargo ship which complies with the relevant requirements of the Safety Convention. **(4) Cargo Ship Safety Radiotelegraphy Certificate.** A certificate issued after inspection to a cargo ship which complies with the Safety Convention radio requirements applicable to cargo ships carrying a radiotelegraph station for the purpose of meeting such requirements. **(5) Cargo Ship Safety Radiotelephony Certificate.** A certificate issued after inspection to a cargo ship which complies with the Safety Convention radio requirements applicable to cargo ships carrying a radiotelephone station for the purpose of meeting such requirements. **(6) Exemption Certificate.** A certificate issued to a ship which is granted partial, conditional, or complete exemption from applicable provisions of the Safety Convention.

Ship or vessel. "Ship" or "vessel" includes every description of watercraft or other artificial contrivance, except aircraft, used or capable of being used as a means of transportation on water whether or not it is actually afloat.

B. MARITIME MOBILE SERVICE

Base Station. A land station in the land mobile service carrying on a service with land mobile stations.

Class I coast station. A coast station (public or limited) licensed to provide a maritime mobile service to ships at sea, including such service over distances up to several thousand miles, whose frequency assignment for this purpose includes appropriate frequencies below 150 kc/s or between 5,000 kc/s and 25,500 kc/s.

Class II coast station. A coast station (public or limited) licensed to provide a maritime mobile service, primarily of a regional character, whose frequency assignment does not include any frequency below 150 kc/s or between 5,000 kc/s and 25,000 kc/s except on a secondary basis under specified conditions intended to minimize the possibility of interference to other stations having priority on these frequencies.

Class III coast station. A coast station (public or limited) licensed to provide a maritime mobile service, primarily of a local character, whose frequency assignment does not include any frequency below 25,000 kc/s.

Coast station. A land station in the maritime mobile service.

Land mobile station. A mobile station in the land mobile service capable of surface movement within the geographical limits of a country or continent.

Land station. A station in the mobile service not intended to be used while in motion.

Limited coast station. A coast station, not open to public correspondence, which serves the operational and business needs of ships.

Limited ship station. A ship station not open to public correspondence.

Marine-utility coast station. A coast station, readily portable for use as a limited coast station at unspecified points ashore within a designated local area.

Marine-utility ship station. A ship station, readily portable for use as a limited ship station on mobile vessels within a designated local area.

Marine-utility station. A coast or ship station in the maritime mobile service having a frequency assignment which is available for both marine-utility coast stations and marine-utility ship stations and licensed under one station authorization to operate as either a marine-utility coast station or a marine-utility ship station according to its location.

Maritime and land mobile service. (1) **Maritime mobile service.** A mobile service between coast stations and ship stations, or between ship stations, in which survival craft stations may also participate. (Aircraft stations, when transmitting on frequencies allocated to the maritime mobile service, may communicate in this service with ship stations and coast stations.) (2) **Land mobile service.** A mobile service between base stations and land mobile stations, or between land mobile stations. (Only land mobile service carried on exclusively for maritime purposes is governed by this part.)

Mobile service. A service of radiocommunication between mobile and land stations, or between mobile stations.

Mobile station. A station in the mobile service intended to be used while in motion or during halts at unspecified points.

Operational designator. The letter "A," "B," or "F," appended to the term "class I," "class II," or "class III," designates that the coast station is licensed to render its normal service by means of (A) telegraphy, (B) telephony, or (F) facsimile. The designator "L" means "local" and is used to indicate (in lieu of a separate class III coast station license for the same station) that a class I or a class II station provides maritime mobile service of a local character on a frequency or frequencies above 30 mc/s in addition to its service on other frequencies.

Public coast station. A coast station open to public correspondence.

Public ship station. (1) A ship station open to public correspondence. (2) Public ship stations authorized to employ telegraphy for public correspondence are further classified according to their hours of service for telegraphy as designated in this section: (a) **First Category.** These stations carry on a continuous service of public correspondence. (b) **Second Category.** These stations carry on a designated service of public correspondence of prescribed but limited duration at least during the period designated for ship stations of the second category by the International Radio Regulations or, in the case of voyages of short duration, as otherwise designated by the Commission in accordance with those Regulations. (c) **Third Category.** These stations carry on a service of public correspondence, the duration of which is prescribed but is less than that of stations of the "Second Category," or is not prescribed but is determined by the master of vessel pursuant to his authority under Section 360 of the Communications Act.

Shipyard land mobile unit. A land vehicle operated and controlled by a shipyard and used for the transportation of shipyard personnel, material, or supplies.

Shipyard base station. A land station, licensed and operated primarily as a limited coast station in the maritime mobile service, which is authorized additionally to be operated on a secondary basis as a base station for communication with shipyard mobile stations of the same licensee within a local geographic area designated by the Commission.

Ship station. A mobile station in the maritime mobile service located on board a vessel, other than a survival craft, which is not permanently moored.

Shipyard mobile station. A land mobile station on a shipyard land mobile unit used for communication solely with one or more shipyard base stations of the same licensee within a local geographic area designated by the Commission.

Survival craft station. A mobile station in the maritime or aeronautical mobile service intended solely for survival purposes and located on any lifeboat, liferaft or other survival equipment.

C. MARITIME RADIO DETERMINATION SERVICE

Direction finder (radio compass). Apparatus capable of receiving clearly perceptible radio signals and capable of taking bearings on these signals from which the true bearing and direction of the point of origin of such signals with respect to the point of reception may be determined.

Maritime radiodetermination service. A radiodetermination service intended for the benefit of ships.

Maritime radiolocation service. A radiolocation service intended for the benefit of ships.

Maritime radionavigation service. A radionavigation service intended for the benefit of ships.

Radar. A radiodetermination system based on the comparison of reference signals with radio signals reflected, or retransmitted, from the position to be determined.

Radiodetermination. The determination of position, or the obtaining of information relating to position, by means of the propagation properties of radio waves.

Radiodetermination service. A service involving the use of radiodetermination.

Radio direction finding. Radiodetermination using the reception of radio waves for the purpose of determining the direction of a station or object.

Radiolocation. Radiodetermination used for purposes other than those of radionavigation.

Radiolocation land station. A station in the radiolocation service not intended to be used while in motion.

Radiolocation mobile station. A station in the radiolocation service intended to be used while in motion or during halts at unspecified points.

Radiolocation service. A radiodetermination service involving the use of radiolocation.

Radionavigation. Radiodetermination used for the purposes of navigation, including obstruction warning.

Radionavigation land station. A station in the radionavigation service not intended to be used while in motion.

Radionavigation mobile station. A station in the radionavigation service intended to be used while in motion or during halts at unspecified points.

Radionavigation service. A radiodetermination service involving the use of radionavigation.

Ship radar station. A ship radionavigation station utilizing radar.

Ship radiolocation station. A radiolocation mobile station located on board a ship and used solely for maritime radiolocation service.

Ship radiolocation test station. A ship radiolocation station used solely for testing maritime radionavigation apparatus incident to its manufacture, installation, repair, servicing, and/or maintenance.

Ship radionavigation station. A radionavigation mobile station located on board a ship and used solely for maritime radionavigation service.

Shore radar station. A shore radionavigation station utilizing radar.

Shore radiolocation station. A radiolocation land station performing a maritime radiolocation service.

Shore radiolocation test station. A shore radiolocation station used solely for testing maritime radiodetermination apparatus incident to its manufacture, installation, repair, servicing, or maintenance.

Shore radiolocation training station. A shore radiolocation station used solely to train and qualify persons in the effective use of maritime radiodetermination.

Shore radionavigation station. A radionavigation land station performing a maritime radionavigation service.

D. MARITIME FIXED SERVICES

Marine control station. An operational fixed station used to control the emissions or operation of a coast station at a separate location.

Marine fixed station. A fixed station, used primarily for safety communication which is established at a designated location in a water area of, or contiguous to, the United States, and isolated from the mainland by water or marsh.

Marine receiver-test station. A fixed station used to simulate transmission from a ship station to a coast station for the purpose of periodically testing the normal receiving installation of a licensed coast station to determine that such receiving installation is in good working condition.

Marine repeater station. An operational fixed station used to retransmit, to a point of destination or to a message routing center, radiocommunications received at a coast station from ship or aircraft stations in the maritime mobile service.

Marine relay station. An operational fixed station used for communication between coast stations or between a coast station and an associated remote control point, which is intended to expedite the movement of message traffic to or from mobile stations in the maritime mobile service.

Operational fixed station. A fixed station, not open to public correspondence, operated by and for the sole use of those agencies operating their own radiocommunication facilities in the public safety, industrial, land transportation, marine, or aviation services.

E. DEVELOPMENTAL MARITIME STATIONS

Developmental fixed station. A fixed station operated for the express purpose of developing equipment or a technique solely for use only in that portion of the nongovernment fixed service which has been specifically allocated the authorized frequency (or frequencies) of the developmental fixed station.

Developmental land station. A land station operated for the express purpose of developing equipment or a technique solely for use only in that portion of the nongovernment mobile service which has been specifically allocated the authorized frequency (or frequencies) of the developmental land station.

Developmental mobile station. A mobile station operated for the express purpose of developing equipment or a technique solely for use only in that portion of the non-Government mobile service which has been specifically allocated the authorized frequency (or frequencies) of the developmental mobile station.

Developmental radiodetermination station. A radiodetermination station operated for the express purpose of developing equipment or a technique solely for use only in that portion of the nongovernment radiodetermination service (including the nongovernment radionavigation service) which has been specifically allocated the authorized frequency (or frequencies) of the developmental radiodetermination station.

Specific classification. The specific classes of developmental stations on land licensed in the maritime mobile service, the maritime radiodetermination service (including maritime radionavigation service), and the maritime fixed services, are the same as the particular class of station followed by the parenthetical indicator "(developmental)", for example: "Public class III coast station (developmental)".

F. OPERATIONAL

Business communication. Radiocommunication pertaining to economic, commercial, or governmental matters related directly to the purposes for which a ship is being used.

Calling. Transmission from a station solely to secure the attention of another station, or other stations, for a particular purpose.

Control point. An operating position associated with a particular station or stations which is: (1) Under the control and supervision of the station licensee or his authorized agent; and (2) A place at which the required monitoring and control facilities are available; and (3) A place at which a duly licensed operator (or other person if the requirement for a licensed operator is waived by the Commission) responsible for the operation of the transmitter(s) is stationed.

Dispatch point. A place from which radiocommunication may be transmitted under supervision of a responsible operator at a control point.

Distress signal. (1) The distress signal is the international radiotelegraph or radiotelephone signal which indicates that a ship, aircraft, or other vehicle is threatened by grave and imminent danger and requests immediate assistance. (2) In radiotelegraphy, the international distress signal consists of the group "three dots, three dashes, three dots", transmitted as a single signal in which the dashes are emphasized so as to be distinguished clearly from the dots. (3) In radiotelephony, the international distress signal consists of the oral enunciation of the word "Mayday", pronounced as the French expression "m'aider". In case of distress, transmission of this particular signal is intended to insure recognition of a radiotelephone distress call by stations of any nationality.

Distress traffic. All messages relative to the immediate assistance required by the ship, aircraft, or other vehicle in distress.

500 kilocycles silent period. The three-minute period twice an hour beginning at x h 15 and x h 45, Greenwich mean time (GMT), during which the International Radio Regulations require that all transmissions (except for certain emissions designated in those Regulations) must cease on all frequencies within a designated frequency-band centered on 500 kc/s.

Operational communication. Radiocommunication concerning the navigation, movement, or management of a ship or ships. (1) **Navigation.** This includes the piloting of a vessel. (2) Movement. This includes information and necessary communications relative to when and where the boat or ship will move or be moved as, for example, rendezvous at a port, basin, or marina, or for maneuvers during a cruise. (3) Management. This includes the obtaining of necessary supplies for the ship, limited to immediate needs, and the scheduling of repairs or modifications to the ship, limited to communications with those directly involved in the repairs or modification or concerned with changes in the movement of the ship because of those repairs or modifications.

Port operations. Communications in or near a port, or in locks or waterways, between coast stations and ship stations, or between ship stations, in which messages are restricted to those relating to the movement and safety of ships and, in emergency, to the safety of persons.

Safety communication. The transmission or reception of distress, alarm, urgency, or safety signals, or any communication preceded by one of these signals, or any form of radiocommunication which, if delayed in transmission or reception, may adversely affect the safety of life or property.

Safety signal. (1) The safety signal is the international radiotelegraph or radiotelephone signal which indicates that the station sending this signal is ready to transmit a message concerning the safety of navigation or giving important meteorological warnings. (2) In radiotelegraphy, the international safety signal consists of three repetitions of the group "TTT", sent before the call, with the letters of each group and the successive groups clearly separated from each other. (3) In radiotelephony, the international safety signal consists of three oral repetitions of the French word "Securite", sent before the call.

Superfluous radiocommunication. Any transmission that is not necessary in properly carrying on the service for which the station is licensed.

Urgency signal. (1) The urgency signal is the international radiotelegraph or radiotelephone signal which indicates that the calling station has a very urgent message to transmit concerning the safety of a ship, aircraft, or other vehicle, or of some person on board or within sight. (2) In radiotelegraphy, the international urgency signal consists of three repetitions of the group "XXX", sent before the call, with the letters of each group and the successive groups clearly separated from each other. (3) In radiotelephony, the international urgency signal consists of three oral repetitions of the word "Pan" pronounced as the French word "panne" and sent before the call.

Watch. The act of listening on a designated frequency.

Working. Radiocommunication carried on, for a purpose other than calling, by any station or stations using telegraphy, telephony, or facsimile.

VII Aviation Services

Aeronautical advisory station. An aeronautical station used for advisory and civil defense communications primarily with private aircraft stations.

Aeronautical enroute station. An aeronautical station carrying on a service with aircraft stations, but which may also carry on a limited communication service with other aeronautical enroute stations.

Aeronautical fixed service. A fixed service intended for the transmission of information relating to air navigation, preparation for and safety of flight.

Aeronautical fixed station. A station in the aeronautical fixed service.

Aeronautical metropolitan station. An aeronautical station used for communication with aircraft, including helicopters, operating between a main air terminal of a metropolitan area and subordinate landing areas.

Aeronautical mobile service. A mobile service between aeronautical stations and aircraft stations, or between aircraft stations, in which survival craft stations may also participate.

Aeronautical multicom land station. An aeronautical station operating in the aeronautical multicom service.

Aeronautical multicom mobile station. A mobile station operating in the aeronautical multicom service.

Aeronautical multicom service. A mobile service not open to public correspondence, used to provide communications essential to conduct of activities being performed by or directed from private aircraft.

Aeronautical public communication service. A communication service carried on between aircraft and land radio stations for the purpose of providing a public communication service for persons aboard aircraft.

Aeronautical public service station. A radio station, ground or aircraft, operated in the aeronautical public communication service.

Aeronautical radionavigation service. A radio navigation service intended for the benefit of aircraft.

Aeronautical search and rescue station. A land or mobile station in the aeronautical mobile service used for communication with aircraft and other aeronautical search and rescue stations pertaining to search and rescue activities with aircraft.

Aeronautical station. A land station in the aeronautical mobile service. In certain instances an aeronautical station may be placed on board a ship.

Aeronautical telemetering land station. A telemetering mobile station used in the flight testing of manned or unmanned aircraft, missiles, or major components thereof.

Aeronautical telemetering mobile station. A telemetering mobile station used in the flight testing of manned or unmanned aircraft, missiles, or major components thereof.

Aeronautical utility land station. A land station located at airdrome control towers and used for control of ground vehicles and aircraft on the ground at airdromes.

Aeronautical utility mobile station. A mobile station used for communication, at airdromes, with the aeronautical utility land station, ground vehicles, and aircraft on the ground.

Air carrier aircraft station. An aircraft station aboard an aircraft engaged in or essential to, transportation of passengers or cargo for hire. For the purpose of the rules in this part an aircraft weighing less than 10,000 lbs. may be considered at the option of the applicant, as a private aircraft even though actually engaged in air carrier operations. The election by the applicant will determine the equipment and frequencies to be employed and the regulations applicable to the aircraft radio station.

Aircraft station. A mobile station in the aeronautical mobile service on board an aircraft.

Airdrome control station. An aeronautical station providing communication between an airdrome control tower and aircraft.

Aviation instructional station. A land or mobile station in the aeronautical mobile service used for radiocommunications pertaining to instructions to students or pilots while actually operating aircraft or engaged in soaring activities.

Aviation services. Aviation services are primarily for the safe, expeditious and economical operation of the aircraft. They include the aeronautical fixed service, aeronautical mobile service, aeronautical radionavigation service, and secondarily, the handling of public correspondence to and from aircraft.

Civil Air Patrol Land Station. A land station used exclusively for communications of the Civil Air Patrol.

Civil Air Patrol Mobile Station. A mobile station used exclusively for communications of the Civil Air Patrol.

Earth-space service. A radiocommunication service between earth stations and space stations.

Earth Station. A station in the earth-space service located either on the earth's surface or on an object which is limited to flight between points on the earth's surface.

Flight test aircraft station. An aircraft station aboard an aircraft used for the transmission of essential communications in connection with the tests of aircraft or major components of aircraft.

Flight test station. An aeronautical station used for the transmission of essential communications in connection with the testing of aircraft or major components of aircraft: Provided, however, flight test stations, when operating on the frequency 3281 kc/s, are designated as land stations, only with respect to operation on the frequency 3281 kc/s.

Glide path station. A directional radio beacon associated with an instrument landing system which provides guidance in the vertical plane to an aircraft for the purpose of approach in landing.

Ground radio station. Any radio station on the ground equipped or engaged in radiocommunication or radio transmission of energy.

Instrument landing system. A radionavigation system which provides aircraft with horizontal and vertical guidance just before and during landing and, at certain fixed points, indicates the distance to the reference point of landing.

Instrument landing system glide path. A system of vertical guidance embodied in the instrument landing system which indicates the vertical deviation of the aircraft from its optimum path of descent.

Instrument landing system localizer. A system of horizontal guidance embodied in the instrument landing system which indicates the horizontal deviation of the aircraft from its optimum path of descent along the axis of the runway.

Landing area. Any locality, either land or water, including airports and intermediate landing fields, which is used, or intended to be used, for the landing and take-off of aircraft, whether or not facilities are provided for shelter, servicing, or repair of aircraft, or for receiving or discharging passengers or cargo.

Localizer station. A radionavigation land station in the aeronautical radionavigation service which provides signals for the lateral guidance of aircraft with respect to a runway center line.

Marker beacon. A transmitter in the aeronautical radionavigation service which radiates vertically a distinctive pattern for providing position information to aircraft.

Marker beacon station. An aeronautical radionavigation land station employing a marker beacon.

Omni-directional range station. A radionavigation land station in the aeronautical radionavigation service providing direct indication of the bearing (omni-bearing) of that station from an aircraft.

Private aircraft station. An aircraft station on board an aircraft not operated as an air carrier.

Public correspondence. Any telecommunication which the offices and stations must, by reason of their being at the disposal of the public, accept for transmission.

Radio altimeter. A radionavigation equipment, on board an aircraft, which makes use of the reflection of radio waves from the ground to determine the height of the aircraft above the ground. (For the purpose of this definition, "ground" refers to the surface of the earth.)

Radionavigation land test station (MTF). A radionavigation land station (Maintenance Test Facility) in the aeronautical radionavigation service which is used as a radionavigation calibration station for the transmission of essential information in connection with the testing and calibration of aircraft navigational aids, receiving equipment, and interrogators at predetermined surface locations. The primary purpose of this facility is to permit maintenance testing by aircraft radio service personnel.

Radionavigation land test station (OTF). A radionavigation land station (Operational Test Facility) in the aeronautical radionavigation service which is used as a radionavigation calibration station for the transmission of essential information in connection with the testing and calibration of aircraft navigational aids, receiving equipment, and interrogators at predetermined surface locations. The primary purpose of this facility is to permit the pilot to check a radionavigation system aboard the aircraft prior to takeoff.

***Space station.** A station in the earth-space service or the space service located on an object which is beyond, or intended to go beyond, the major portion of the earth's atmosphere and which is not intended for flight between points on the earth's surface.

Surveillance radar station. A radionavigation land station in the aeronautical radionavigation service employing radar to display the presence of aircraft within its range.

VIII Public Safety Radio Services

Fire Radio Service. A public safety service of radiocommunication essential to official fire activities.

Forestry-Conservation Radio Service. A public safety service of radiocommunication essential to forestry-conservation activities.

Highway Maintenance Radio Service. A public safety service of radiocommunication essential to official highway activities.

Interzone station. A fixed station in the Police Radio Service using radiotelegraphy (A1 emission) for communication with zone stations within the zone and with interzone stations in other zones.

Local Government Radio Service. A service of radiocommunication essential to official activities of states, possessions, and territories, including counties, towns, cities, and similar governmental subdivisions.

Police Radio Service. A public safety service of radiocommunication essential to official police activities.

Public safety radio services. Any service of radiocommunication essential either to the discharge of non-Federal government functions or the alleviation of an emergency endangering life or property, the radio transmitting facilities of which are defined as fixed, land, mobile, or radiolocation stations.

Safety service. A radiocommunication service used permanently or temporarily for the safeguarding of human life and property.

Special Emergency Radio Service. A public safety service of radiocommunication essential to the alleviation of an emergency endangering life or property.

State Guard Radio Service. A public safety service of radiocommunication essential to official activities of state guards or comparable organizations of states, territories, possessions, or the District of Columbia.

Zone station. A fixed station in the Police Radio Service using radiotelegraphy (A1 emission) for communication with other similar stations in the same zone and with an interzone station.

IX Industrial Radio Services

Community antenna television systems. The term "community antenna television system" ("CATV system") means any facility which, in whole or in part, receives directly or indirectly over the air and amplifies or otherwise modifies the signals transmitting programs broadcast by one or more television stations and distributes such signals by wire or cable to subscribing members of the public who pay for such service, but such term shall not include (1) any such facility which serves fewer than 50 subscribers, or (2) any such facility which serves only the residents of one or more apartment dwellings under common ownership, control, or management, and commercial establishments located on the premises of such an apartment house.

Distant signal. The term "distant signal" means the signal of a television broadcast station which is extended or received beyond the Grade B contour of that station.

Grade A and Grade B contours. The terms "Grade A contour" and "Grade B contour" means the field intensity contours.

Independent station. The term "independent station" means a television station which is not affiliated with any national television network organization.

Network programing. The term "network programing" means the programing supplied by a national television network organization.

Principal community contour. Signal contour which a television station is required to place over its entire principal community.

Substantially duplicated. The term "substantially duplicated" means regularly duplicated by the network programing of one or more other stations, singly or collectively, in a normal week during the hours of 6 to 11 p.m., local time, for a total of 14 or more hours.

X Land Transportation Radio Services

Automobile Emergency Radio Service. The term "Automobile Emergency Radio Service" as used in this part means a radiocommunication service for use in connection with the dispatching of emergency road service vehicles for the purpose of providing assistance to disabled automotive vehicles used on streets or highways.

Common carrier. As used in the Motor Carrier Radio Service, a person who holds himself out to the general public to engage in the transportation of passengers or property without discrimination, for compensation as a regular occupation or business.

Contract carrier. As used in the Motor Carrier Radio Service, a person who under individual contracts or agreements engages in the transportation of passengers or property for compensation as a regular occupation or business.

Land transportation radio services. Any private service of radiocommunication essential to the conduct of certain land transportation activities, the transmitting facilities of which are defined as fixed, land, mobile or radiolocation stations.

Mobile relay station. A base station in the mobile service, authorized primarily to retransmit automatically on a mobile service frequency, communications originated either by associated mobile units or by an associated control station. (Authorized in the Railroad Radio Service only.)

Mobile Repeater station. A mobile station in the mobile service, authorized to retransmit automatically on a mobile service frequency, communications originated either by associated pack-carried or hand-carried mobile units or by other mobile or base stations directed to such pack-carried or hand-carried units. (Authorized in the Railroad Radio Service only.)

Motor carrier. Any streetcar, bus, truck, or other land motor vehicle operated over public streets or highways by a common or contract carrier and used for the transportation of passengers or property (freight) for compensation: Provided, however, that motor vehicles used as taxicabs, livery vehicles, or school buses, and motor vehicles used for sightseeing or special charter purposes, shall not be included within the meaning of this term as used in the Motor Carrier Radio Service.

Motor Carrier Radio Service. A radiocommunication service for use in connection with the operation of a motor carrier land transportation system.

Railroad Radio Service. Radiocommunication service for use in connection with the operation and maintenance of a railroad common carrier.

Taxicab **Radio Service.** The term "Taxicab Radio Service", as used in this part means a radiocommunication service for use in connection with the transportation facilities of a taxicab common carrier.

Urban area. As used in the Motor Carrier Radio Service, one or more contiguous, incorporated or unincorporated cities, boroughs, towns, or villages, having aggregate population of 2,500 or more persons.

XI Citizens Radio Service

Citizens Radio Service. A radiocommunications service of fixed, land, and mobile stations intended for short-distance personal or business radiocommunications, radio signaling, and control of remote objects or devices by radio; all to the extent that these uses are not specifically prohibited in this part.

Class A station. A station in the citizens Radio Service licensed to be operated on an assigned frequency in the 460-470 mc/s band and with input power of 60 watts or less.

Class B station. A station in the Citizens Radio Service licensed to be operated on an authorized frequency in the 460-470 mc/s band and with input power of 5 watts or less.

Class C station. A station in the Citizens Radio Service licensed to be operated on an authorized frequency in the 26.96-27.23 mc/s band, or on the frequency 27.255 mc/s, for the control of remote objects or devices by radio, or for the remote actuation of devices which are used solely as a means of attracting attention, or on an authorized frequency in the 72-76 mc/s band for the control of model aircraft only.

Class D station. A station in the Citizens Radio Service licensed to be operated on an authorized frequency in the 26.96-27.23 mc/s band or on the frequency 27.255 mc/s, with input power of 5 watts or less, and for radiotelephony only.

Remote control. The term "remote control" when applied to the use or operation of a citizens radio station means control of the transmitting equipment of that station from any place other than the location of the transmitting equipment, except that direct mechanical control or direct electrical control by wired connections of transmitting equipment from some other point on the same premises, craft or vehicle shall not be considered to be remote control.

XII Amateur Radio Service

Amateur mobile station. An amateur station that is so constructed that it may conveniently be transferred to or from a mobile unit or from one such unit to another, and is ordinarily used while such mobile unit is in motion.

Amateur operator. A person interested in radio technique solely with a personal aim and without pecuniary interest, holding a valid license issued by the Federal Communications Commission authorizing him to operate licensed amateur stations.

Amateur portable station. An amateur station that is so constructed that it may conveniently be moved about from place to place for communication, but which is not operated while in motion.

Amateur radiocommunication. Radiocommunication between amateur stations solely with a personal aim and without pecuniary interest.

Amateur service. A radio service carried on by amateur stations.

Amateur station. A station used by an amateur operator, and embracing all radio transmitting apparatus at a particular location used for amateur service and operated under a single instrument of authorization.

XIII Disaster Communications Service

Associated station. A disaster station is considered to be associated with a licensed station in some other service when both stations are licensed to the same licensee at the same location and both stations are included in at least one coordinated disaster communications plan of the area concerned. A portable station or a mobile station in the Disaster Communications Service will be considered to be associated with the station in the other service which is located at its base of operations.

Competent local authority. That authority within a community or larger area which is so designated in the coordinated disaster communications plan for the area concerned, including any alternate authority who may be so designated in such plan. In the absence of the specifically designated authority, the individual in charge of the net control station, or his representative, for the organized disaster station network established in accordance with the coordinated disaster communications plan, shall be considered as competent authority for the activation of the stations of that network. Duly designated civil defense officials will be considered competent local authority in the organization or operation of disaster communications radio networks and stations, and in the coordination of disaster communications plans.

Disaster. An occurrence of such nature as to involve the health or safety of a community or large area, or the health or safety of any group of individuals in an isolated area to whom no normal means of communications are available, and include, but are not limited to, floods, earthquakes, hurricanes, explosions, aircraft or train wrecks, and consequences of armed attack.

Disaster communications. Communications essential to the establishment and maintenance of communication channels to be used in connection with disasters or other incidents involving loss of communications facilities normally available or which demand the temporary establishment of communications facilities beyond those normally available, including communications necessary or incidental to drills and simulated disaster relief activity on the part of persons or organizations participating in the use of such communication channels; or communications or signals essential to the public welfare, or that of any segment of the public, including communications directly concerning safety of life, preservation of property, maintenance of law and order, and alleviation of human suffering and need, in the case of any actual or imminent disaster or other such incident.

Disaster Communications Service. A service of fixed, land, and mobile stations licensed, or authorized, to provide essential communications incident to or in connection with disasters or other incidents which involve loss of communications facilities normally available or which require the temporary establishment of communications facilities beyond those normally available.

Disaster station. Any government or nongovernment radio station able to function as a fixed, land, or mobile station and authorized, if government, by its controlling federal government agency or licensed, if nongovernment, by the Federal Communications Commission to operate in the Disaster Communications Service. A single disaster station may consist of more than one unit, each capable of being operated independently as a fixed, land, or mobile station.

Portable station. A land station in the Disaster Communications Service which is capable of being moved from place to place and is in fact, from time to time, moved to and operated at unspecified fixed locations for the purpose of communicating with other fixed, land, or mobile stations.

XIV Domestic Public Radio Services

Auxiliary test station. A fixed station used for test transmissions only, operating on mobile station frequencies from a specified fixed location, for the purpose of determining the performance of fixed receiving equipment which is remotely located from the base station with which it is associated, or where the receiving equipment is located with the base station and both are remotely located from the control point of the station.

Central office. A landline termination center used for switching and interconnection of public message communication circuits.

Central office station. A fixed station used for transmitting communications to rural subscriber stations associated therewith.

Domestic fixed public service. A fixed service, the stations of which are open to public correspondence, for radiocommunication between points all of which lie within: (a) the State of Alaska, or (b) the State of Hawaii, or (c) the remaining 48 states and the District of Columbia, or (d) a single possession of the United States.

Domestic public land mobile radio service. A public communication service for hire between land mobile stations wherever located and their associated base stations which are located within the United States or its possessions, or between land mobile stations in the United States and base stations in Canada.

Domestic public radio service. The land mobile and domestic fixed public services the stations of which are open to public correspondence.

Effective radiated power. The product of the antenna power input and the antenna power gain. This product should be expressed in watts. (If specified for a particular direction, effective radiated power is based on the antenna power gain in that direction only.)

Exchange. A unit of a communication company or companies for the administration of communication service in a specified area, which usually embraces a city, town, or village and its environs, and consisting of one or more central offices, together with the associated plant, used in furnishing communication service in that area.

Exchange area. The geographic area included within the boundaries of an exchange.

Fixed microwave auxiliary station. A fixed station used in connection with (1) the alignment of microwave transmitting and receiving antenna systems and equipment, (2) coordination of microwave radio survey operations, and (3) cue and contact control of television pickup station operations.

Frequency tolerance. The frequency tolerance, expressed as a percentage or in cycles per second, is the maximum permissible deviation, with respect to the reference frequency of the corresponding characteristic frequency of an emission.

General communication. Two-way voice communication, through a base station, between a common carrier land mobile station and a landline telephone station connected to a public message landline telephone system, or between two common carrier land mobile stations via a base station.

Inter-office station. A fixed station in the domestic fixed public service which is used exclusively for interconnection of telephone central offices.

Local television transmission service. A domestic public radiocommunication service for the transmission of television material and related communications.

Message center. The point at which messages from members of the public are accepted by the carrier for transmission to the addressee.

Microwave frequencies. As used in this part, this term refers to frequencies of 890 mc and above.

Miscellaneous common carriers. Communications common carriers which are not engaged in the business of providing either a public landline message telephone service or public message telegraph service.

Mobile microwave auxiliary station. A mobile station used in connection with (1) the alignment of microwave transmitting and receiving antenna systems and equipment, (2) coordination of microwave radio survey operations, and (3) cue and contact control of television pickup station operations.

Point-to-point microwave radio service. A domestic public radio service rendered on microwave frequencies by fixed stations between points which lie within the United States or between points in its possessions or to points in Canada or Mexico.

Private line service. A service whereby facilities for communication between two or more designated points are set aside for the exclusive use or availability for use of a particular customer and authorized users during stated periods of time.

WHY DO YOU WANT TO SUCCEED?

There are several answers to this question. You may want to succeed for the very human reason that you want more money with which to enjoy life, or you may have a family for whom you want to provide those comforts they so well deserve -- a home, a new car, good clothes, life insurance, and financial security.

Your ambition to succeed may be prompted by the desire to bring happiness to an aged father, mother, or relative whose chief hope in life is to see you enjoy prosperity and prestige, to see you on the pinnacle of success.

Pause for just a minute and think -- what is your reason for wanting success? With this reason in mind, resolve firmly that you will never allow your ambition to weaken. Resolve that you will never swerve from the direct path of your goal. Make this resolution now and keep it, so the years to come will be happier and more prosperous for you.

ACHIEVEMENT THROUGH ELECTRONICS

nri

TRAINING KIT MANUAL

1T

NATIONAL RADIO INSTITUTE • WASHINGTON, D. C.

TRAINING KIT MANUAL 1T

PRACTICAL DEMONSTRATIONS
IN BASIC ELECTRONICS

A Plan For Studying The Experiments

As you know, these Experimental Kits are intended to come to you on a definite schedule. This arrangement is so that you will study the necessary theory in your regular lessons before you carry out any corresponding experiments. This permits you to adopt either of the following plans of study:

1. You may wish to complete one or two experiments in a kit, do a lesson, and then return to the kit for one or two more experiments. This plan permits the experiments in one kit to be finished about the time the next kit is due. Thus, the lessons and experiments run along together, and provide you with a varied program of study.
2. You may prefer to break away from your lessons and to complete all the experiments in a kit at one time before going back to your lessons. This plan has the advantage that you do not waste any time getting out and putting away materials, but it can be followed only if you can leave your equipment set up long enough to finish.

Whichever plan you follow, you can begin NOW with the experiments in this kit. However, be sure to read the preliminary information on pages one through sixteen before you begin, so you will know just how the experiments are to be carried out. In a similar manner, begin on future kits as soon as you receive them.

NOTICE

NRI has set up the CONAR Division of the National Radio Institute to handle the sale of professional test equipment and other electronic equipment. NRI has had unsurpassed experience in the design of quality kits. All CONAR kits are designed and produced by the National Radio Institute. The transistorized volt-ohmmeter you will build as part of your training is the CONAR Model 212. This is the same professional tvom you will see advertised nationwide. Several of the parts you received in this kit, including the meter, will be used in the assembly of your tvom.

INSTRUCTIONS FOR PERFORMING EXPERIMENTS 1 THROUGH 10

LECTURE-ROOM DEMONSTRATIONS YOU PERFORM IN YOUR OWN HOME

How many times have you heard the expression, "Seeing is believing"? Probably many times, because it is human nature to doubt something you cannot see or touch.

Although you can learn how a piece of equipment works from pictures and words, the average person understands better if he can actually set up equipment and make tests himself to see how it works.

You must have a knowledge of theory before you can work successfully in the radio-TV-electronics field. However, unless you know how to apply theory and make tests, your knowledge is useless. Theory and practical application must go hand-in-hand.

The NRI Course of training is a well-balanced combination of theory and practical instruction. Practical demonstrations and experiments are given in this manual and the following manuals.

Doing these experiments will give you actual experience in handling parts and making measurements, and will help you understand explanations of more advanced circuit actions. This type of experience is more valuable to you than class or lecture-room demonstrations by an instructor in which you take no active part, and you can do the experiments at your own convenience.

This practical work with experimental equipment will help you develop confidence in your own ability and will provide what you need to become a practical technician.

The experiments will help you to solve technical problems you will encounter in your work. You will see for yourself what happens when a particular part is defective, and you will learn how to detect and correct errors and how to adjust circuits.

Every experiment in every manual is important, because it is an actual working demonstration. Do not pass over any of them hurriedly, even though you may feel that you already know the results.

If you look underneath the chassis of any modern piece of electronic equipment, you will see that the connections are soldered. A soldered connection is the most reliable type of connection to make in commercial production because it will not deteriorate much during the entire life of the electronic equipment.

When you repair defective equipment, you must be able to find the defective stage and then the defective part. However, the ability to find what is wrong is of little use unless you also know how to take out the defective part and how to solder the connections for a new part. Furthermore, you may often have to unsolder one or more connections during your tests in order to find the defective part.

In the first section of this manual, you will study the fundamentals of soldering and learn how to make a good soldered connection using actual electronic parts. You will make these connections in ex-

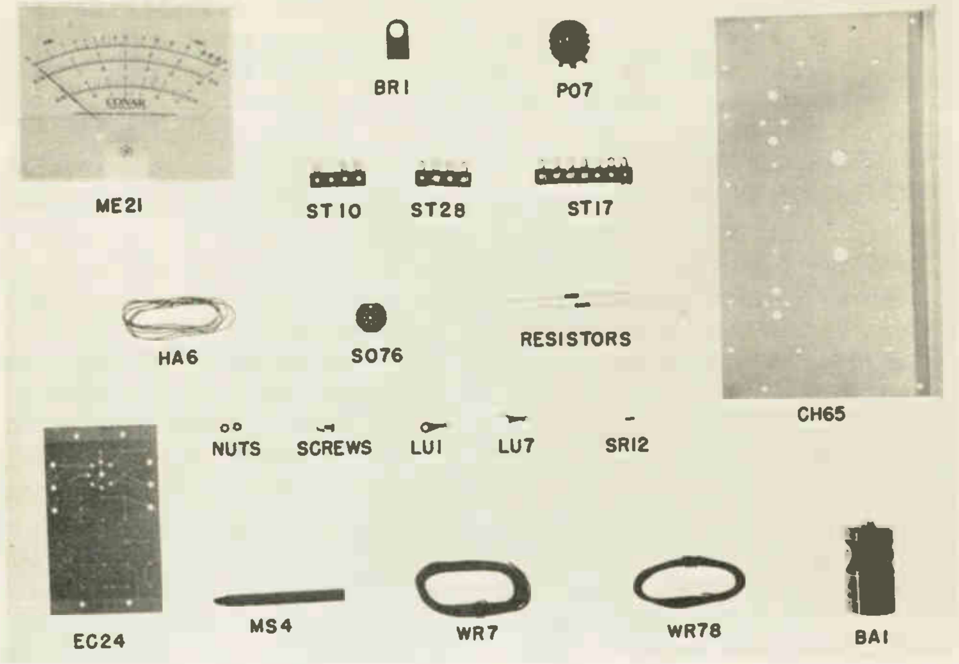

Fig. 1. Parts used in this Experimental Manual are shown here and listed below.

Quan.	Part No.	Description	Price Each
2	BA1	Size D flashlight cell	.20
1	BR1	Pot mounting bracket	.05
1	CH65	Chassis plate	.93
1	EC24	Etched circuit board	1.10
1	HA6	Solder	.41
1	LU1	Solder lug, small	12/.15
2	LU7	Solder lug, large	12/.15
1	ME21	Meter	10.92
1	MS4	Marking crayon	.05
6	NU1	6-32 hex nut	12/.15
2	NU5	4-40 hex nut	12/.15
1	PO7	1000-ohm pot w/lockwasher/nut	.75
1	RE28*	470-ohm resistor	.15
2	RE29	4700-ohm resistor	.15
3	RE30	1000-ohm resistor	.15
2	RE33	22,000-ohm resistor	.15
2	RE36	100,000-ohm resistor	.15
1	RE50	6800-ohm resistor	.15
1	RE52	82,000-ohm resistor	.15
2	RE56	680-ohm resistor	.15
1	RE165	15,000-ohm, 5% resistor	.24
6	SC1	1/4″ X 6-32 machine screw	12/.15
2	SC6	1/4″ X 4-40 machine screw	12/.15
1	SO76	7-pin tube socket	.12
2	SR12	Silicon diode	.67
1	ST10	3-lug terminal strip	.05
1	ST17	7-lug terminal strip	.12
1	ST28	4-lug terminal strip	.10
1	WR7	25′ red hookup wire	.50
1	WR78	6′ black hookup wire	.12

*All resistors are 1/2-watt, 10% tolerance unless otherwise specified.

actly the same way that you would in working on commercial equipment. The solder, hookup wire, and other parts that are included in this kit are standard items, just like those that you might use in working on any piece of electronic equipment. In later experiments, you will have practice in working from schematic diagrams. You will also assemble a number of simple circuits to demonstrate some basic electrical laws.

HOW THE MANUALS ARE ARRANGED

The manual for each kit in your Practical Demonstration Course contains the instructions for performing ten experiments. These experiments are numbered consecutively throughout the whole series; Experiments 1-10 are in the first manual, 11-20 in the second, etc. At the end of each experiment is a Statement that you are to complete, so that you can check your work as you go along. When the ten statements have been answered, be sure to submit the training Kit Report to NRI for grading.

In each manual, the figures are numbered to correspond to each experiment. Each figure number has two parts. The first part is the number of the experiment in which it appears, and the second part is the number of the figure within the experiment. For example, Fig. 1-3 would be the third figure in Experiment 1; Fig. 6-2 would be the second figure in Experiment 6. If there are any figures that do not apply to one particular experiment, they will be numbered consecutively in each manual, starting with Fig. 1.

CONTENTS OF THIS KIT

The parts included in your first kit are pictured in Fig. 1 and listed below. Each part that you receive in your kits is assigned a part number. The part number and description appears below Fig. 1. When you need a part for the experiments, you will be given the part value, a description, and in some cases the part number.

Now check the parts that you receive against this list to make certain that you have all of the parts. *Do not lose or discard any of these parts because you will use many of them again in later experiments.*

For your convenience, most of the parts are packed on cardboard under a clear plastic film. This protects the parts during shipment and also makes it easy to inventory your parts. To remove the parts, cut around them with a sharp knife or a razor blade.

IMPORTANT: If any part of this kit is obviously defective or has been damaged during shipment, please return the defective part to NRI for replacement, following the procedure given on the "Packing and Returned Material Slip" enclosed in this kit.

Preparing For The Experiments

Before you start the experiments, there are several things you will need to do. You will need a place to work and tools to work with.

You do not need an elaborate workbench. A folding card table set up near an electrical outlet will be satisfactory. Do not use a metal-top table, because it could cause short circuits that might damage the equipment. If you have to use a metal-top table, cover the top with a nonconductor, such as cardboard or linoleum.

TOOLS YOU WILL NEED

The tools you need to do these experiments are the same as those you will use in all kinds of electronic work. They are pictured in Fig. 2, and listed under the figure. None of these tools are supplied with this kit. Probably you already have some of these tools, since the average home usually does have a few tools for simple repair work.

You can get those tools you do not have from hardware stores, radio-supply

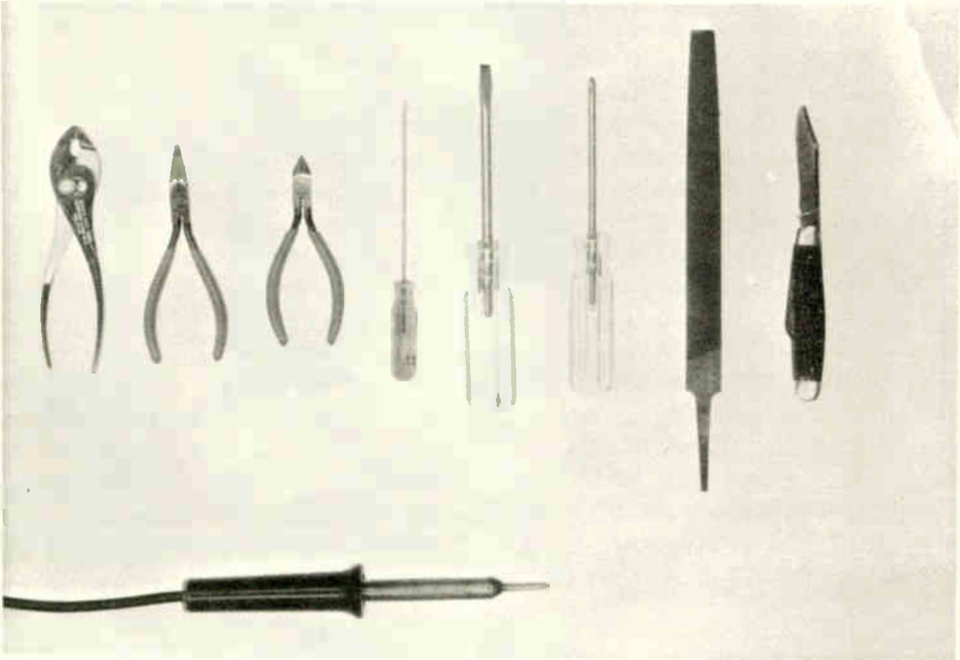

Fig. 2. These are the tools you will need to do these experiments. You probably already have many of them. Get the best ones you can afford; you will be using them throughout your course as well as when you do service work. These tools are not supplied with your kits. From left to right, all-purpose pliers, longnose pliers, diagonal cutters, small screwdriver, medium size screwdriver, Phillips screwdriver, metal-cutting file, and pocket knife. Below the tools is a soldering iron.

houses, or mail-order firms. Since you will use the tools in all of your electronic work, they are a worthwhile investment. Select good quality tools that "feel right" in your hand.

Pliers. The technician needs three types of pliers: longnose pliers, diagonal cutters, and ordinary slip-joint pliers. Each type has its own purpose and should be used for that purpose only. Pliers are designed primarily for holding, bending, and cutting. Many people use them for other purposes so they often ruin them or mar the material on which they are working.

Perhaps the pliers most often used in electronics are the longnose type. Although you may use longnose pliers to hold a nut in position so that it can be started on a screw, you should never use them to tighten nuts. You may spring the jaws so the points will not meet or you could actually break one of the jaws. Use your longnose pliers to hold wires in position for soldering, to remove wires, or for hard-to-reach places.

Diagonal cutting pliers, or "side cutters" as they are often called, are used for most cutting operations. Because the cutting jaws are at an angle, these pliers are ideal for cutting wires close to terminals.

Combination slip-joint pliers, often called "combination pliers," are also in common use. Because of the slip joint, the jaws can be opened wider at the hinge pin so that larger diameters can be gripped. These pliers come in 5, 6, 8, and 10-inch sizes. The thin-type, 6-inch size is best for electronics work.

Screwdrivers. Practically everyone is familiar with the standard screwdriver. The screwdriver is intended for one principal purpose - to loosen or tighten screws. Because the average person uses a screwdriver as a can opener, a pry or pinch bar, and even as a chisel, the screwdriver is one of the most abused tools.

The technician needs three screwdrivers - one with a small blade for loosening setscrews in dial and control knobs and one with a medium blade for general purpose work. He also needs a Phillips screwdriver because screws with a special head known as a "Phillips head" are often used in electronic equipment. Screwdrivers with plastic handles are best because the plastic is a good insulator. Later on you will need a special type of screwdriver, known as an "alignment tool." This is a non-metallic tool for special uses, but you won't need it now.

Files. There are more than twenty types of files. Each type comes in sizes from three to eighteen inches. They may be either single or double cut and are classified according to the different grades of coarseness or fineness, depending upon the size and spacing of the teeth.

The type most often used in electronics is a 10-inch second-cut mill file. It is used to keep the tip of the soldering iron in good condition by removing small amounts of metal, leaving the filed surface smooth. This type of file is also useful in brightening lugs for easier soldering.

Knife. A good knife is useful when preparing wires for connection to other parts; a sturdy pocket knife is fine.

Soldering Iron. The soldering iron is used more often by servicemen than any other tool. Since you will use it often and it is so important, you should choose it carefully. A number of soldering irons suitable for electronics work are shown in

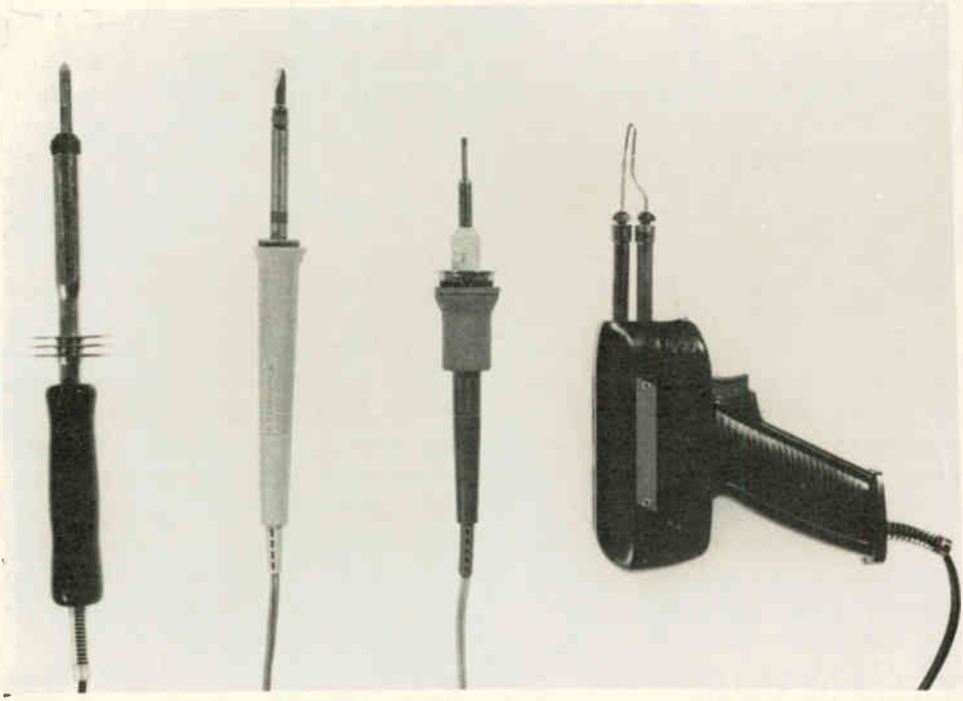

Fig. 3. Several soldering irons suitable for electronics work.

Fig. 3. It is best to buy a soldering iron from a firm that specializes in electronics parts. You should obtain your iron from your local wholesaler, from a mail-order wholesaler, or from the CONAR Instruments Division of NRI.

Hardware stores sometimes carry soldering irons in stock, but they may have only the large type that is used for heavy work, such as automobile radiator repair or roofing work. These irons are too heavy for easy handling and too big to be used where small parts are crowded together.

From left to right in Fig. 3, the first iron is called a medium duty iron. This type of iron generally has a rating of from 50 to 150 watts and is used where a relatively large amount of heat is needed, such as when soldering to the chassis.

The two irons in the center are "pencil" type irons. These types have replaceable heating elements and tips. They are available with various wattage ratings, usually 25 to 40 watts, suitable for general electronic soldering, and 40 to 50 watts, for heavier duty work. These "pencil" irons are the types most suitable for the beginner as they are lightweight and easy to handle. Perhaps the most suitable iron for the beginner would be one like the third iron from the left in Fig. 3. A 37-1/2 element and a chisel-shaped tip make an ideal choice of element and tip.

At the right in the photo is a soldering gun. A gun of this type has the advantage over the iron in that it heats and cools very quickly. Thus, it is excellent for a serviceman making house calls or a technician working on equipment in a plant. He plugs the gun in when he arrives at the job and it is ready for use immediately. Everyone going into electronics, whether on a part-time or full-time basis, will find a gun useful. However, it is not quite as easy to turn out well-soldered connections with a gun as it is with an iron. Therefore, the beginner should start with a conventional soldering iron and learn to use it correctly and later, if he so desires, he can use a soldering gun.

As mentioned previously, the most suitable single iron for general service work and for use in your kits is an electric iron with a tip about an inch long and 1/8" to 1/4" in diameter. The tip should be of the chisel type with two flat surfaces. The wattage rating should not be more than 50 watts, because a high-wattage iron is bulky, and if its barrel touches parts, it may damage them.

When you buy an iron, be sure you get a soldering iron stand with it, to rest the hot iron on when it is not in use. Or get an iron that is designed so that the handle is heavier than the tip end. Then the iron will balance when it is laid down with the tip off the bench.

The average electric soldering iron will operate on ac or dc at 117 volts. Power-line voltages may vary between 110 and 120 volts; an iron designed for 117-volt operation may be used on any voltage between 105 volts and 130 volts.

Although the modern soldering iron is a rugged tool, it should never be abused. Do not use it as a hammer, drop it, or attempt to cool it quickly by plunging it into water. When properly cared for, an iron will last for years.

Although some irons have pre-tinned tips, most tips must be tinned before use. If your iron has a bright, shiny tip or a dull gray tip, it has been pre-tinned, and it is ready for use. If the tip is a natural copper color, you must tin it before using it.

TINNING A SOLDERING IRON

You cannot solder properly unless your soldering iron is properly tinned. Therefore, your first step in learning how to solder is to learn how to tin a soldering iron.

The tip of the soldering iron is made of copper. When an untinned soldering iron is heated, the copper combines with the oxygen in the air, forming a dark coating of copper oxide on the tip of the iron. If you try to use an untinned iron, the copper oxide coating will act as a heat insulator and keep the heat of the iron from the parts you are trying to solder. It will be practically impossible to heat the part sufficiently to melt the solder properly.

You can prevent this by covering the tip of the iron with solder. This is called "tinning" the iron. The solder will form a protective layer over the copper tip so that the oxygen cannot get at the copper and corrode it. The tinned tip will be a good conductor of heat, and you will be able to heat the parts enough to solder them properly.

Preparing the Tip. The first step in tinning a soldering iron is to examine the tip. A photograph of the tip of a new soldering iron that has not been tinned is shown in Fig. 4A, and a photograph of a soldering iron that has been used and needs re-tinning is shown in Fig. 4B. Notice that the tip of the new iron is reasonably smooth, whereas the tip of the iron that has been used is pitted, dirty, and uneven.

If your soldering iron is in good condi-

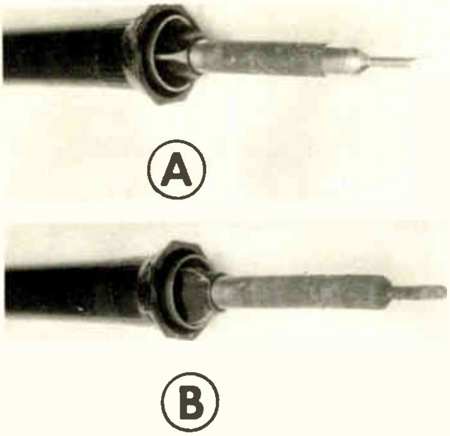

Fig. 4. If your soldering iron is new and has not been tinned as at (A), or if it has been used and is pitted as at (B), it will need tinning.

tion, like the one shown in Fig. 4A, you can plug it into an electrical outlet and start heating it. On the other hand, if you have an iron that has been used and looks like Fig. 4B, you should file the tip smooth before you start to heat it. Even though your iron may be in good condition, read the following instructions carefully, because after your iron has been used for some time, it will become pitted like the one shown in Fig. 4B. You will have to go through this procedure to re-tin it.

To file the tip of the iron, rest the iron on a vise or a similar metal support, as shown in Fig. 5. Grasp the iron in one hand and proceed to file one of the surfaces flat as shown. Try to file the surface at approximately the same angle as that of the original tip. Do not remove any more metal than is necessary, but make sure that you file the surface until all of the dark spots and holes in the surface are gone. When you have completed the operation, the tip of the iron should look as it does in Fig. 6.

After you have filed one surface of the tip, turn the iron over. In other words, rotate the iron 180°, and file the surface flat on the opposite side of the tip. Again, remove no more metal than is necessary, but make sure you file the surface until it is clean. Try to file at the same angle as the first surface, as shown in Fig. 7.

If your iron has a pyramid-shaped tip, turn the iron a quarter turn and file one of the other surfaces. Then turn the iron over and file the last surface. When you

Fig. 5. To file the tip of your iron, hold it against a vise as shown here.

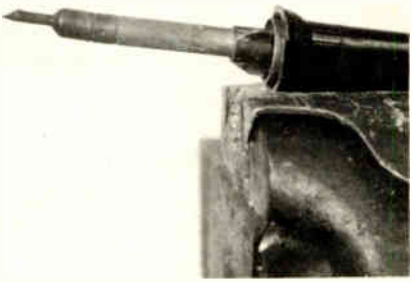

Fig. 6. When you have filed one surface, your iron should look like this.

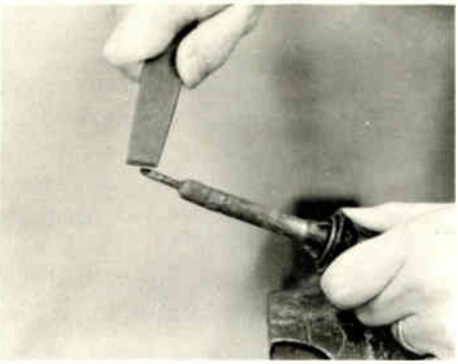

Fig. 7. File the opposite surface at the same angle as the first surface, as shown.

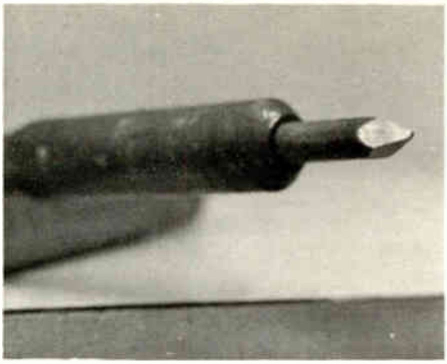

Fig. 8. Your iron should look like this after filing all four surfaces on its tip.

have filed all tip surfaces, the tip of the iron should look like the one shown in Fig. 8. Notice that the sides are approximately even.

Before you start to heat the iron, examine the edges of the flat surfaces on the tip. If the edges are rough, smooth them by careful rubbing with a piece of sandpaper.

Tinning the Iron. After you have prepared the surface for tinning, or if you are tinning a new iron that is in good condition, plug the iron in and wait for it to heat. As the iron heats, periodically touch the end of the solder to the tip so you will know when the iron is hot enough to melt the solder. You should tin it as soon as it reaches a high enough temperature, because the longer an untinned iron is heated, the more copper oxide will form on the tip.

When the iron has reached operating temperature, again rest it on a vise and lightly file one surface as shown in Fig. 5. Once you have filed the surface lightly so that it is shiny, quickly set the file down, pick up the roll of solder, and touch the end of the solder to the tip of the iron. Move the solder around the tip until the entire surface is tinned, as shown in Fig. 9. After you have tinned one surface of the tip, turn the iron and go through the same procedure of lightly filing the other surfaces, and then applying solder.

After you have tinned the surfaces of the tip, use a clean cloth to wipe off any excess solder. Hold the cloth loosely as shown in Fig. 10 to avoid burning your hand. When you have your iron tinned, it is ready for use. Unplug it, and set it aside until you are ready to start soldering.

Fig. 9. How to apply solder to tin the tip of the iron.

Fig. 10. Wiping excess solder from the iron with a piece of cloth.

Notice that the solder you received in this kit contains a rosin core that acts as a cleaning agent and prepares the metal surface to receive the solder. It is difficult to make a good soldered connection using plain solder alone; another material called flux must be applied along with the solder. Rosin flux is used in this case. Only rosin core solder should be used in soldering electronic equipment.

Hardware and other stores sell some solder with an acid core. Acid flux in any form should never be used in electronic equipment. The acid will corrode the leads and terminals and may damage some of the parts. Use only rosin core solder in electronics work; do not use liquid or paste flux. Solder similar to that which we have supplied in this kit should be used in all your electronics work.

IMPORTANT NOTICE

In checking students' problems, NRI has found that poor soldering is more frequently the cause of failure to get proper results than all other troubles combined. Therefore, be sure to perform every step in each experiment to learn all you can about soldering.

DO NOT SKIP ANY STEPS

MOUNTING THE PARTS

Most of your experiments will be carried out on your experimental chassis plate which is shown in the parts photo, Fig. 1. You will mount several parts on the chassis plate before you begin the experiments.

The parts supplied with this kit are shown in Fig. 1 and identified in the list below the photograph.

Gather the following parts and place them on your worktable. Then they will be handy when you are ready to use them:

1 Chassis plate (CH65)
1 7-lug terminal strip (ST17)
1 3-lug terminal strip (ST10)
1 4-lug terminal strip (ST28)
1 Potentiometer mounting bracket (BR1)
1 1K-ohm potentiometer (PO7)
1 Solder lug (LU1)
6 1/4" X 6-32 screws (SC1)
6 6-32 hex nuts (NU1)
1 Marking crayon (MS4)

Notice that we have supplied two sizes of screws and nuts. The size of a machine screw is given by its diameter and the number of threads per inch. The first number is the diameter. Thus, the 6-32 screws (SC1) are larger in diameter than the 4-40 screws (SC6), but the 4-40 screws have a finer thread. The length of a screw is given in fractions of an inch.

Follow the instructions as you mount the parts on your chassis and do not attach any parts until instructed to do so.

Place the chassis upright on your worktable so that the holes are positioned as shown in Fig. 11. The bent lip should be away from you and pointing upward. To

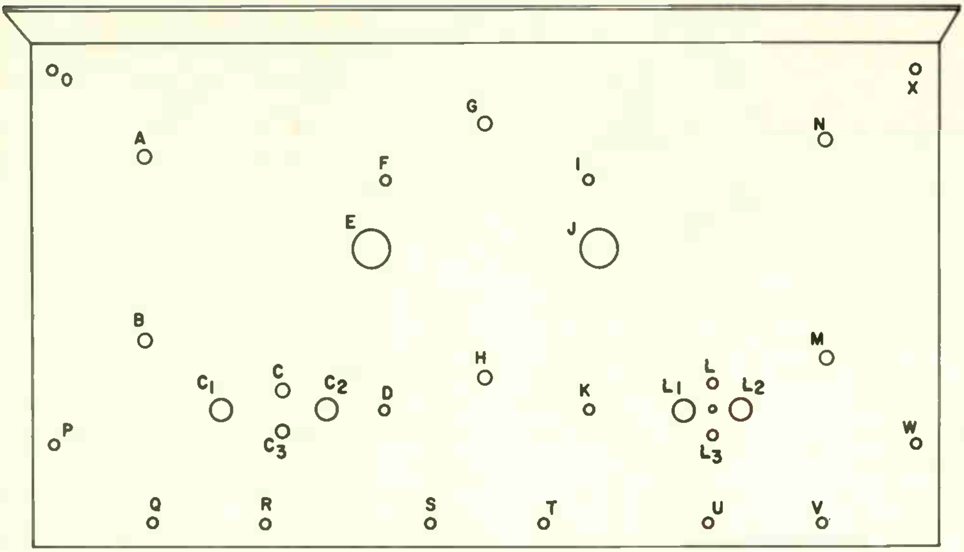

Fig. 11. Chassis hole identification.

help you locate the parts correctly, we have given the holes identifying letters. You can use the marking crayon to label these holes on the chassis. If you prefer, you can put small pieces of tape near these holes and mark on the tape with a pen.

Fig. 12 shows the chassis with the parts

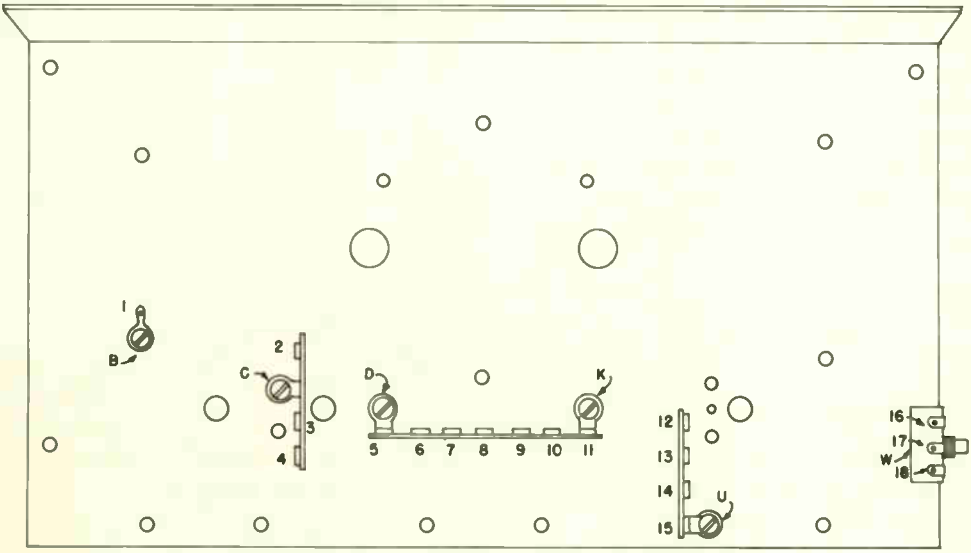

Fig. 12. Parts mounted on the chassis and the terminal identification number.

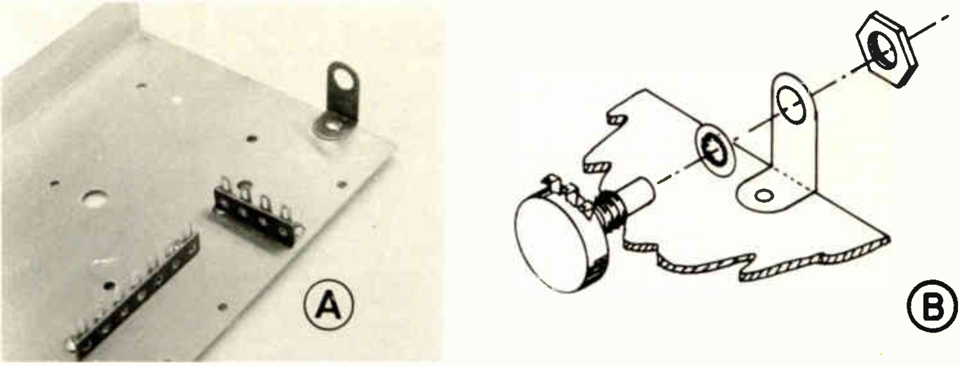

Fig. 13. (A) Mounting the potentiometer bracket; (B) mounting the potentiometer.

mounted on it. Be sure to mount the parts at the correct location and position them as shown in the drawing.

Mount the 3-lug terminal strip at hole C, as shown in Fig. 12. Pass a 1/4" X 6-32 screw down through the mounting foot in the terminal strip and through hole C in the chassis. Attach a 6-32 hex nut. Position the terminal strip as shown and tighten the screw. Hold the nut with pliers as you tighten the screw.

Install the 7-lug terminal strip at holes D and K. Use 1/4" X 6-32 screws and nuts. Position the strip exactly as shown in Fig. 12. Pass a screw down through the left mounting foot and hole D and attach a nut. Pass a screw through the other mounting foot and through hole K. Attach a nut and tighten both screws.

Mount the 4-lug terminal strip at hole U. Use a 1/4" X 6-32 screw and nut. Position the terminal strip as shown in Fig. 12 and tighten the screw.

Install the potentiometer mounting bracket at hole W. See Fig. 13A. Use a 1/4" X 6-32 screw and nut. Pass the screw down through the small mounting hole in the bracket and through hole W in the chassis. Attach the nut and tighten the screw.

Install the potentiometer in the potentiometer mounting bracket. As shown in Fig. 13B, slip the large lockwasher over the shaft and bushing of the potentiometer and slip the bushing through the hole in the bracket mounted on the chassis. Attach the large control nut, turn the potentiometer so its terminals are upward; then tighten the control nut.

Bend the solder lug at about a 45° angle, as shown in Fig. 14. Mount the solder lug at hole B, using a 1/4" X 6-32 screw and nut. Tighten the screw.

The numbers appearing in Fig. 12 are the terminal identification numbers. They will be used throughout this kit for identifying the terminals when making connections.

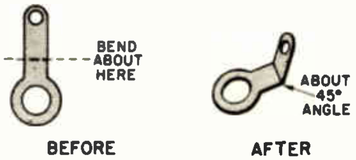

Fig. 14. Before you mount the solder lug, bend it as shown here.

Learning To Solder

Our experience in teaching students has shown that over 75% of the troubles encountered by students and technicians is due to poor soldering! You might think from this that good soldering is difficult, but this is not true. If you watch an experienced man work with a soldering iron, it looks quite simple. The experienced technician follows the two basic rules given below to make good soldering easy.

First: Have the materials to be joined and the tip of the iron clean and free from grease. If the terminals or wires are not bright, scrape them with a knife or with a piece of fine sandpaper until they are clean and bright.

Second: Have the sections to be joined hot enough to melt the solder so that it will run freely to all parts of the connection and form a good bond.

If you follow these two basic rules, you will never have soldering trouble. If you ignore them, you may spend hours looking for defective parts when the trouble is simply a poorly soldered connection.

SOLDERING TECHNIQUES

Perhaps the most important step in making a good soldered connection is to make sure that the parts you are attempting to solder together are clean. For example, if you try to solder a capacitor lead to a terminal strip, and the capacitor lead is not clean, you will find it practically impossible to get the solder to stick to the lead.

All leads, whether they are resistor or capacitor leads or merely wires to be soldered, should be tinned before you attempt to solder them. Most of the resistors and capacitors that you will receive in your kits have been tinned by the manufacturer. However, in the manufacturing processes, the tinned surface sometimes becomes covered with wax or other impurities. These leads should be cleaned and retinned whenever necessary.

You can use approximately the same procedure to tin a lead as you used to tin the tip of your soldering iron. The first step is to clean the lead. You can either scrape the lead carefully with a knife, as

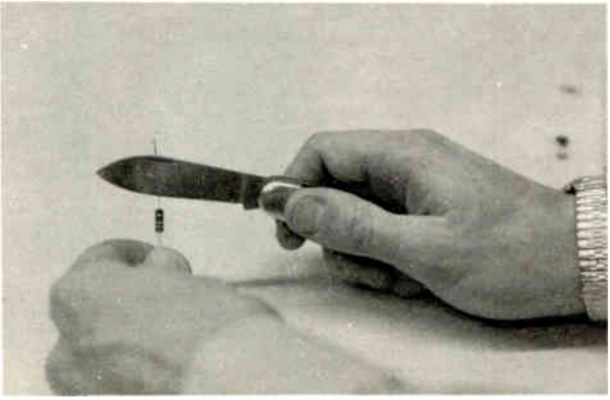

Fig. 15. How to use a knife to clean a resistor lead.

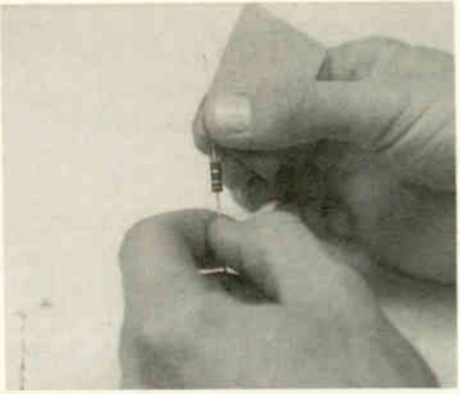

Fig. 16. Using sandpaper to clean a lead.

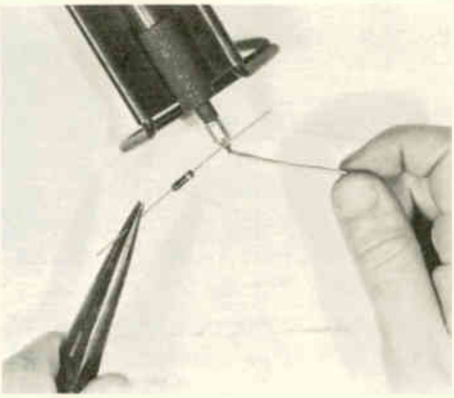

Fig. 17. How to tin a resistor lead.

shown in Fig. 15, or you can use a small piece of fine sandpaper. Hold the lead in the sandpaper, as shown in Fig. 16, and draw the sandpaper over the lead several times.

After you have cleaned the lead, hold the part with your longnose pliers and touch it to the tip of your soldering iron, as shown in Fig. 17. Then touch the solder to the lead. Allow a small amount of solder to melt onto the lead and onto the tip of the iron. Move the lead back and forth through the solder to tin the entire lead. If you apply enough heat to melt the solder thoroughly, the solder will flow smoothly over the lead, as shown in Fig. 18. Tin the other lead in the same way.

Lugs on terminal strips also should be cleaned and tinned before you attempt to solder a wire or a lead to the lug. Usually, brushing over the terminal quickly with a piece of sandpaper will remove any dirt or grease that may be on the terminal. Sometimes it will be necessary to scrape the terminal with a knife or file.

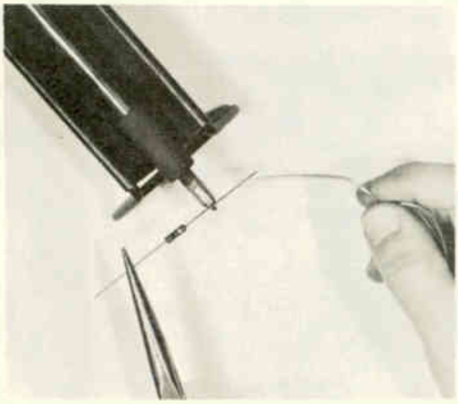

Fig. 18. A tinned resistor lead.

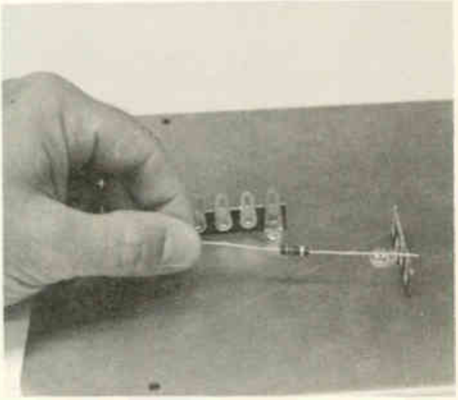

Fig. 19. Making a connection to terminal.

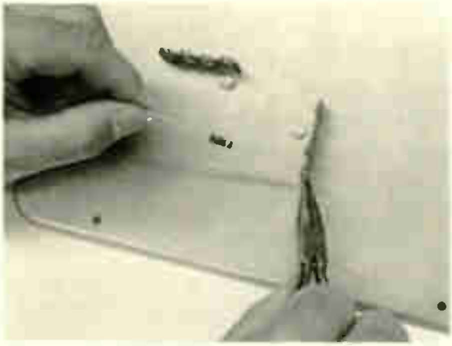

Fig. 20. Bending the lead.

The tube socket pins and lugs on the terminal strips that you will receive in your kits have been tinned. You should have no trouble in soldering to these terminals. However, before soldering to them, carefully examine them to be sure they are clean. If they are not, clean and tin them to avoid soldering difficulties later.

To solder a lead to a terminal strip or solder lug, place the lead through the opening in the terminal lug, as shown in Fig. 19. Bend the end of the lead slightly as in Fig. 20 so that the lead can be placed in contact with the metal part of the lug. Do not wrap the lead around the terminal strip lug unless you are told to do so. This type of connection is too difficult to remove. Later, when you begin wiring equipment that you will leave assembled permanently, you will wrap the leads around the various terminals in order to insure strong mechanical and electrical connections.

When you have the lead in place, hold your soldering iron against the terminal and against the lead, as shown in Fig. 21, to heat both of them to the solder-melting point. Unless you heat them both, you will not make a good connection.

Fig. 21. Soldering a connection.

After they are hot enough, touch the end of the solder to the terminal and lead, so that the solder will flow freely over the resistor lead and the terminal. Do not use too much solder. You want only enough to cover the resistor lead and hold it to the terminal. If you use too much, the solder will flow down the terminal strip and may short to the chassis. A properly soldered connection showing the correct amount of solder is shown in Fig. 22, and a connection with an excessive amount of solder is shown in Fig. 23.

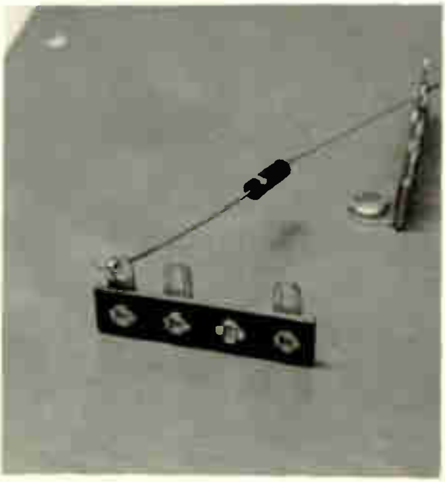

Fig. 22. Good solder connection.

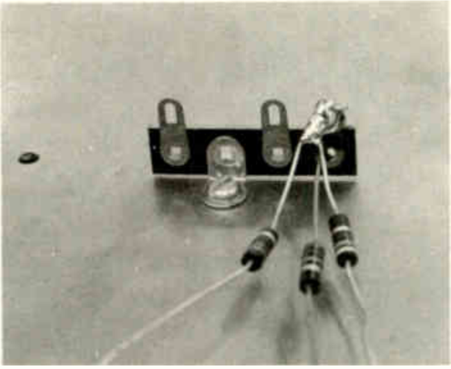

Fig. 23. Poor solder connection (too much solder).

When soldering a connection, do not be in a hurry to get the soldering iron off the connection. In most cases, it is better to hold the iron on the connection a little too long than it is not to hold the iron on long enough. When you are starting to solder, watch each connection carefully. Hold the iron on the connection long enough to allow the solder to flow freely. Solder should melt and flow in, around, and over all the leads you are attempting to solder to a terminal. The solder should also flow freely over the terminal. If you hold the iron on the terminal only long enough to melt the solder and have it start to flow, you will find that you have a rough-looking joint, and the chances are that if you apply pressure to the leads, they will pull loose. On the other hand, if you hold the iron on the joint long enough to allow the solder to melt completely and flow freely over the joint, you will have a smooth-looking connection that will be mechanically strong. This is extremely important - make sure that the solder flows freely over each connection you make.

Using Too Much Solder. Avoid using too much solder. It takes very little solder to make a good electrical connection. Usually, if you heat the terminal and lead sufficiently, you will find that a drop of solder will be all that is needed. Do not hold the soldering iron in place and simply melt more and more solder onto the joint. Once you have one drop of solder flowing around the joint, lift the solder off the terminal, but continue to heat the connection so that the solder that you have on the terminal flows around the leads and over the terminal. This may be all the solder you need. If not, add more solder and allow it to flow into the joint. If you use too much, the solder will flow between the pins and the chassis, and between the chassis and terminal strip lugs.

It is particularly important that you heat large wires thoroughly. You will often find in your radio, TV, or electronics work that you must solder transformer leads in place. Usually the leads from a transformer, particularly the leads from the filament winding on a TV replacement power transformer, will be of a fairly large size. In addition, they are made of copper, which is a good heat conductor. As a result, they can carry away a substantial amount of heat. You will have to be sure that you have the iron in good contact with the lead when making this type of connection.

Etched Circuit Wiring. Etched or "printed" circuit boards are used in many radio and TV receivers as well as in other types of electronic equipment. You can expect to have to wire and to repair circuit boards. Therefore, you should know how to do so.

Examine the etched circuit board included in your kit (NRI part EC24). This is fairly typical of the boards used in commercial equipment. The board consists of a sheet of phenolic, which is an insulating material, with a pattern of copper foil strips bonded to one side. Notice that the copper foil connects together holes in the circuit board. When parts are mounted on the board with their leads extending through these holes and soldered to the copper, the copper foil provides the electrical paths which connect the parts together to form circuitry.

We call them "etched" circuit boards because of the way the boards are made. Each board is cut from a large sheet of phenolic to which a sheet of copper foil has been bonded. The desired copper foil pattern is transferred to the board by a photographic process. The board is then placed in a highly corrosive solution which etches away the unwanted copper foil, leaving the desired foil pattern.

After the etching is completed, the board is cleaned and the holes are drilled or punched and the lettering and other markings are printed on the phenolic.

Parts are usually mounted on the phenolic side of the board and they are supported by their leads, as shown in Fig. 24. The leads are passed through the holes in the board and soldered to the foil. When you install a part, bend the lead outward slightly to hold the part until you can solder the leads. Place the tip of your iron in contact with the lead and the foil and apply solder. Allow a small amount of solder to melt and flow into and around the joint. After the solder cools, cut off the lead flush with the top of the soldered connection. Fig. 25 shows an etched circuit board with good soldered connections.

As you go through these experiments, pay particular attention to each soldered connection you make. Tin the part leads before attempting to solder them; heat each connection thoroughly; inspect each connection and wiggle the leads after it is soldered to make sure that it is a good solid connection. Try to develop sound soldering habits; they will save you a great deal of time and difficulty, not only in your experiments, but all through your electronics career.

Performing the Experiments. To get the most benefit from the experimental course, you should follow a logical, planned procedure in each experiment. When you start a new manual, always study first the introduction at the beginning of the book. Then perform the experiments one at a time, in the correct order, by observing the following procedures:

1. Read through the instructions and discussions for the entire experiment once very slowly, and study any parts that are not immediately clear to you. Do not touch a single tool or part until you make this preliminary study.

2. Lay out on your worktable the

Fig. 24. Phenolic side of an etched circuit board with the parts installed.

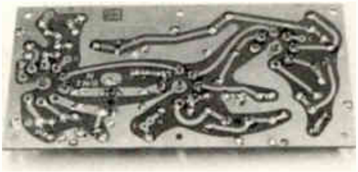

Fig. 25. Foil side of an etched circuit board, showing the parts installed.

parts and tools needed for the experiment to be performed.

3. Carry out the experiments one step at a time. Record your results whenever spaces are provided in the manual for this purpose. Additional observations and comments can be written in the margins of the pages for future reference.

4. Study the discussion at the end of the experiment very carefully, and analyze your results. After finishing an experiment, you should be able to tell in your own words exactly what you proved and how you did it.

5. Complete the Report Statement by writing the Statement Number on your Training Kit Report sheet in the space provided. Then enter the number of your choice for completing the Statement in the next column. Use the additional columns to the right for Statements that have more than one part.

6. When you have completed all ten experiments in the manual and have answered all of the statements, send in your Report Sheet for grading. Do not send in the manual.

EXPERIMENT 1

Purpose: To mount parts in a circuit; and to make soldered connections to these parts.

Introductory Discussion: Solder will hold parts together mechanically and fuse parts together so that they are, in effect, a single unit. A good soldered joint has little or no resistance and protects the surfaces of the parts from oxidation. Good soldered connections are a clue to the technician's ability. A man with an average knowledge of theory who can make good soldered connections will have less trouble than an expert on theory who cannot solder! In this experiment, you will mount parts and make several soldered connections. This experiment may seem simple, but do not pass over it quickly. The points that will be brought out are all very important.

Soldering ability is not hard to acquire and you should make this your first goal.

Experimental Procedure: Before you start the experiment, make sure your workbench is cleared so you will not lose any parts or have anything in your way. Gather your tools and the parts you will need in the experiment. At this time you should have a potentiometer, a solder lug and three terminal strips mounted on the chassis.

In the experiment, you will need the chassis with the parts mounted on it and the following parts:

3 1000-ohm resistors (RE30; brown-black-red-silver)
Rosin-core solder

Step 1: To prepare the parts to be soldered.

If you have the parts mounted on the chassis correctly, you are ready to wire the circuit by soldering resistors to various terminals. Plug in your soldering iron so that it can be heating.

Tin each lead of the three resistors until they are bright and shiny.

As you were instructed previously, you can use a knife or a small piece of sandpaper folded and held between the thumb and forefinger to clean the leads if they will not tin easily.

Test the iron by touching the end of the solder to the tinned tip of the iron. If the solder melts readily, the iron is ready for use.

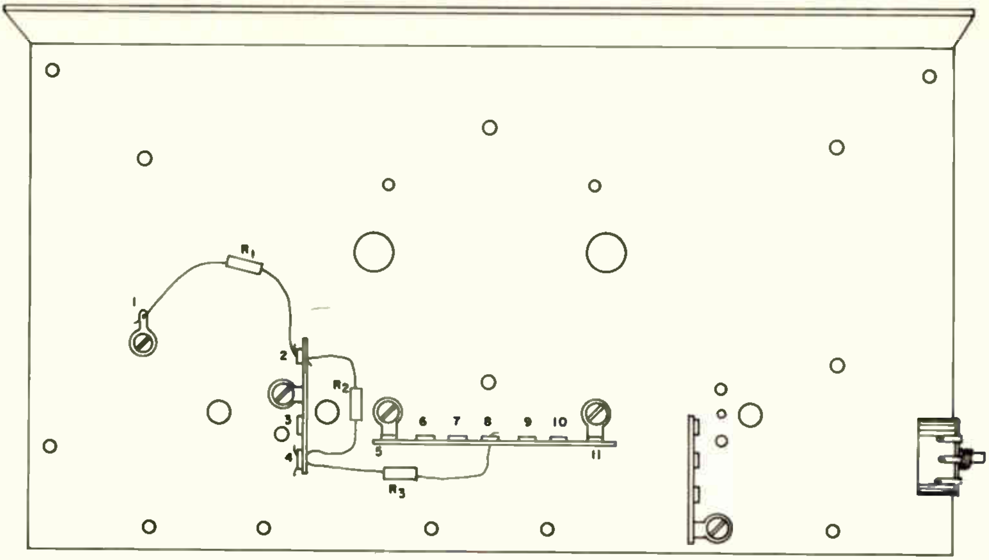

Fig. 1-1. Top view of the chassis, showing the resistors you will install in this experiment.

IMPORTANT: Do not cut the leads of any parts you received in this kit unless you are instructed to do so in the experiment. You will use most of the parts again in future experiments.

Fig. 1-1 shows you where you are to connect the resistors. The resistors are to be mounted so that the resistors and the leads are to be at least 1/2" above the chassis. As we mentioned earlier, we have given each terminal an identifying number. We will use these terminal numbers in this kit to indicate where the connections are to be made so as to simplify the instructions.

Connect the lead of one of the resistors to terminal 1, which is the solder lug mounted at hole B. Push the end of the lead through the hole in the solder lug and solder, as shown in Fig. 1-2.

Bring the tip of your soldering iron into contact with both the solder lug and the resistor lead, as in Fig. 1-2. Position the iron so that one flat surface of the tip is against the terminal. This permits maximum transfer of heat from the tip of the iron to the connection.

Touch the solder to the point where the terminal and the lead meet, and allow the solder to melt. Notice that the rosin flux flows out of the solder as the solder

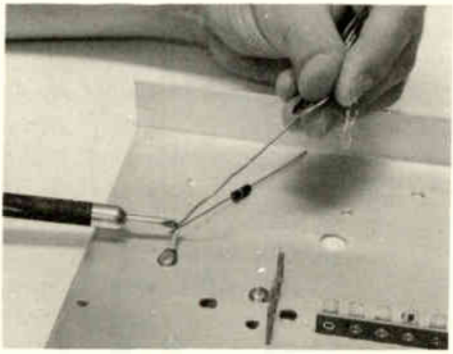

Fig. 1-2. Soldering the resistor lead to the terminal.

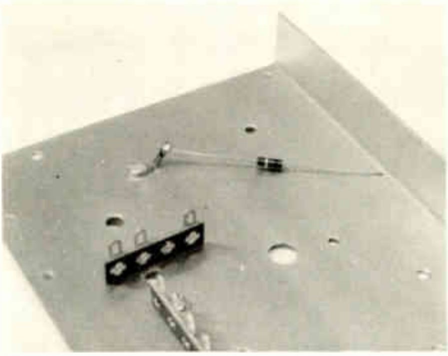

Fig. 1-3. Resistor R_1 soldered to terminal 1.

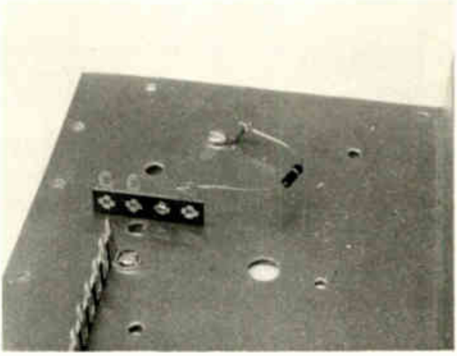

Fig. 1-4. Resistor R_1 in place on chassis.

melts. Remove the roll of solder and continue to heat the joint.

After the solder flows into the connection and coats the terminal and lead, remove the heat and allow the joint to cool and harden. Do not disturb the connection until the solder hardens.

If your solder joint is made correctly, the lead will be covered with solder where it touches the terminal and the solder should have a clean smooth appearance. Fig. 1-3 shows a good solder connection. The space between the resistor lead and the terminal is filled with solder and the solder also seals the connection.

It is a good idea to test each connection after it has cooled. To do this, grasp the resistor lead you have just soldered between the connection and the resistor body with your longnose pliers. Twist the lead gently and move it back and forth. If the lead does not move, you probably have a good soldered connection. If the lead breaks loose, or if the connection has a brown crust on it, re-melt the solder with your iron and let it cool again.

If you did make a poor solder connection, it may have been due to insufficient heat or to dirt on the lead or terminal. A poor joint can also result from your moving the lead before the joint has cooled.

Another problem which you might encounter is the "rosin" joint. This is a connection having a layer of rosin between the wire and the terminal. A rosin joint is indicated by a brown crusty appearance on the connection. You can correct a rosin joint by reheating the connection and allowing the rosin to boil out. As you heat the joint, you will see the vapor from the rosin rising from it.

With your longnose pliers, grasp the free lead of the resistor and slip it through the slot in terminal 2. Position the resistor as shown in Fig. 1-1. Twist the resistor slightly so the lead stays near the top of the slot in the terminal. Bend the end of the lead passing through the terminal so the lead touches the terminal, as shown in Fig. 1-4. Do not solder the connection at this time.

Step 2: To mount resistor R_2.

Now take another resistor and push the end of one lead about 1/8″ through the slot in terminal 2. Bend the end slightly to bring it into contact with the terminal. Solder both leads to terminal 2. Place the tip of your soldering iron in contact with both leads and the terminal, with a flat surface against the terminal. Touch your solder to the connection and allow a small amount of the solder to melt. Remove the roll of solder and allow the molten solder to flow into the connection. Remove the heat and let the joint cool.

Test each connection by twisting and trying to move each lead. If the joint does not break loose, and the solder looks smooth, you probably have an acceptable connection. If not, reheat the connection, remelt the solder and allow it to cool and test the connections again.

Bend the leads of resistor R_2 at a right angle about 1/2" from the body of the resistor and position the resistor as shown in Fig. 1-1. Connect the free lead of resistor R_2 to terminal 4. Do not solder it at this time, since another lead will be connected to the same terminal.

Step 3: To mount resistor R_3.

Connect another resistor, R_3, from terminal 4 to terminal 8. This time make the connection without detailed instructions. Bend the leads as required and position the resistor as shown in Fig. 1-1. Note that the body of the resistor should be about 1/2" to 3/4" from the 7-lug terminal strip. Solder and test both connections.

If you have done your work correctly, your chassis should look like Fig. 1-1. You should have a total of three resistors and four temporary soldered connections. We call them "temporary" because they can be disconnected easily, as you will see later. The solder provides both the mechanical strength and the electrical path between the leads and the terminals.

By contrast, a permanent connection does not rely on the solder for physical strength. Usually the wire is twisted or wrapped around the terminal for physical strength before the connection is soldered.

You will make only temporary soldered connections in the experiments in this manual. However, you will make permanent connections in later experiments. The instructions on how to make them will be given at that time.

Look over the connections you have made and examine them critically. Check to see if any solder has run down the terminal where it may make contact with the chassis and cause a short circuit. This condition is illustrated in Fig. 1-5. Also, look at each connection to see if solder has flowed to all parts of the joints. Look for big lumps of solder on the terminal. They indicate too little heat or too much solder.

Excess solder will do no harm, provided it does not short terminals together, short a terminal to the chassis, or contain excessive rosin. However, it looks messy and is a waste of solder. Too little heat means a poor connection; the cure is to hold the lead in position and reheat the joint.

Next you will unsolder the connections in order to learn the proper techniques for doing this.

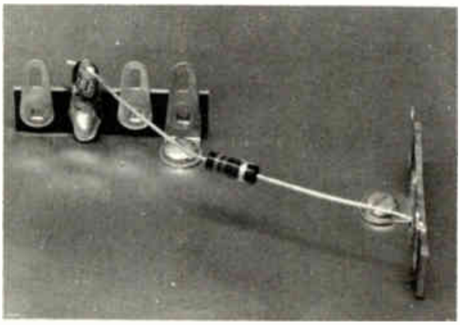

Fig. 1-5. A terminal shorted to the chassis by excessive solder.

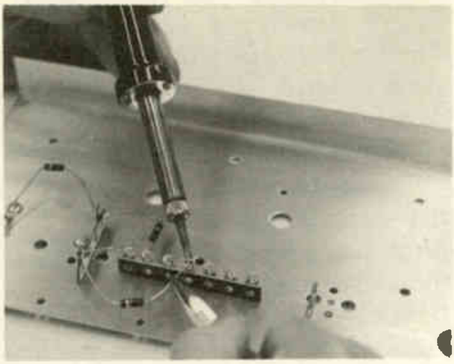

Fig. 1-6. Removing R_3 from terminal 8.

Step 4: To learn to unsolder connections.

Grasp the lead of R_3 connected to terminal 8 with your longnose pliers. See Fig. 1-6. Then touch the tip of your soldering iron to the connection. As soon as the solder melts, pull the lead out of the terminal. Wipe the tip of your iron with a cloth to remove the excess solder, and then touch the tip of the iron to the connections to terminal 4. Grasp the lead of resistor R_3 with your longnose pliers and, as soon as the solder melts, pull that lead free. Lay the resistor on your workbench. Grasp the lead of resistor R_2 connected to terminal 4. Apply heat to the terminal, and when the solder melts, pull the lead free. Wipe the excess solder from your iron with a cloth and then apply heat to the second lead of resistor R_2 which is connected to terminal 2. Remove the resistor and lay it on your work surface.

Use the procedure which we have outlined to unsolder the remaining connections and to remove resistor R_1.

Step 5: To clean parts so they will be ready for reuse.

Whenever you remove parts, clean the leads, lugs, and terminals so that you can use the parts again and connect other parts to the same lugs and terminals.

To practice this technique, first use your longnose pliers to straighten the resistor leads. Then, wipe any excess solder from the tip of your iron with a piece of cloth, and place the iron on the holder so that you can get to the tip easily. In one hand, hold a piece of cloth so that there are several thicknesses between your thumb and forefinger. With your longnose pliers in your other hand, grasp a resistor lead close to the body of the resistor. Hold the end of the lead against the tip of the iron until the solder on the lead melts, and quickly pull the hot lead through the cloth, as shown in Fig. 1-7. This will remove all excess solder and leave the lead surface clean and bright. Do this on all resistor leads that have been used in this experiment.

There are several methods of removing the solder from terminal and solder lugs. Probably the easiest and most efficient method to use on small pieces of elec-

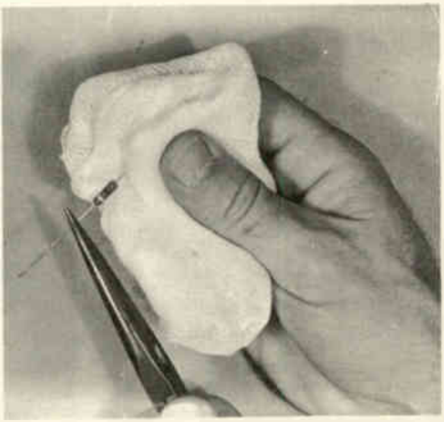

Fig. 1-7. Removing the excessive solder from a resistor lead.

tronic equipment, such as the experimental chassis you received in this kit, is to turn the chassis upside down so that the terminals are pointing downward. Apply the tip of the iron to the end of the terminal, and when the solder melts most of it will run onto the tinned surface of the iron. Wipe the excess solder from the tip and repeat the procedure on the other lugs on the terminal strip. If a thin film of solder remains in the terminal holes, wipe the excess solder from the tip of the iron and reheat the lug. Push a resistor lead through the hole to remove the solder.

In addition to removing the solder from the terminals, this method will remove any excess solder that may be on the terminal strip lugs near the chassis.

Removing excess solder from terminals, tube socket pins and other types of solder lugs in large pieces of electronic equipment that you cannot pick up and turn upside down requires a slightly different procedure. In this case, with the terminals pointing upward, wipe the excess solder from the tip of your iron and keep the cloth in one hand while you work. Touch the tip of the iron to the side of the lug; when the solder melts, some of it will run onto the tinned surface of the iron. Wipe off the solder and keep repeating the process until all surplus solder has been removed. If you have trouble getting the solder out of the hole in a lug, heat the lug and push a resistor lead through the hole. The solder that accumulates on the resistor lead can then be easily removed.

The same procedure should be used to remove solder from tube socket pins and terminal strip lugs.

Discussion: In this first experiment, you began acquiring one of the most important skills a technician must have -- the ability to make good soldered connections. You have had practice in mounting actual electronics parts and soldering them into place. You have been able to see how solder looks as it cools and hardens. You should not expect to be an expert at soldering at this time; it takes considerable practice. However, if you carefully follow the procedures discussed in this experiment, you should have no trouble making good soldered connections and you will soon become an expert with a soldering iron.

You have also had practice in the equally important task of unsoldering, and you have learned how to clean the parts so they will be ready for reuse. This is important because often the serviceman must disconnect one part in order to check another. When you disconnect a part or lead, you should carefully prepare it and the terminal from which you removed it before resoldering the lead back into position.

Instructions for Statement No. 1: In this statement, there are two sentences to be completed, each having several choices preceded by numbers. Only one of the choices in each group correctly completes a sentence in the statement. Read the first sentence, and put a circle around the number preceding the choice that completes it. Do the same for the second sentence.

Statement No. 1: In this experiment, I used

(1) temporary
(2) permanent

connections; and I found that as molten solder becomes hard, its appearance is

(1) a copper color.
(2) a shiny gray color.
(3) a dull black color.

SOLDERING TIPS

Always use a clean, hot, well-tinned iron.
Always heat the junction to be soldered enough to melt the solder.
Always use a rosin-core solder.
Always tin part leads to be soldered.
Always test all leads in each joint after solder cools.
Always keep iron on joint until the rosin has boiled out of the joint.
Never try to solder dirty or untinned leads or terminals.
Never melt solder on the iron tip and carry it to the junction.
Never use acid-core solder or pastes for radio and electronic work.
Never drip solder off iron on to joint.
Never let leads move while solder is setting.

Turn now to the enclosed Training Kit Report sheet. Fill in the top part with your name, address, student number and Kit number, 1T. Write the number 1 in the first box of the column with the heading, "Statement No." This statement is in two parts. Therefore, place the number of your choice for the first part in the second column and place the number of your choice for the second part of the statement in the third column. As an example, assume that the first statement was:

San Francisco is located in the

(1) East
(2) South
(3) West

And it is in the state of

(1) Nebraska.
(2) California.
(3) New York.

The correct answers are (3) for the first part and (2) for the second part. Therefore, you would place the Statement number in the first column, the number 3 as your answer for the first part is the second column, and the number 2 in the third column.

EXPERIMENT 2

Purpose: To learn how to wire and repair etched circuit boards.

Introductory Discussion: Etched circuit boards are often used where compactness, ease of wiring or freedom from circuit variations are important. The vast majority of radio and TV receivers use etched circuit boards. Thus, it is likely that when you repair a receiver you will have to make repairs on etched circuit boards.

Etched circuit boards are fragile. They can be damaged by rough handling or poor workmanship. The phenolic will crack or break when subjected to excessive pressure. This results in breaks in the copper foil strips and produces open circuits.

The copper foil is glued to the circuit board. When overheated, the glue will weaken and the copper foil strips will pull loose from the board. However, the board will withstand a surprisingly large amount of heat before either the phenolic or the foil becomes damaged.

In performing this experiment, you will develop skill in working on etched circuit boards. This will prepare you for work on your future experimental kits and for practical work as a technician.

Experimental Procedure: In this experiment, in addition to your chassis, soldering iron and solder, you will need the following:

1	Etched circuit board (EC24)
2	22,000-ohm resistors (RE33; red-red-orange-silver)
1	7-pin tube socket (SO76)
	Red hookup wire
	Solder

Plug in your soldering iron so that it can be heating. Inspect the tip. If the tip is not clean, wipe it with a cloth and apply a thin coating of solder. If you wipe the tip frequently, it will last longer. Also, you will seldom have to file and retin the tip.

In this experiment, you will practice soldering to the etched circuit board and you will make repairs on the copper foil. The foil near holes A through H is for practice only. Do not be concerned if you damage it in performing this experiment. However, the remainder of the board will be used in later experiments. Therefore, you should exercise reasonable care in working on the board.

Step 1: To wire a circuit on the etched circuit board.

In order to become proficient at working on circuit boards, you will have to develop a feel for soldering to the copper foil. Before mounting any parts, you will determine how much heat the foil can withstand.

Place your etched board on your worktable with the foil side up. Touch the tip of your soldering iron to the foil near hole B. Hold the soldering iron nearly straight up with the tip at the edge of the hole, as shown in Fig. 2-1. Touch the end of your solder to a point where the tip touches the foil. Allow about 1/4" of solder to melt and flow onto the foil. When the solder spreads out smoothly on the foil, remove the heat and allow the foil to cool. Do not be concerned if the hole is covered with solder.

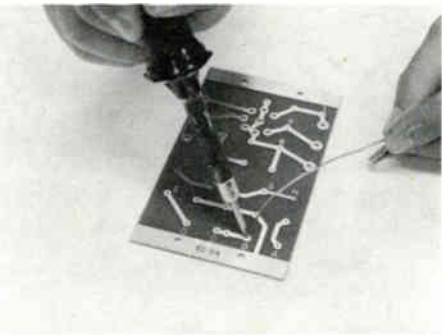

Fig. 2-1. Applying heat and solder to the foil.

In a similar manner, apply heat to the foil surrounding hole A. Touch your solder to the iron and the foil and melt about 1/4" of the solder. Continue to heat the foil until the foil begins to loosen. This may take up to 15 seconds, depending upon the wattage rating of your iron and the condition of the tip. Remove the heat from the foil.

Notice that the phenolic around the overheated foil is charred slightly. Use a knife or your longnose pliers to peel the damaged foil off the board.

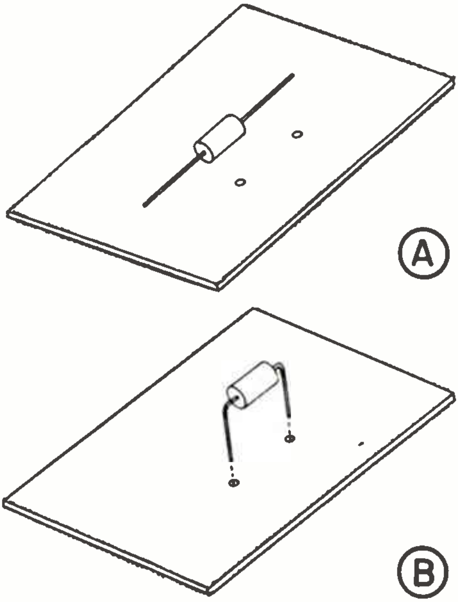

Fig. 2-2. (A) Measuring the resistor against the mounting holes; (B) resistor leads bent to correct spacing.

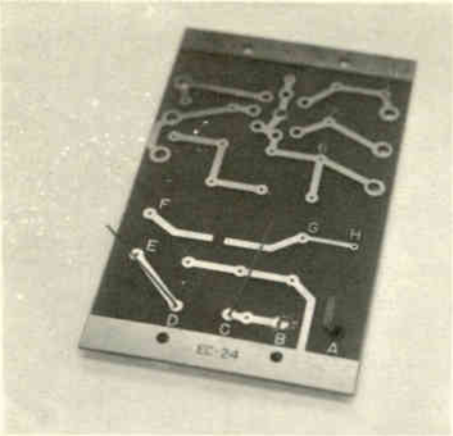

Fig. 2-3. Leads are bent outward to hold the resistor in place.

The brief experience which you have gained will give you some idea of how long it takes to make a connection and how long it takes to damage the circuit board. Next, you will mount and solder parts to the circuit board.

Install one of the 22,000-ohm resistors (red-red-orange-silver) on the phenolic side of the circuit board at holes C and D. Use the following procedure: First, "measure" the resistor against the spacing between the holes, as shown in Fig. 2-2A. In this case, the spacing between the holes is about 1/4" greater than the length of the body of the resistor, so bend both leads at right angles about 1/8" from the body of the resistor. Fig. 2-2B shows the leads ready for insertion in the holes.

Next, slip the leads through holes C and D and push the resistor down against the board. Bend the leads outward slightly, as shown in Fig. 2-3, to hold the resistor in place.

Turn the foil side of the circuit board up to solder the connections. Position the soldering iron so that the tip is in contact with both the foil and the lead. Touch the end of your solder to the point where the tip, lead and foil meet and allow about 1/4" of the solder to melt. Continue to heat the connection until the solder flows smoothly and completely surrounds the lead. Then, remove the iron and allow the connection to cool.

Finally, use your diagonal cutters to cut off the lead flush with the top of the solder connection.

Use the procedure outlined here to solder the other resistor lead to the foil.

Fig. 2-4 shows typical poorly soldered

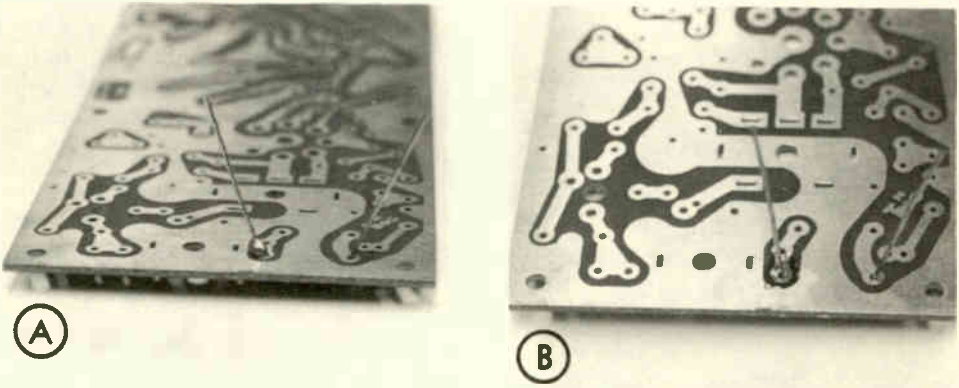

Fig. 2-4. Typical examples of poorly soldered connections.

connections. At A, too little heat was used; the solder adheres to the lead, but not to the foil. This connection could be improved by simply applying more heat. In Fig. 2-4B, too little solder was used, resulting in a minimum of strength and reliability. To improve this connection, you would apply both heat and solder.

Step 2: To demonstrate methods for removing components from etched circuit boards.

Wedge the blade of your small screwdriver between the board and the body of the resistor near hole C. (If the resistor is flat against the board, slip the screwdriver blade under the lead at hole C.) Heat the solder at hole C and lift the resistor enough to pull the lead from the hole.

Stand the circuit board on edge on your worktable. On the phenolic side of the board, grasp the lead of the resistor connected at hole D. With your forefinger and thumb pressing against the board, apply a lifting pressure to the resistor lead. Heat the connection at hole D on the foil side and when the solder melts, pull the resistor from the board and discard it.

Now you should clean the holes so that a new resistor can be installed. Heat the solder at one of the holes. While the solder is molten, insert a toothpick into the hole from the foil side of the board. Remove the soldering iron and let the foil and solder cool. When you remove the toothpick, the hole will be left clear.

Step 3: To demonstrate techniques for repairing etched circuit boards.

Cut through the foil between holes D and E to simulate a crack in the foil. You can use your pocket knife. Fig. 2-5 shows how to make a clean cut safely.

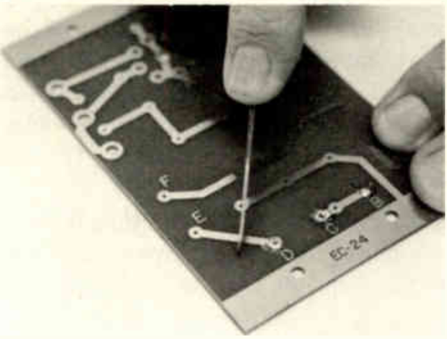

Fig. 2-5. Cutting the foil to simulate a crack in the board.

Heat the foil near the cut and melt a small amount of solder onto the foil. Use the tip of your iron to "run" the solder across the crack. The solder should adhere to the foil on both sides and bridge the narrow gap. If necessary, apply a little more solder to make a reliable repair.

A wider break, such as the one between holes F and G, requires a slightly different repair. You solder a short piece of bare wire across the break in the foil.

Remove about 2" of insulation from a length of red hookup wire. There are several ways of removing the insulation. You can peel the insulation off with a knife, or you can cut the insulation with your diagonal cutters, knife or wire strippers and simply pull off the unwanted piece. Another technique is to crush the insulation with pliers and then peel off the pieces. When stripping the insulation off wire, it is important to avoid nicking or cutting the wire because this will weaken the wire and make it break easily.

As you did previously for the narrow break, heat the foil on both sides of the break and tin the foil with solder. Lay the bare wire across the break in the foil and solder the wire to the foil. Run solder along the wire and foil for about 1/2″ on each side of the break. Using your diagonal cutters, cut off the wire beyond the solder. This should leave about 1″ of wire bridging the break in the foil.

Step 4: To install parts on the foil side of the circuit board.

Bend the leads of a 22,000-ohm resistor (red-red-orange-silver) at right angles close to the body of the resistor, and insert the leads through holes C and D from the foil side of the board. Position the resistor about 1/16″ to 1/8″ from the board. This will leave room for soldering the connections. Bend the leads outward slightly to hold the resistor in place.

Solder one lead of the resistor to the foil. Apply heat to both the foil and the lead and apply solder. Allow the solder to flow freely over the connection. Remove the heat and let the joint cool. In a similar manner, solder the other resistor lead to the foil. You will use this resistor in later experiments, so do not cut off the leads! (Normally, after installing a part from the foil side as you have just done, you would clip off the excess lead length on the other side of the board.)

Locate the 7-pin tube socket. The socket has 7 pin connections and a center locating pin. You will install the tube socket on the *foil* side of the circuit board instead of from the phenolic side. Align the pins over the holes on the circuit board. Notice that there is an open space between the pins. Install the socket on the board by pushing firmly. When the socket is properly installed, the pins project about 1/16″ on the phenolic side of the board.

With the socket in position, you are ready to solder. Since the tube socket pins on the phenolic side of the board will become quite hot as you solder them to the board, it would be a good idea to lay the board on a newspaper to protect your worktable. Hold the soldering iron so the tip is at the junction of the foil and a pin of the tube socket.

The flat surface of the soldering iron tip should be turned toward the pin. Apply solder to the foil and to the pin. Melt about 1/4″ of solder and let it flow around the pin. Solder should adhere to one half or more of the perimeter of the pin and to the foil. Remove the heat and let the solder cool. In the same manner, solder the six remaining pins of the tube socket. Do not try to solder the center locating pin. Fig. 2-6 shows the socket soldered in place.

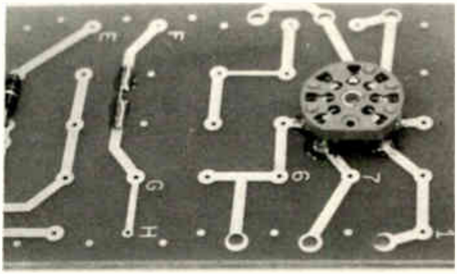

Fig. 2-6. Tube socket mounted on the etched circuit board.

Discussion: In this experiment, you have experienced working on a typical etched circuit board. You learned that you can solder to the circuit board with a moderate amount of heat. If the iron is clean and tinned, a connection can be soldered in a matter of seconds; it takes a considerable length of time to overheat and damage the circuit board.

In Step 2, you learned how to install components on the circuit board. First, you determined the lead spacing and bent the leads so you could insert the leads in the holes; then you pushed the part down against the circuit board and bent the lead to hold the part in place. Then you soldered the connection, allowed it to cool, and cut off the excess lead length, close to the soldered connection. In a good solder connection, the solder adheres to both the lead and to the foil and the solder has a smooth appearance.

You also learned how to remove parts from the etched circuit board. This is important because frequently you will have to disconnect a part to make tests and when you determine which part is bad, you will have to replace it. Before replacing a lead, clean the hole in the board. Otherwise, you may break the foil loose when you try to insert the lead.

In Step 4, you learned how to install parts on the foil side of the board. This is useful because you will sometimes find it easier to replace a part on the foil side of the board. Also, interconnecting jumper wires are sometimes connected on the foil side of the board in some pieces of equipment.

The circuit board with the tube socket attached will be used in later experiments.

Instructions for Statement No. 2: In order to answer the Report Statement for this experiment, you will have to make a few connections on your etched circuit board and trace the connections. You will need your red hookup wire.

Cut a 2" length of hookup wire and remove about 1/4" of insulation from each end. Push one end through hole E from the phenolic side of your circuit board. The holes are identified on the foil side of the board. Bend the wire and push the other end through hole F from the same side of the board. Solder both connections.

Cut a 3" length of hookup wire and remove about 1/4" insulation from each end. Push one end of the wire through hole G and push the other end through the hole identified by the number 7 from the phenolic side of the board. Solder both connections.

Trace the connections on the circuit board and answer the Report Statement. After you have completed the Report Statement, unsolder and remove the resistor and the pieces of hookup wire. Clean the holes which you used on your circuit board and clean and straighten the resistor leads.

Statement No. 2: When I traced the wiring, I found that the resistor

(1) was
(2) was not

electrically connected to the tube socket.

Using Schematic Diagrams

To service any type of electronic equipment, the technician must know how the parts are connected in the circuit.

The electrical connections in a circuit can be shown by means of a schematic diagram. In a schematic diagram, symbols are used to indicate the various parts, and the connections between the parts are shown by lines.

You have already seen many of the symbols used in schematic diagrams in your lesson texts. You have also seen some simple schematic diagrams. It is extremely important for you to become familiar with the various symbols used, and also to learn how to read schematic diagrams. You will have to use this type of diagram throughout your career, because manufacturers of electronic equipment seldom supply pictorial wiring diagrams. Even if you have a pictorial diagram, it is far easier to work from a schematic once you learn how to use it.

In your experiments, you will start first with simple schematics, and gradually work up to more complex ones. In time, you will be as much at ease reading a complex schematic diagram as you are reading your evening newspaper. You will soon learn the value of this type of diagram and see how much easier it is to use than the pictorial type.

SYMBOLS USED

Before you can read schematic diagrams, you must be able to recognize the symbols used in them. Fig. 26 shows the symbols commonly used to represent resistors, capacitors, and ground connections. Study these symbols so that you will be sure to recognize them the next time you see them. You will use them in these experiments.

Fig. 26. Symbols often used in schematics.

Connections and Crossovers. Often in a schematic diagram, one lead crosses over another. In some cases, there will be a connection between the two leads; in other cases, there will be no connection. There are three different systems in use to indicate whether or not there is a connection; the one that is used in any particular diagram depends on the preferences of the person making the diagram. You might think that this would be confusing, but it is usually very simple to see which system has been used.

Fig. 27 shows the three systems. Notice that in System 1 when there is a dot used on some crossovers and no dot used on the others, the dot indicates a connection, and the crossover without the dot indicates that there is no connection.

In System 2, a straight crossover is used to show a connection, and a loop is used to show no connection. You can easily tell when this system has been used. If you notice some crossovers with the loop, and some without the loop, you know that the straight crossovers represent connections, and the crossovers with the loop indicate no connection. Similarly, if you see some crossovers with dots and others without, you will know that System 1 has been used.

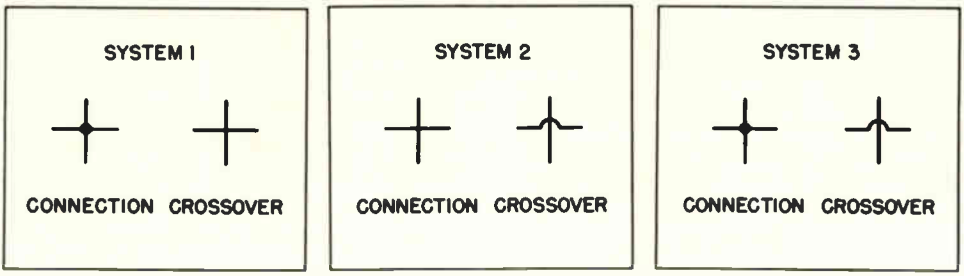

Fig. 27. Three systems used on schematics to show connections and crossovers on wires.

System 3 is a combination of the first two. We will use this system in the drawings in the experiments. The crossover with a dot indicates a connection. The crossover with a loop indicates no connection. Study these three systems - become familiar with them now, and you will have no trouble later.

Tubes. The various symbols used to represent the elements in a tube are shown in Fig. 28. The symbol for the heater is shown at A, the symbol for the cathode at B, for the grid at C, for the plate at D, and for the whole tube at E. This tube is called a triode - it has three elements plus a heater. Notice the little numbers beside each of the elements. These tell you which pin each element is connected to inside the tube. The tube we have shown is a 6C4. In this particular tube, the plate is connected to pins 5 and 1; the grid to pin 6, the cathode to pin 7, and the heater to pins 3 and 4. Nothing is connected to pin 2.

Diodes. The symbol for a semiconductor diode is shown in Fig. 29. The two elements of a diode are the cathode and the anode. The "arrow" in the symbol points toward the cathode terminal.

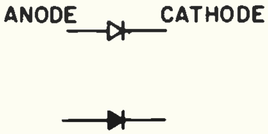

Fig. 29. Schematic symbols for a semiconductor diode.

Transistors. There are several types of transistors in wide usage. The symbols for two types are shown in Fig. 30. At A and B, we have bipolar transistors. As you can see, the only difference between the NPN and PNP symbols is the direction of the arrow. The e, b, and c labels identify the emitter, base and collector of both transistors.

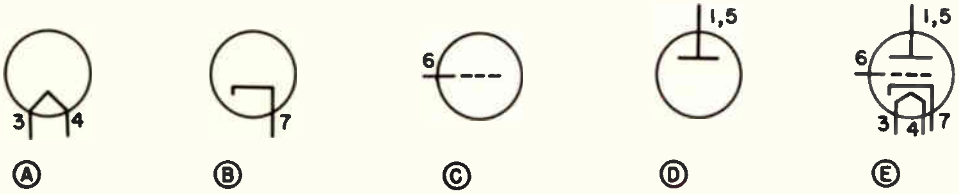

Fig. 28. Symbols used to represent the elements in a tube. Shown is tube type 6C4.

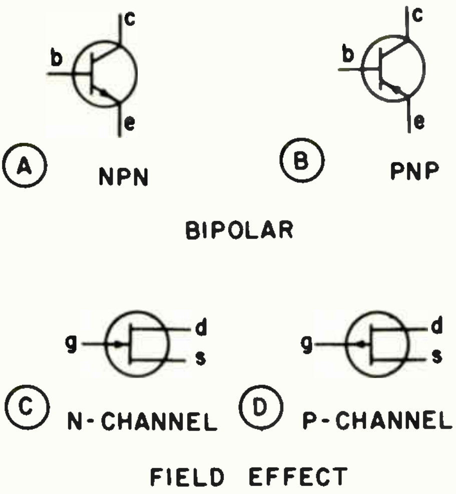

Fig. 30. Schematic symbols for transistors.

The symbols for junction field-effect transistors (FET's) are shown in Figs. 30C and 30D. You can see that the direction of the arrow is toward the junction for the N-channel and away from the junction for the P-channel FET's. In both cases, the s, g and d represent the source, gate and drain terminals. You will learn other transistor symbols later in your course.

Meters. Fig. 31 shows symbols used to represent meters on schematic diagrams. In the symbols in Fig. 31A, the letters inside the circle indicate the type of meter: V for voltmeter, μa for microammeter, ma for milliammeter, and ohm for ohmmeter. Fig. 31B shows semi-pictorial symbols that are sometimes used.

READING A SCHEMATIC

When working with schematic diagrams, you must remember that the schematic diagram shows the electrical connections, not the actual physical connections. An example of this can be seen in Fig. 32A. The schematic diagram shows the capacitor C_1 connected on the left to resistor R_1. From the junction of these two components there is a line going to the plate of the tube V_1.

In your work you will be interested only in the electrical connections. It will be unimportant to know whether the capacitor and resistor are first connected together and a lead run from the junction of the two to the tube socket, or whether the two are connected directly to the tube socket. Electrically both connections are the same.

The other side of capacitor C_1 is connected to the grid of the tube marked V_2. The schematic diagram shows C_1 connected to R_2 and then a line going from the junction over to the grid. The pictorial wiring diagram shows that both the capacitor and the resistor are connected directly to the grid terminal on the socket.

Notice on the schematic diagram that the lower end of resistor R_2 is connected to ground. In the wiring diagram, we see

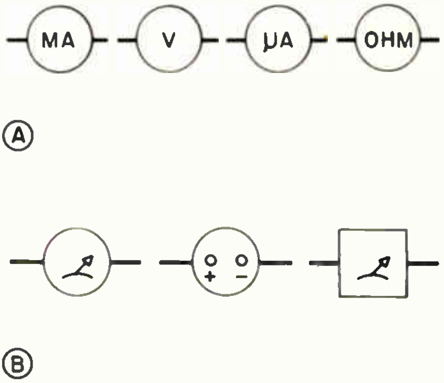

Fig. 31. Symbols used on schematics to represent meters.

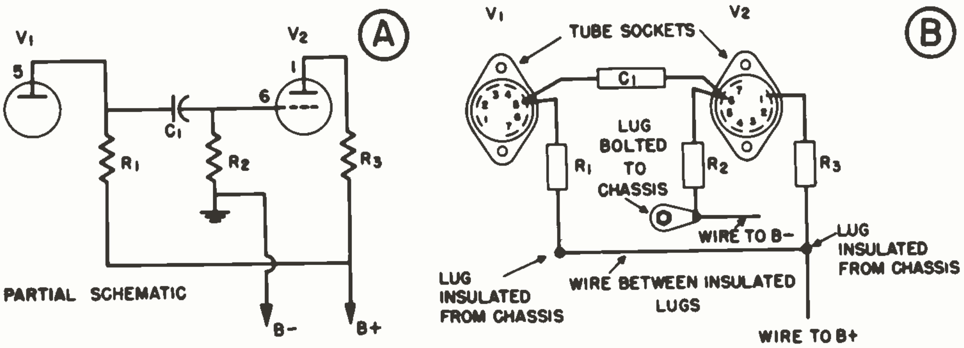

Fig. 32. (A) A schematic diagram; (B), actual wiring diagram of the same circuit.

that R_2 connects to a lug that is bolted to the chassis. Any number of ground connections can be made in this way to the chassis. When this is done, the chassis is used as part of the circuit; the chassis connects directly to B-. In some equipment the chassis is not used as part of the circuit. You will see later how to tell from a schematic diagram whether or not the chassis is part of the circuit. This information will be given to you on the schematic diagram.

Study Fig. 32 carefully. Find an electrical circuit on the schematic diagram, and then trace out the circuit on the pictorial wiring diagram. This will be valuable practical experience for you and will help you to become familiar with schematic diagrams.

EXPERIMENT 3

Purpose: To obtain practical experience in wiring from a schematic diagram.

Introductory Discussion: Fig. 3-1 is a pictorial diagram showing the actual physical location of the parts in the circuit you will wire in this experiment.

Fig. 3-2 shows the same circuit in schematic form. The circuit is that of a simple power supply. If an ac voltage were connected between terminals 1 and 2, a variable positive dc voltage would be available between terminals 17 and 15.

In a simple circuit of this type a pictorial diagram may seem easier to follow than a schematic diagram. However, a glance under the chassis of any electronic device will show how complex the pictorial diagram would become. In fact, it would be practically impossible to show how the parts are connected with a photograph or pictorial drawing. On the other hand, it is easy to show the connections with a schematic diagram.

Experimental Procedure: In this experiment, in addition to the chassis with the terminal strips and potentiometer mounted on it, you will need:

3 1000-ohm resistors (RE30; brown-black-red-silver)
1 Silicon diode (SR12)
Hookup wire
Solder

As you can see in Fig. 3-1, the diode appears similar to a resistor and is somewhat smaller. The diode is a semiconductor device which passes current in one direction only. Current can pass from cathode to anode but not from anode to

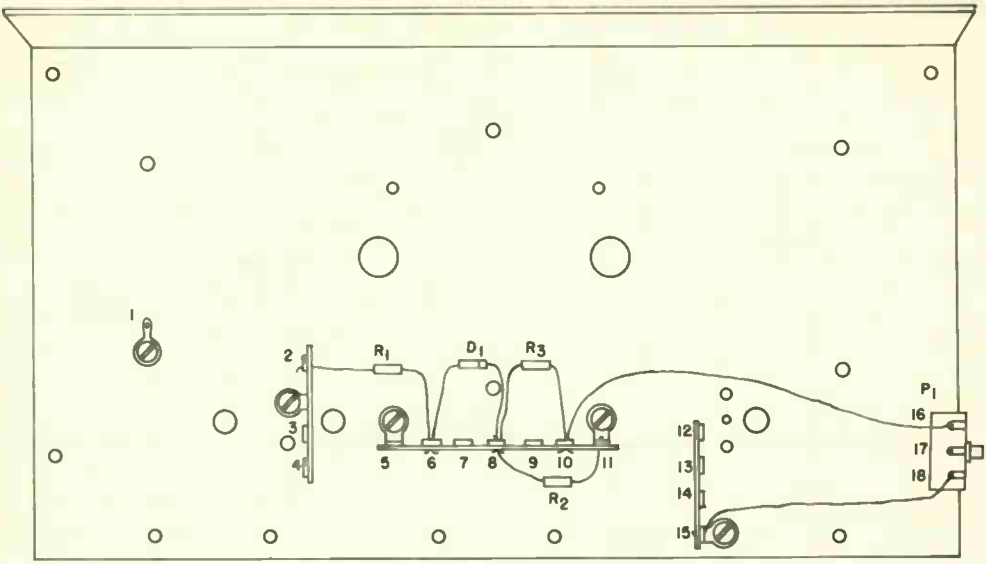

Fig. 3-1. Pictorial diagram of the circuit used in Step 1.

cathode. Thus, the diode is capable of rectifying an ac voltage.

The cathode and anode terminals of a diode are identified in one of several ways. You will usually find colored bands or a plus sign near one end of the diode, or one end of the diode may be tapered. The band, taper or other markings indicate the cathode lead of the diode as shown in Fig. 3-3.

Step 1: To determine what connections are to be made.

First, carefully study Fig. 3-2. Resistor R_1 is connected between terminal 2, which is the "input" terminal, or the terminal to which the ac voltage would be applied, and the diode D_1. The cathode lead of diode D_1 is connected to resistors R_2 and R_3. One lead of R_2 is grounded.

Resistor R_3 is connected between the junction of diode D_1 and resistor R_2 and the potentiometer, P_1. Potentiometer P_1 is connected between R_3 and ground.

Notice the ground symbols on the diagram. The metal chassis forms the common connection between the ground points.

Where possible, leads of the parts which are wired together are connected to a common terminal. For example, the cathode lead of D_1, one lead of R_2 and one lead of R_3 can all be soldered to the same terminal.

When instructed to use hookup wire, cut a length of your red wire and remove about 1/4″ of insulation from each end before making the connection. See that the insulation is about 1/16″ back from the actual solder connection. Never try to solder to the insulation.

When we instruct you to use a short length of bare wire, use your wire strippers, diagonal cutters or longnose pliers to remove the insulation from a short length of hookup wire.

In the next step, you will perform the actual wiring.

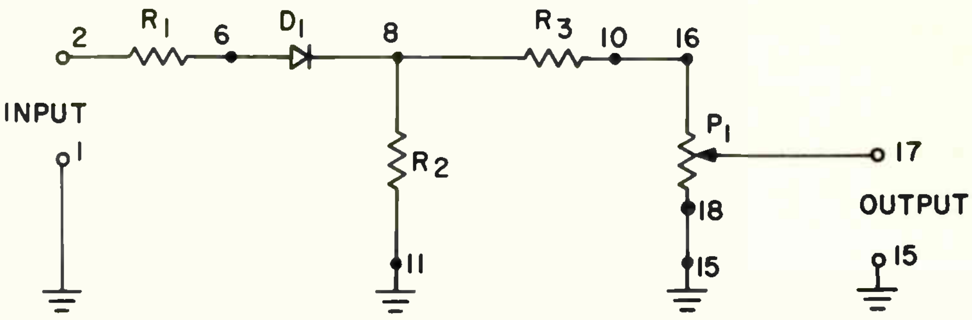

Fig. 3-2. Circuit used in Experiment 3.

Step 2: To wire the circuits from the schematic diagram.

In this step, you will mount the parts and connect wires between them to form the circuit shown in the schematic diagram in Fig. 3-2.

Connect resistor R_1 to terminals 2 and 6 as shown in Fig. 3-2. You can choose any of the three resistors since they are all the same value. Bend the leads so that the ends are spaced properly to slip through the slots in terminals 2 and 6. Slip the leads through the terminals and solder terminal 2.

Connect the diode to terminals 6 and 8 with the proper polarity. The cathode and anode leads are identified in Fig. 3-3. The cathode lead of each diode is on the right. Connect the cathode lead to terminal 8 and connect the anode lead to terminal 6. Solder terminal 6.

On the schematic diagram, notice that the cathode lead of the diode and one lead of resistor R_2 are connected together. Also, R_2 is connected from the junction with the diode lead to ground. Therefore, connect R_2 between terminals 8 and 11 as shown in Fig. 3-1. Solder terminal 11.

Next connect resistor R_3. On the schematic, this resistor is connected between the junction of diode D_1 and resistor R_2 and terminal 16 of the potentiometer. For convenience, we connect the resistor between terminals 8 and 10 and use hookup wire to complete the connection.

Install the resistor and solder terminal 8. Connect a length of hookup wire from

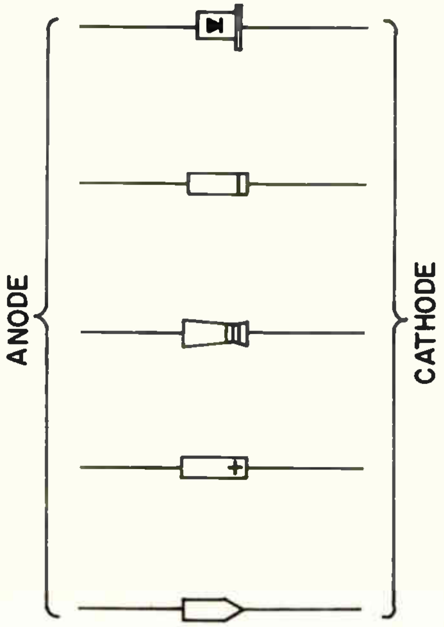

Fig. 3-3. Methods used to identify the leads of semiconductor diodes.

terminal 10 to terminal 16 and solder both connections.

The potentiometer is connected between resistor R_3 and ground. Thus, we must ground terminal 18. Again, we choose a convenient grounded terminal, which is terminal 15. Connect a length of hookup wire from terminal 18 to terminal 15 to complete the wiring. The center terminal of the potentiometer, terminal 17, is the "output" terminal.

This completes your wiring. You should have made all of the connections shown in Fig. 3-1. To make certain, check your wiring as follows:

1. There should be a resistor, R_1, between terminals 2 and 6.
2. Diode D_1 should be connected between terminals 6 and 8, with the cathode lead to terminal 8.
3. Resistor R_2 should be connected between terminals 8 and 11.
4. Resistor R_3 should be connected between terminals 8 and 10.
5. There should be hookup wire from terminal 10 to terminal 16 on the potentiometer.
6. There should be a length of hookup wire from terminal 18 on the potentiometer to terminal 15.

You should make a habit of checking your connections in this way each time you finish wiring a circuit. By checking your work, you may find and correct errors that could be serious or difficult to find later. When you check your work, pay particular attention to the soldered connections. Be sure that all connections are soldered properly. If not, resolder them.

When you are satisfied with your work, unsolder all of the connections and remove the parts. Straighten the resistor and diode leads and remove the excess solder from all terminals. Use the techniques you learned in Experiment 1.

Remove the 1000-ohm potentiometer from the mounting bracket and carefully clean the terminals. Remove the potentiometer mounting bracket and put it with the potentiometer. You will use these in a later Training Kit.

Discussion: In this experiment, we have taken you step-by-step through the wiring of a circuit from a schematic diagram. You have checked your work by comparing the actual parts layout with a list of the connections and with a pictorial diagram. This layout is not the only one that could be made from the schematic of Fig. 3-1. The same electrical circuit could have been made with the leads routed along different paths.

You should practice drawing schematic diagrams because such practice will help you to become more familiar with schematic symbols and will aid you later in tracing circuits. You need not start with elaborate diagrams; simple circuits like those shown in this experiment will be satisfactory.

The schematic diagram shows electrical connections only. Therefore, additional information is needed in order to wire more complex circuits. Experienced technicians usually sketch a layout before wiring. However, once a circuit is wired, it is easy to trace the circuit by following the schematic diagram.

Instructions for Statement No. 3: This statement is a test of your ability to relate a physical parts layout to a schematic diagram of that layout. Fig. 3-4 shows a circuit wired on your experimental chassis using resistors, a diode and a potentiometer.

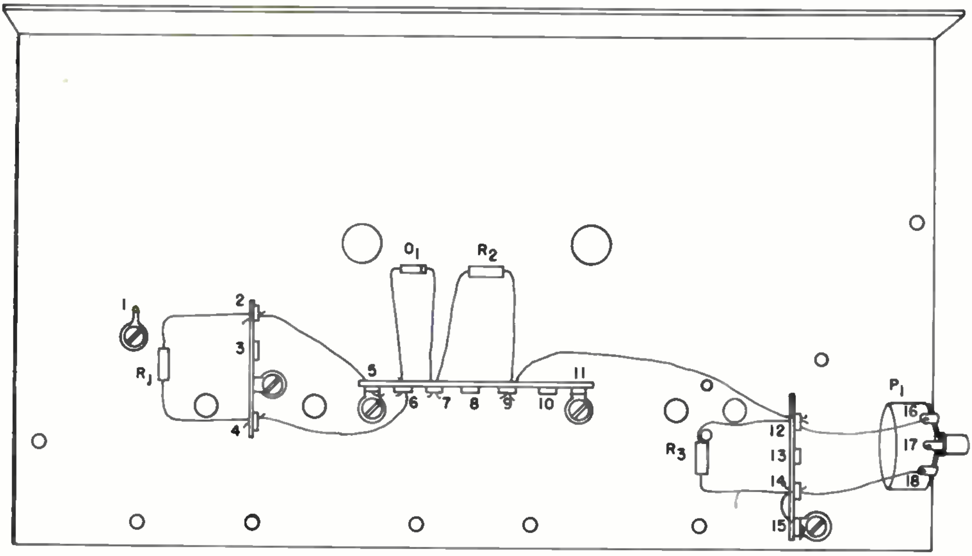

Fig. 3-4. Pictorial diagram of the circuit shown in Statement 3.

Study this circuit carefully and compare the arrangement with the four schematics in Fig. 3-5. When you are certain you have the schematic which corresponds to the circuit of Fig. 3-4, complete the statement here and on your Report Sheet.

Statement No. 3: The schematic diagram of the circuit in Fig. 3-4 is Fig. 3-5:

[✓ *(1) A*]
(2) B
(3) C
(4) D

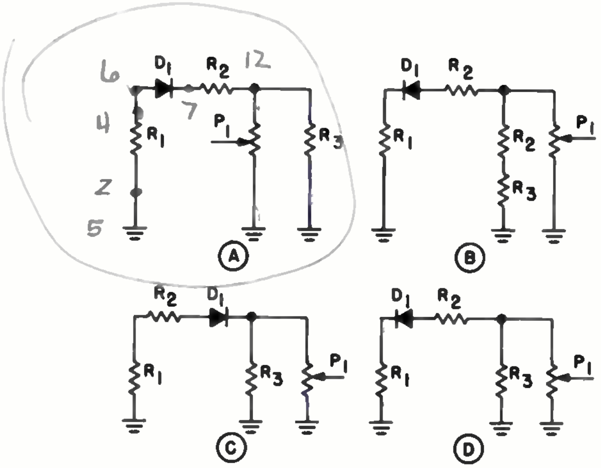

Fig. 3-5. Schematics for use with Statement No. 3.

IDENTIFYING RESISTORS

As you go ahead with your experiments, and when you work on your own, you will need to be able to identify the value of resistors.

Although the value is stamped on some resistors, on most 1/2-watt, 1-watt, and 2-watt resistors the value is indicated by means of colored bands on the resistor. You should learn to read this color code so that you can identify resistors quickly.

The colored bands on the resistor usually are nearer to one end than the other. Thus, to read the color code, turn the resistor so that the colored bands are toward the left end of the resistor as shown in Fig. 33.

Each color represents a number. These are given in Fig. 33. The first band, labeled A, gives the first figure in the value; the second band, labeled B, gives the second figure in the value; the third band, labeled C, gives the number of zeros after the second figure in the value, and the fourth band gives the tolerance of the resistor (silver for ±10% tolerance, gold for ±5% tolerance). If the tolerance is ±10%, it means that the actual value of the resistor may be as much as 10% higher or lower than the value indicated. If it is ±5%, the actual value may be up to 5% higher or lower than the value indicated.

COLOR C GIVES THE NUMBER OF CIPHERS FOLLOWING THE FIRST TWO FIGURES.

COLOR D GIVES THE TOLERANCE

GOLD BAND INDICATES ±5%
SILVER BAND INDICATES ±10%
NO BAND INDICATES ±20%

Fig. 33. Standard resistor color code.

Some resistors may have a fifth color band. This band will follow the tolerance band (to the right) and is used to indicate a military reliability level. The fifth band will be Brown, Red, Orange or Yellow which indicate increasing percent of reliability. In your work you can simply ignore the fifth band.

To find the value, you need to look only at the first three bands. For example, suppose you have a resistor color-coded red, red, and black. Referring to the chart, you see that red represents 2. Therefore, the first two figures in the value are both 2. As we have said, the third band indicates the number of zeros in the value. Since black represents 0, when the third band is black, there are no zeros in the value. So the value of the resistor is 22 ohms.

If the resistor had been color-coded red, red, and brown, the first two figures would again be 2. Brown represents 1, so there would be one zero, and the value would be 220 ohms. Red, red, and red would indicate a value of 2200 ohms (often written 2.2K ohms, where the K stands for 1000); red-red-orange, a value of 22,000 ohms (often written 22K-ohms); red-red-yellow, a value of 220,000 ohms (or 220K ohms or .22 meg; a megohm is 1,000,000 ohms); red-red-green, a value of 2,200,000 ohms (or 2.2 megohms); and red-red-blue, a value of 22,000,000 ohms (or 22 megohms).

Look over the resistors you have received, and practice reading the color codes on them. You can check the values by referring to the parts list given in Fig. 1. In the next experiment you will have some practice in picking out resistors of different values.

EXPERIMENT 4

Purpose: To construct a circuit using only a schematic diagram for guidance.

Introductory Discussion: If you read construction articles in any of the radio-TV-electronics magazines, you will see that step-by-step wiring instructions are rarely given; you work from a schematic diagram. Thus, if you wanted to build some of this equipment, you would have to work out the placement of the parts and other details for yourself.

We want you to become so familiar with schematic diagrams that you can look at one and picture the arrangement of the parts. That is not hard if you start with simple circuits like those you have built so far, and gradually work up to more complex circuits. The manufacturer's servicing information on any equipment usually has a complete schematic diagram and the parts values. If you are servicing the equipment, you will have to find the defective part, determine its value, and make the replacement.

Usually connections between parts are shown by a line that follows the shortest path between the two parts. However, this is not always true. The only sure way to find the part is to trace the circuit. Often it is more convenient to run a lead over a somewhat longer path to avoid crowding a section of the diagram. An example of this is given in Fig. 4-1. We could have drawn a horizontal line directly from pin 4 of V_1 to pin 3 of V_2 to show that they are connected. However, the line would have had to cross a number of other lines, thus crowding the diagram, and perhaps causing some confusion. Drawing the line as in Fig. 4-1 avoids confusion.

Tracing circuits on a schematic diagram is in many ways like tracing a road between your home and another city on a

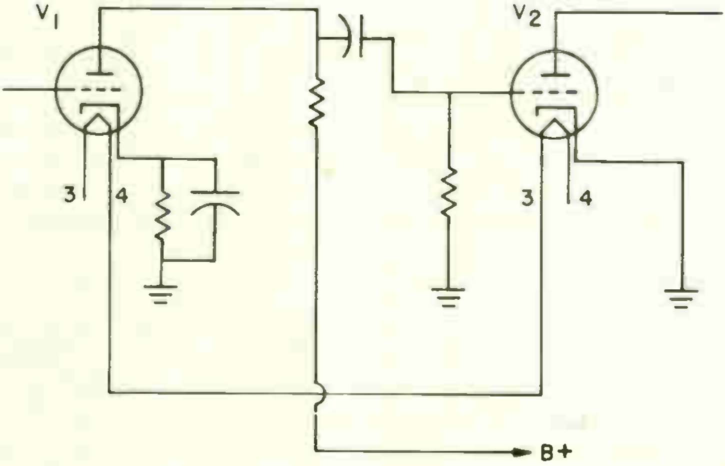

Fig. 4-1. Typical schematic diagram showing a two-stage tube circuit.

road map. You will seldom find a road that goes in a straight line from one place to another. Instead, the road will turn time and time again; you may have to go a certain distance on one road and then turn onto another. So it is in tracing the circuit on a schematic diagram. You start at one point in the circuit and trace toward another point. You may find a direct circuit between the two points, but more often you will find the circuits are connected by something other than a direct connection. In addition, you may find that to get from one point to the other you have to trace the circuit to some intermediate point, and then from that point on through an additional circuit to the point that you are interested in reaching.

Frequently in service work you will have to trace out the actual wiring in a receiver and compare the wiring with a schematic diagram. We cannot stress too strongly how important it is for you to learn to use this type of diagram. This is why we will concentrate on learning how to use diagrams.

When you work from a schematic diagram in the experiments, there may be several ways in which the various leads can be run. In general, try to use the shortest possible route. When we work on the more complicated circuits, we will give detailed instructions on exactly where to place each important lead; but during these early experiments, we will leave you on your own as much as possible to give you all the practical experience we can.

When you build equipment from a schematic diagram, you should carefully check each circuit you wire to make sure it is wired correctly. Also make sure that each connection is properly soldered. Even if you learn to work from a schematic, the equipment you build will not work properly unless all connections are properly soldered. Many people waste a great deal of time because of careless wiring and poorly soldered connections, which could easily have been spotted if a little extra time had been taken to check the work. Start right now by checking each circuit you wire against the schematic diagram and by checking each soldered connection you make. These are good habits, and the sooner you acquire them the better.

Experimental Procedure: For this experiment, in addition to the chassis with the solder lug and terminal strips, you will need the following:

1 1000-ohm resistor
1 22,000-ohm resistor
1 100,000-ohm resistor
2 1/4" X 4-40 screws
2 4-40 hex nuts
1 Etched circuit board (EC24)
Hookup wire
Solder

Use the resistor color code chart shown in Fig. 33 to help identify the three resistors used in this experiment.

Check your experimental chassis and make certain that the terminals are clean and all excess solder has been removed. At the same time, check the tip of your soldering iron to be sure it is clean and well-tinned.

For this experiment, you will use the tube socket on your circuit board and the terminals on your chassis. You will mount the circuit board along the edge of the chassis and connect "jumper" wires from the tube socket terminals in the copper foil to the 7-lug terminal strip on the chassis.

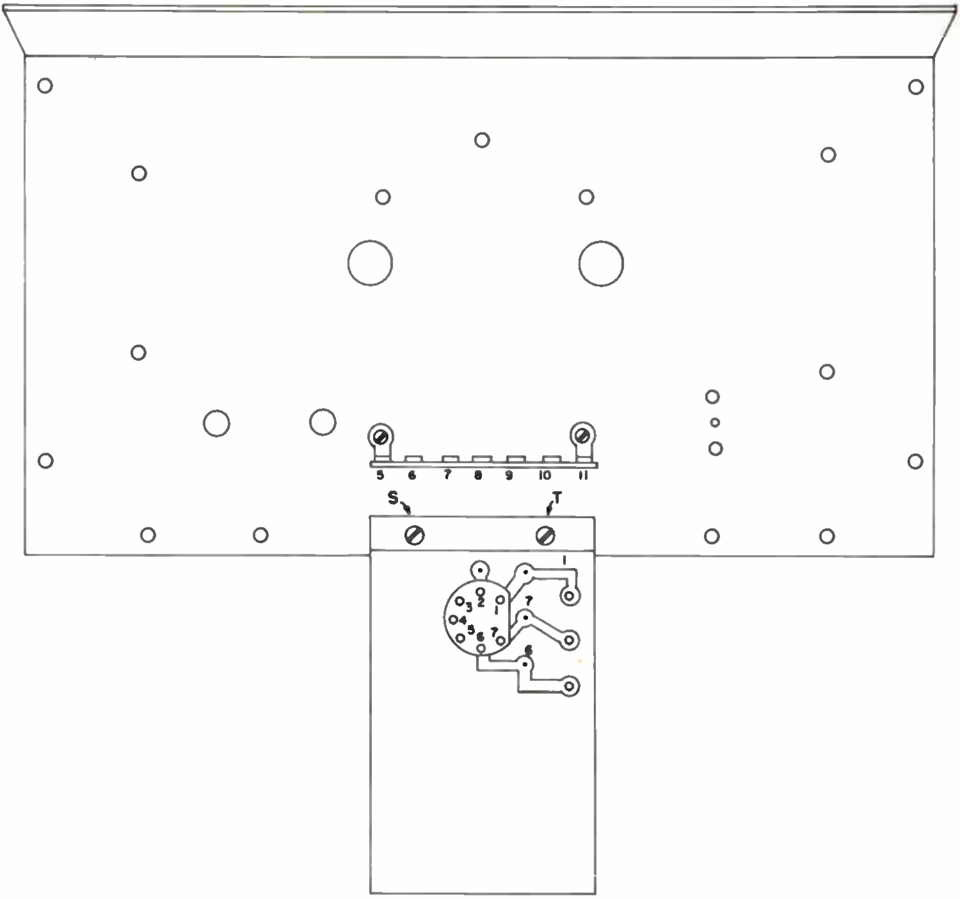

Fig. 4-2. Mounting the circuit board on the experimental chassis.

Mount the circuit board over holes S and T in the chassis (the holes are identified in Fig. 11 and Fig. 4-2). Position the circuit board over the edge of the chassis as shown in Fig. 4-2. Note that the tube socket is toward the chassis and the foil side of the board is turned upward. Attach the board with 1/4" X 4-40 screws through the mounting holes in the circuit board and chassis. Attach two 4-40 nuts and tighten.

The pins on the tube socket or tube are numbered from the blank space in a counterclockwise direction when viewed from the top. As shown in Fig. 4-3, pin 1 is at the right of the blank space, pin 2 is next, and so on. Pin 7 is to the left of the blank space. The pin in the center of the socket is not numbered. We will be primarily interested in pins 1, 6, and 7 of the socket. Connections to these holes are labeled on the foil side of EC24.

Refer to Fig. 4-4 as you make the following connections. Connect a short length of hookup wire from the hole in the foil which connects to pin 1 of the tube socket to terminal 8 on the 7-lug terminal strip. Remove about 1/4" insula-

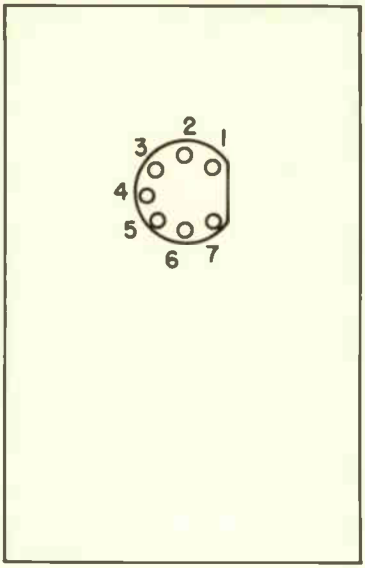

Fig. 4-3. Identifying the tube socket pins on the etched circuit board.

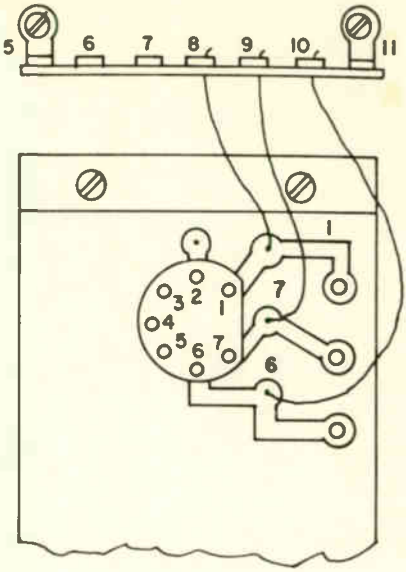

Fig. 4-4. Wiring connecting the tube socket to the terminal strip.

tion from each end of the wire. Slip the end of the wire through the hole in the circuit board from the foil side and solder to the foil.

Similarly, connect a short length of hookup wire from the hole in the foil at pin 7 to terminal 9.

In the same manner, connect a short length of hookup wire from the hole in the foil at pin 6 to terminal 10.

We often refer to a terminal or a conductor connected to a tube socket pin by the tube pin number or even by the element of the tube connected to that pin when a tube is inserted in the socket. Thus, the terminals on the chassis may be identified by the tube socket pin numbers, or as the grid, cathode and plate terminal of the 6C4 tube.

When working from schematic diagrams, remember that ground symbols indicate connections to the common return point (the chassis in this case) and that these connections can be made to anything that is connected to the chassis electrically. As your chassis is presently set up, you can use terminals 1, 5, 11, and 15 as ground connections.

If you are connecting two or more leads to a given point, do not solder until all leads are in position.

In this experiment, you are to wire a circuit directly from a schematic diagram. The diagram you are to use is shown in Fig. 4-5. The tube socket pins are indicated by the open circles nearest the tube symbol. All of the other terminals, which are shown by black dots, represent terminals on the terminal strip.

Before mounting a part, make a trial fit to determine where the part should be located. Sometimes this technique is used by experienced technicians in order to get a neat layout and prevent undue crowding of parts.

Step 1: To mount resistor R_1.

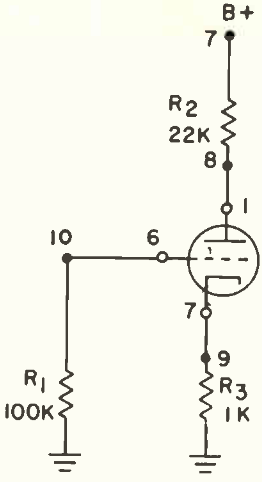

Fig. 4-5. Circuit used in Step 1.

First, find R_1 on the schematic diagram in Fig. 4-5. Notice that it is a 100,000-ohm resistor. Select a 100,000-ohm resistor from among the parts you have collected for this experiment.

From the schematic, you can see that R_1 is connected between pin 6 of the tube socket and ground. Because these connections will be made on the terminal strip, the connection will be made to terminal 10 and a ground terminal.

As stated earlier, there are four places where you can make your ground connection. The solder lug, terminal 1, and the mounting feet of the terminal strips, terminals 5, 11 and 15, are bolted directly to the chassis. Thus, they make electrical contact with the chassis and can be used for ground connections.

Connect one end of the 100,000-ohm resistor to terminal 10 and connect the other end to whichever ground point you find to be most convenient. Bend the resistor leads so that they do not touch the chassis. Also, they should not make contact with any other terminals. Solder terminal 10. Do not solder the ground terminal because you may want to make other connections to it.

Step 2: To mount resistor R_2.

Find resistor R_2 on the schematic diagram. You will see that it is a 22,000-ohm resistor (indicated by 22K on the diagram). You can also see that R_2 is connected from pin 1 of the tube socket, which is the same as terminal 8 on the terminal strip to terminal 7. Terminal 7 is marked "B+" on the schematic. Connect one lead of the 22,000-ohm resistor and solder these connections.

Step 3: To mount resistor R_3.

R_3 is a 1000-ohm resistor. On the schematic, R_3 is between pin 7 of the tube socket and ground.

Install the resistor between terminal 9 on the terminal strip (which is electrically the same as pin 7) and ground. You will have to choose a ground terminal. There are no more connections to be made. Thus, you can solder all connections which you have not yet soldered.

Step 4: To check your work.

After all wiring is in place, check your work against the schematic diagram. This check should now show:

1. A 100,000-ohm resistor between tube socket pin 6 and a ground terminal.
2. A 22,000-ohm resistor between tube socket pin 1 and terminal 7.
3. A 1000-ohm resistor between pin 7 of the tube socket and ground.

Discussion: In this experiment, you have gained experience in working from a schematic diagram. You have practiced reading resistor color codes, and you have again practiced making solder connections. You will use each of these skills every time you work on any electronic equipment.

After you have looked over your work to be sure that it is electrically equivalent to the circuit shown in Fig. 4-5, turn to the back of this manual. On page 77 you will see Fig. 4-6. This shows two ways in which you might have arranged your parts. However, these are not the only possible ways to mount the parts. As long as your arrangement is electrically the same as Fig. 4-5, you have done the experiment correctly.

Instructions For Statement No. 4: After carefully checking your work, answer the statement here and on your Report Sheet. Then unsolder the connections and remove the resistors. Disconnect the three jumper wires from the terminal strip and from the circuit board. Remove the circuit board from the chassis, clean the holes, and put the board aside. Finally, clean the resistor leads and terminals so that they will be ready for use in later experiments.

Statement No. 4: When I wired the circuit used in this experiment, I connected the 22,000-ohm resistor to the:

[✓ *(1) plate*]
(2) cathode
(3) grid

terminal of the tube socket.

Learning to Use A Meter

An electric current is invisible, odorless and tasteless. In other words, we cannot tell that a wire is carrying current unless we use some special means of detecting it.

Although a bell or light bulb can be used to show the presence of current, neither of these devices will indicate how much current is flowing. The current in the circuit must be at a certain level before the bell will ring or the bulb will light. For example, the light bulb will light to full brilliance when its greatest current is flowing through it. As the current is decreased, the light will grow dimmer. Finally, it will reach a point where the light will give no visual indication of current, even though current may still be present in the circuit. Something is needed that will show not only whether there is current flowing, but also how much current is flowing. A meter will do both of these jobs.

MEASURING CURRENT

A meter that is used to measure current is known as an ammeter. An ammeter indicates current in amperes. The ampere, however, is much too large a unit for most measurements in electronics, so we use a meter that indicates either milliamperes (ma) or microamperes (μa). A milliampere equals one-thousandth of an ampere and a microampere equals one-millionth of an ampere. Such meters are called milliammeters and microammeters. They are made the same and operate in the same manner as an ammeter. The only difference is that the milliammeter and microammeter are much more sensitive and will respond to much smaller currents.

The meter you will use in your experiments has a range of 0 to 200 microamperes. This means that a full scale reading on the meter indicates that 200 microamperes are flowing through the meter. When the meter pointer is at half scale, half of 200 microamperes or 100 microamperes are flowing through the meter. When the meter pointer is at 1/10th scale, 20 microamperes are flowing through the meter.

PREPARING THE METER

The meter supplied in this kit is an extremely delicate instrument. It contains a jewel movement similar to that of a fine watch. Therefore, the meter must be handled with care at all times. We cannot replace any meter that has been damaged through careless handling or improper usage. If you follow carefully the instructions given, you will have no trouble with the meter. However, if you fail to follow the instructions, you may damage your meter and have to replace it.

The meter case is plastic. It can easily be scratched with a screwdriver or similar tool, or by scraping it across your workbench. Also, the plastic can be permanently damaged by heat. Be sure that you do not accidentally touch the soldering iron to the meter case.

While you are performing these experiments, the meter will be left in its box. You will connect wires to the meter terminals so that you will have easy access to the meter.

You will need the following:

- 2 Large solder lugs (LU7)
- 1 Meter (ME21)
- 2 Diodes (SR12)
- Hookup wire
- Solder

Your meter is supplied with mounting hardware and two large nuts for each terminal. These parts are in an envelope in the meter box. Save all of the hardware as you will have need for it later.

To prepare the meter, place a soft pad or towel on your workbench. Next, remove the meter from the box and place the meter carefully on the pad or towel, face down, and with the top of the meter away from you.

Remove the wire from the meter terminals. The terminals were shorted together to prevent damage to the meter during shipment. If the meter is shaken or dropped, the physical movement will cause the meter pointer to move. A voltage is generated in the coil attached to the pointer. The short circuit across the meter terminals permits the current to flow through the terminals and back through the coil. This cancels the tendency of the coil to move and protects the meter from violent pointer swing.

You will now attach the large solder lugs to the meter terminals. First, attach a large nut to one of the terminals and run it all the way down. Then slip a large solder lug over the terminal and secure it with another nut. Position the solder lug so it points toward the bottom of the meter case and tighten the nut. Hold the lower nut with a small wrench or pliers and tighten the outer nut. Do not allow the terminal to turn, since this could damage the connection inside the meter case.

In a similar manner, attach two nuts and a solder lug to the other meter terminal and tighten the nuts.

Now you will identify the lugs on the back of the meter. The one on the left as you face the back of the meter is the positive, or plus terminal of the meter; the one on the right is the negative or minus terminal. The terminals may be further identified by plus or minus signs stamped on the plastic or on the ends of the screws or "POS" and "NEG" printed near the terminals.

Examine the two diodes supplied with this kit. Refer to Fig. 3-3 to help you identify the cathode leads.

Connect the lead at the cathode end of one diode to the positive terminal of the meter. This is diode D_1 in Fig. 34. Slip the end of the lead through the lug attached to the terminal. Do not solder at this time. Slip the anode lead of D_1 through the negative terminal lug.

Connect the second diode, D_2, to the meter terminals also, but with the opposite polarity. Slip the cathode lead through the negative terminal lug and the anode lead through the positive terminal lug. Do not solder at this time.

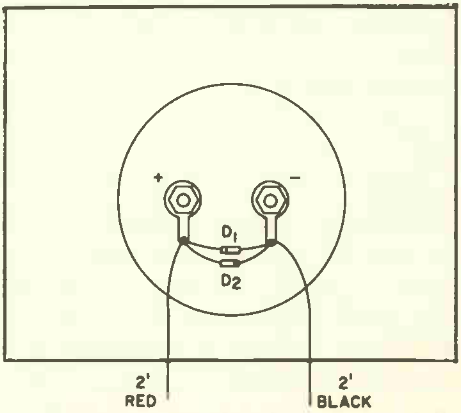

Fig. 34. Connections to the meter movement.

Prepare 2-foot lengths of red and black hookup wire. Remove about 1/4" of insulation from each end of each wire.

Connect the 2-foot length of red hookup wire to the positive meter terminal lug. Check to see that all three leads are through the hole in the terminal; then solder the connection. Be sure all three leads are soldered. After the solder cools, test the connection.

In a similar manner, connect and solder the length of black hookup wire to the negative meter terminal lug. Compare your wiring with Fig. 34 to see that you have done the work correctly.

Next, you will connect the meter leads to terminals on your chassis. Refer to Fig. 35. Connect the red lead from the meter to terminal 14. Connect the black lead from the meter to terminal 12.

Connect a 6" length of hookup wire from terminal 14 to terminal 10. Solder terminal 14.

In order to simplify the instructions, we will call terminal 10 the "positive meter terminal" and we will call terminal 12 the "negative meter terminal."

Put the meter in its box, face up. Do not attempt to make any measurements with your meter until instructed to do so.

The diodes, which you connected to the meter, are used to help protect the meter movement from excessive current. When a voltage of about .6 volt is present, one of the diodes will conduct and provide a low resistance path around the meter movement. We use two diodes connected with the opposite polarities to provide protection regardless of the polarity of the excessive voltage.

In normal operation, the voltage across the meter terminals will not exceed .15 volt. Therefore, the diodes have no significant effect on the operation of the meter unless excessive voltage is applied.

SETTING THE METER POINTER TO ZERO

The meter pointer should rest directly

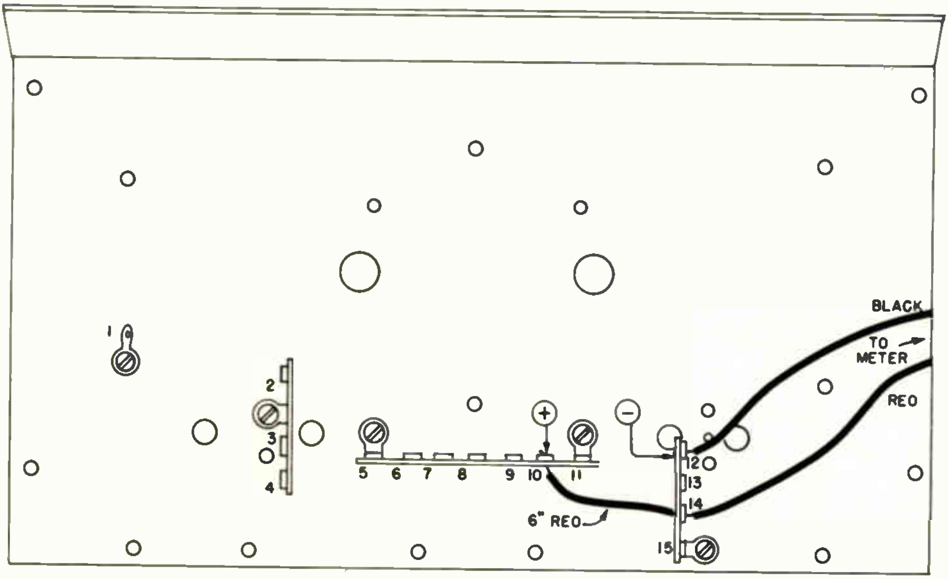

Fig. 35. The meter leads connected to terminals 12 and 14 with a jumper from 10 to 14.

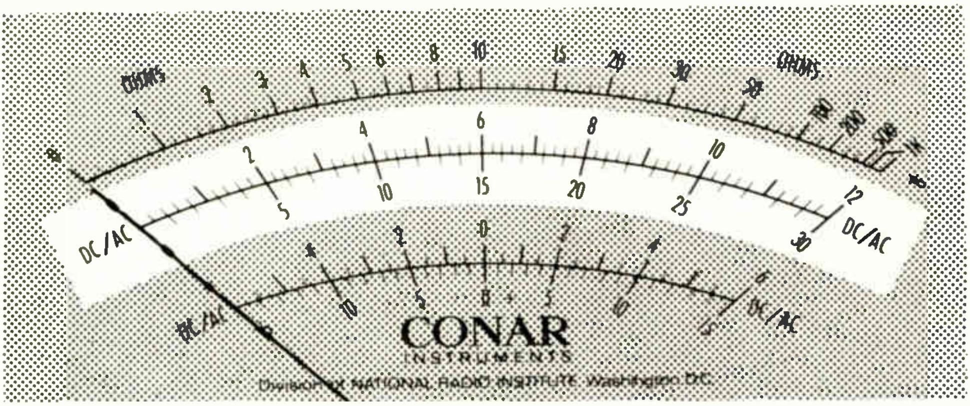

Fig. 36. The 0-12 and 0-30 volt scales on your meter.

over zero as shown in Fig. 36 when the meter is not in use. To set the pointer to zero, use a screwdriver blade that fits in the plastic screw slot on the meter face. Too small or too large a blade can damage the screw. Turn this screw, and notice that the meter pointer can be placed to the right or to the left of zero. Leave the screw adjusted so the meter pointer is over the zero mark. It is unlikely that you will have to make this adjustment again.

READING THE METER

The first time you look at the face of the meter you received in this kit, you may think that the meter is complicated and that it will be difficult to read. As a matter of fact, it is no more difficult to read a meter than it is to tell time on a clock. Of course, a meter may be something new to you, and it will take some practice to learn how to read it quickly. However, it will not be long before you will be able to read it at a glance.

At this time we will concentrate on the 0 to 12 and 0 to 30 volt scales. As you will see, the two scales may often be used together to help you obtain precise readings. These two scales are shown in white in Fig. 36. The 0 to 12 volt scale is the upper scale and has the numbers 0, 2, 4, 6, 8, 10 and 12 printed in black. The 0 to 30 volt scale is the lower scale and has the

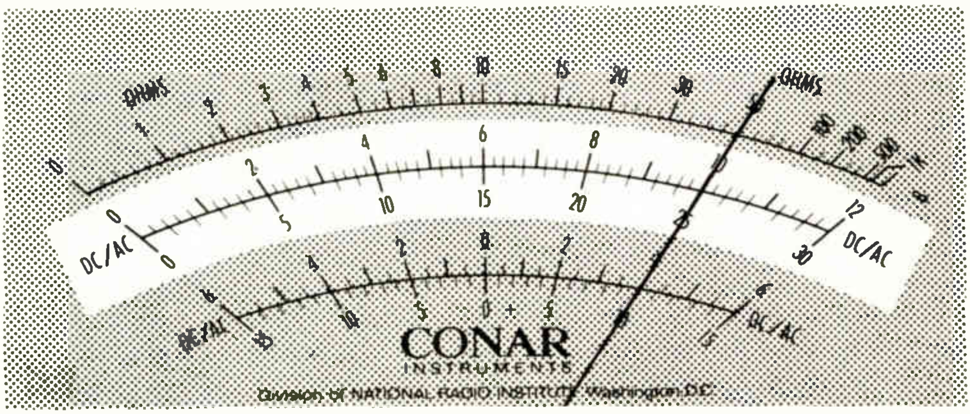

Fig. 37. A meter reading of 25 or 10.

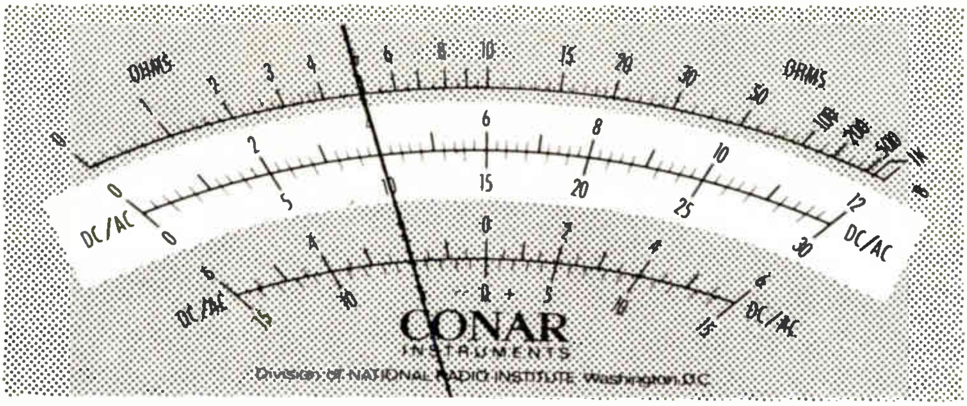

Fig. 38. A meter reading of 10 or 4.

numbers 0, 5, 10, 15, 20, 25 and 30 printed in black. Notice that the 0 to 12 volt scale has several short marks as well as some longer unnumbered marks. The 0 to 30 volt scale has four short unnumbered marks between each number.

Now look at the meter shown in Fig. 37. In this case the pointer is indicating 10 on the 0 to 12 volt scale and shows 25 on the 0 to 30 volt scale. If the pointer is as shown in Fig. 38, the reading would be 10 on the 0 to 30 volt scale and 4 on the 0 to 12 volt scale. These readings are quite easy to determine, as you can see, but what happens if the pointer is somewhere between the numbers on the scale?

Look at the scale shown in Fig. 39. Now the pointer is over one of the short marks of the 0 to 12 volt scale, but is between two short marks on the 0 to 30 volt scale! To read this value, note that on the 0 to 12 volt scale there are nine marks (or ten spaces) between 6 and 8; eight short marks and one long mark. The long mark represents 7 volts, and each short mark represents 0.2V. The pointer in Fig. 39 is on the third short mark following the 6 volt mark. Since each short mark is 0.2V, the pointer shows a reading of 6.6 volts.

Now, what is the reading of Fig. 39 on the 0 to 30 volt scale? First, notice that

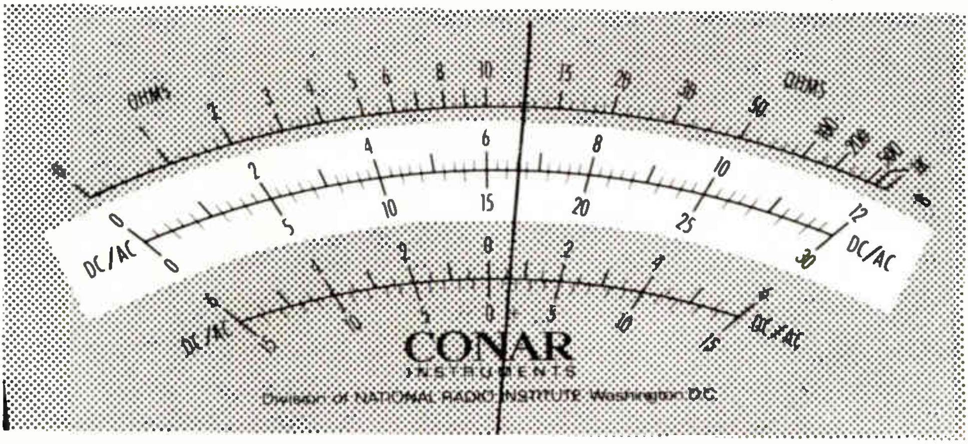

Fig. 39. Another sample meter reading.

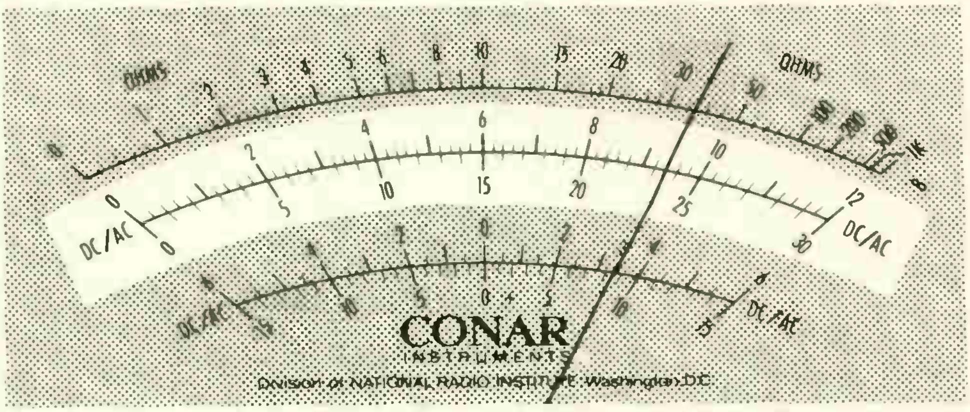

Fig. 40. Study this meter reading and see if you can tell what it is.

between 15 and 20 there are four short marks. Each mark, therefore, represents one volt. The pointer is halfway between the first and second marks following 15 so the reading is 16.5 volts. You can tell that the pointer is exactly halfway between the two marks by looking at the upper (0 to 12 volt) scale. On this scale, every other mark falls exactly halfway between the one volt marks on the 0 to 30 volt scale. This means that while the 0 to 30 volt scale is marked in one volt steps, you can determine readings to one half a volt by looking at the divisions on the 0 to 12 volt scale.

Let's look at another example. Take a look at the scale shown in Fig. 40. Using the reasoning that we applied in the previous examples, can you tell what the reading would be on the 0 to 12 and 0 to 30 volt scales? If you have trouble, go back and reread the material in the previous paragraphs. After careful study you should have no difficulty in seeing that the readings are 9.4 volts and 23.5 volts respectively on the 0 to 12 and 0 to 30 volt scales.

There is always the possibility that the pointer will not fall precisely on one of the short marks of the 0 to 12 volt scale. How are these values read? Take a look at Fig. 41. Notice here that the pointer is halfway between the second and third short marks after 4 on the 0 to 12 volt

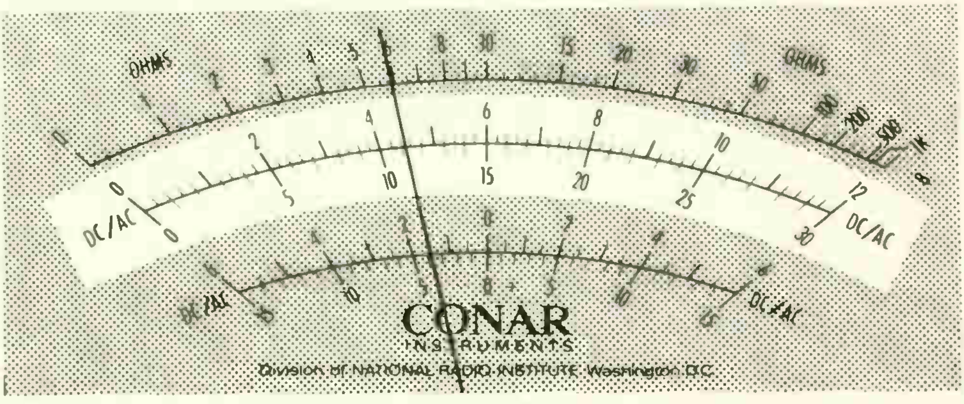

Fig. 41. Here is another meter reading for you to practice on.

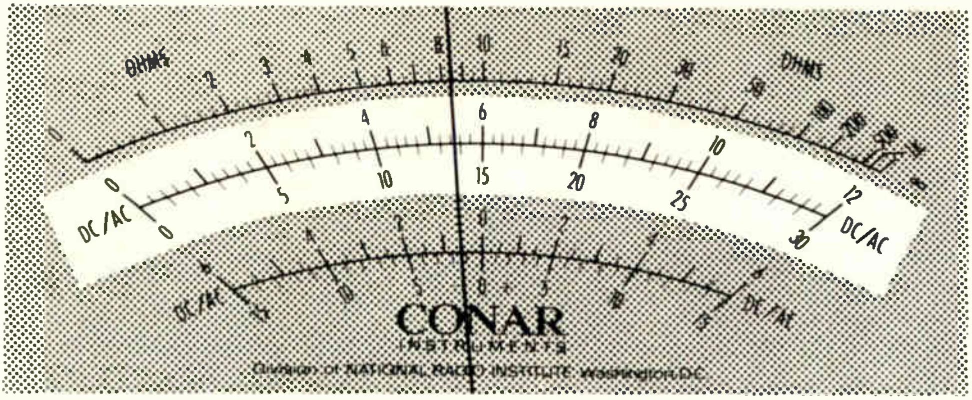

Fig. 42. What is the indication on this meter?

scale. This would be a reading of 4.5 volts. On the 0 to 30 volt scale it is just as easy. The pointer falls one fourth of the way between the first and second mark after 10, so the reading is 11.25 volts.

As a final example, try your hand at reading the two values indicated in Fig. 42. Again, the pointer does not fall on any of the scale marks of either scale. Let us see how close we can come to reading the meter by applying what we have already learned. On the 0 to 12 volt scale, the pointer is between 5 and 6. We can be more exact than that; it appears to be halfway between the second and third marks following the (unmarked) 5 volt mark. The first mark is 5.2 volts, the second mark is 5.4 volts and the third mark is 5.6 volts. Therefore the reading is between 5.4 and 5.6 volts. How much, is the question. The pointer falls about halfway between 5.4 and 5.6 volts so we would call it 5.5 volts. There is, of course, some uncertainty in this reading. For the purposes of your experiments, you would read it as 5.5 volts.

What reading does Fig. 42 represent on the 0 to 30 volt scale? Well, it is somewhere between 10 and 15 volts. Each short mark represents one volt, so the reading would be between 13 and 14 volts. Remember that the short mark on the *upper* scale (0 to 12 volts) is exactly halfway between the 13 and 14 volt marks, or in other words represents 13.5 volts. The pointer falls to the right of this mark so the reading must be between 13.5 and 14.0 volts. We would probably call this 13.75 volts; any value from 13.7 to 13.8 volts would be sufficient.

Building A Simple Series Circuit

You have already studied Ohm's Law and you know that there is a definite relationship between the voltage, current and resistance in a circuit. In Experiment 5, you will see just what happens to the current when you change either the resistance in the circuit or the voltage applied to the circuit. Before you begin Experiment 5 you will prepare the chassis by installing some parts on it. Then, when you begin Experiment 5 you will add some more parts and perform the Experiment.

In addition to your meter and chassis, you will need:

- 2 4.7K-ohm resistors (yellow-violet-red-silver)
- 1 6.8K-ohm resistor (blue-gray-red-silver)
- 1 1.5-volt flashlight cell
- Black hookup wire
- Red hookup wire
- Solder

Inspect the tip of your soldering iron. If necessary, file and retin the tip.

You will connect the three resistors to terminals 7, 8, 9 and 10 on your chassis. The chassis with the resistors in place is shown in Fig. 43. Begin by connecting one lead of a 4.7K-ohm resistor to terminal 10. (There should already be a red wire connected to terminal 10.) Temporarily solder the lead and the red wire to terminal 10. Bend the resistor leads near the body of the resistor and push the free lead through the slot in terminal 9. Connect one lead of another 4.7K-ohm resistor to terminal 9. Solder terminal 9. Connect the other lead of this resistor to terminal 8. Connect one lead of the 6.8K-ohm resistor from terminal 8 to terminal 7 as shown in Fig. 43. Solder terminal 8.

Remove 1/4" of insulation from each end of a 10" length of red hookup wire. Connect and solder one end to terminal 7. Leave the other end free.

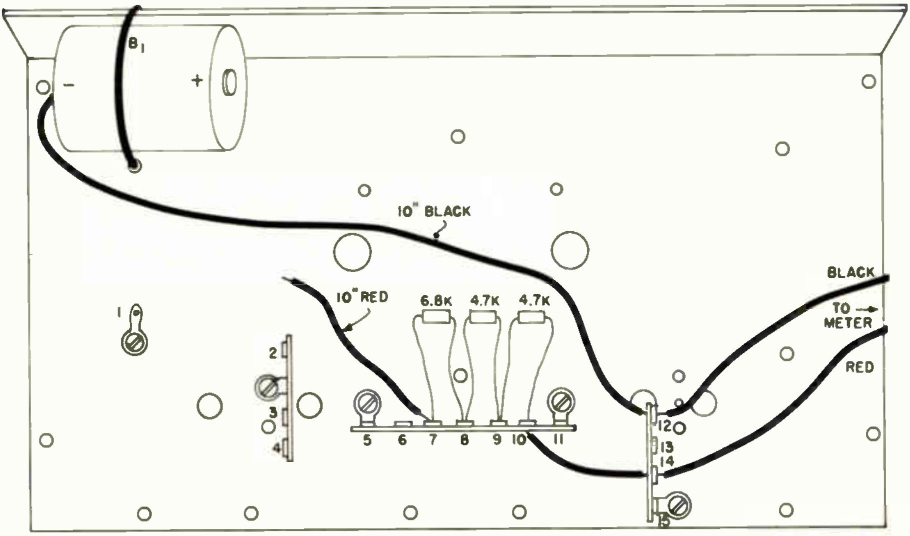

Fig. 43. Experimental chassis wired for Experiment 5.

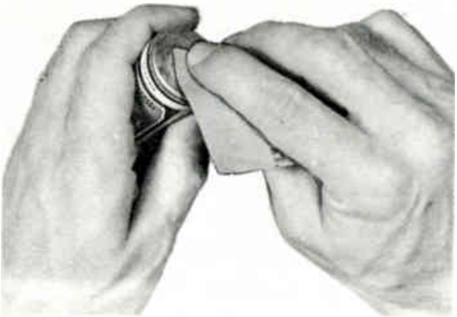

Fig. 44. How to clean the center of the bottom of a flashlight cell with a piece of sandpaper.

You should now have three series-connected resistors going from the positive meter terminal (terminal 10) to terminal 7. The total resistance between terminal 7 and the positive meter terminal is the sum of the values of the three resistors; a total of about 16,000 ohms.

You now have a 0-200 microampere meter with approximately 16,000 ohms in series with it.

In order to measure current, your meter must be connected to a source of voltage with the proper polarity. The positive terminal of the voltage source must always be connected to the lead or circuit point that goes to the positive meter terminal.

At first, we will use a flashlight cell which produces 1.5 volts dc as a source of voltage. To do this, you are to connect a wire from the negative meter terminal, terminal 12, to the negative battery terminal. Notice that one end of your flashlight cell has a raised portion while the other end is flat. The negative battery terminal is the end with no raised section. Clean a spot in the middle of the bottom of the cell with a piece of fine sandpaper, as shown in Fig. 44.

Be sure that your soldering iron tip is clean and hot. Then, hold the end of your roll of solder on the negative terminal of the cell and touch your soldering iron to the solder. Rub the iron around so that the terminal becomes well-tinned.

Now cut a 10" length of black hookup wire and remove 1/4" of insulation from each end. Place one end of the 10" length black hookup wire on the tinned area of the negative terminal of the cell. Touch the tip of your soldering iron to the wire and the tinned portion of the cell. The solder should melt and run over the wire. Remove the heat and allow the joint to cool. If the solder does not flow smoothly over the wire, add a little more solder as you heat the connection.

If you like, you can use a piece of hookup wire to secure the cell in place along the bend in the chassis as shown in Fig. 43. Note that the negative terminal is toward the left side of the chassis.

Fig. 45. Schematic symbol for a battery.

The symbol we use on schematic diagrams to represent a battery is shown in Fig. 45. Each pair of lines represents one cell of the battery. The short wide line represents the negative terminal and the longer thin line represents the positive terminal. To represent one cell, we use only one pair of lines; but to represent several cells, we do not try to show the exact number, as two or more pairs are sufficient.

EXPERIMENT 5

Purpose: To show that current flowing in a series circuit will change when the

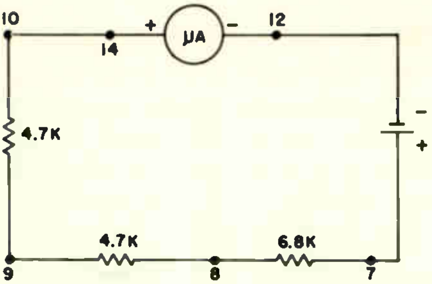

Fig. 5-1. The circuit you will use in Step 1 of Experiment 5.

resistance in the circuit or the voltage applied to the circuit is changed.

Introductory Discussion: Although the circuit you will use in this experiment is a simple circuit, it will act in the same way that a more complex circuit would act when either the resistance or voltage is changed.

This experiment will demonstrate Ohm's Law, which is one of the most important laws you will study. Do each step of the experiment carefully and make sure you understand exactly what you are doing and what the changes in current that you observe mean.

Experimental Procedure: In this experiment, in addition to the meter, chassis and the circuit you have just wired, you will need the following:

1 1.5-volt flashlight cell
Hookup wire

The first circuit you will use is shown in Fig. 5-1. When you read the meter, use the 30-volt scale which you practiced reading previously.

Step 1: To connect 1.5 volts across the meter and series resistor combination.

Touch the red wire from terminal 7 to the positive terminal of the flashlight cell. This closes the circuit and causes current to flow.

Observe the pointer on your meter. It should be slightly below one-half scale. If you get no reading, look for a bad connection or a short circuit. Check to be sure that your circuit is wired as shown in Fig. 5-1. Trace the wiring from terminals 12 and 10 back to the terminals on the meter. Also check for a short circuit between the meter terminals or leads.

The meter scale which you are using in this experiment (Fig. 5-2) is the 0 to 30 volt scale. However, in this experiment you are using this scale only as a relative indication of the amount of current in the circuit. The meter indicates a current of about 100 microamperes, since you know that a full scale reading (30) repre-

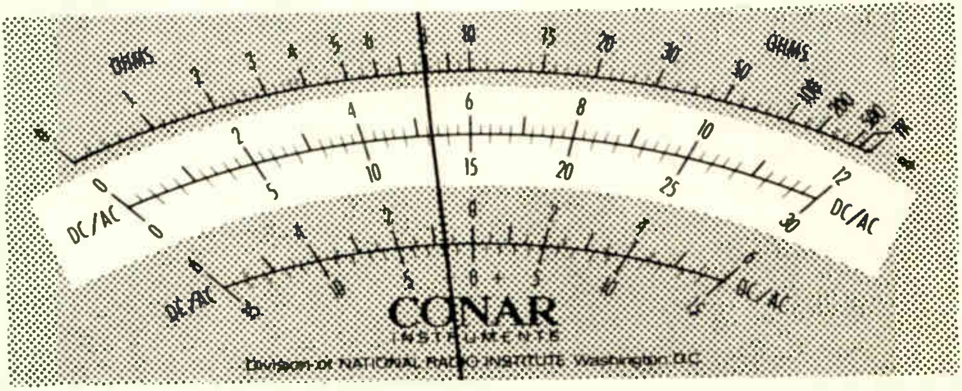

Fig. 5-2. The meter reading of Step 1 should be approximately 13 on the 0-30 scale.

STEP	READING
1	13,5
2	27,5
3	23,2

Fig. 5-3. Record your reading for Experiment 5 here.

sents a current of 200 microamperes.

In later experiments you will learn that the 0 to 30 volt scale will also be used to indicate 0 to 3 volts, and 0 to 300 volts. The 0 to 12 volt scale will also be used to indicate ranges of 0 to 1.2 volts, 0 to 120 volts and 0 to 1200 volts. For the time being, however, you need only be concerned with relative scale indications on the 0 to 30 volt scale. Read the meter carefully and write the reading of the meter in the space provided for Step 1 in Fig. 5-3. Remove the red wire from the positive terminal of the flashlight cell to open the circuit.

Step 2: To determine the effect of increasing the voltage in a series circuit.

To do this, you will connect another flashlight cell in series with the cell you used in Step 1. This is shown in the schematic diagram in Fig. 5-4.

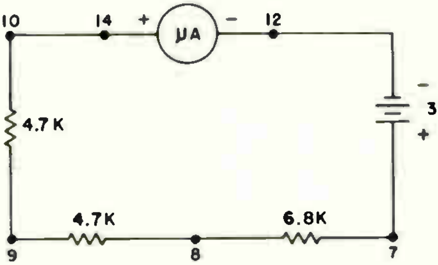

Fig. 5-4. Circuit to use for Step 2.

Clean the positive terminal of the second flashlight cell with a piece of fine sandpaper. Hold your soldering iron on the terminal and apply solder. Melt

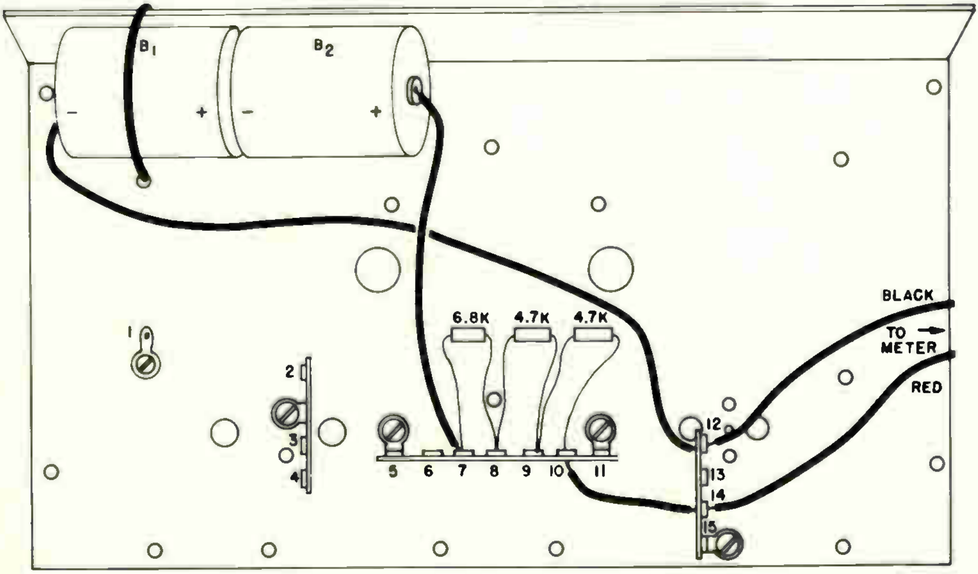

Fig. 5-5. Series resistor with 3-volt battery.

enough solder on the terminal to tin it. Rub the tip of the iron around so that the terminal is well-tinned.

Place the free end of the red wire connected to terminal 7 on the tinned area of the positive terminal of this flashlight cell and apply heat to solder the wire to the terminal. Use additional solder if necessary.

Now, to complete the circuit, hold the positive end of the first flashlight cell against the negative terminal of the second flashlight cell, as shown in Fig. 5-5. This places the two 1.5-volt cells in series, thus forming a 3-volt battery.

The meter pointer should swing to the right to just under 30 on the 30-volt scale. Look at the meter carefully, read the value as closely as you can, and write the reading in the space reserved in Fig. 5-3.

Step 3: To show that the amount of current will change when the resistance is changed.

The circuit you will use is shown in Fig. 5-6. Unsolder the red wire from the positive terminal of the second flashlight cell and from terminal 7 and set the cell to one side. Solder one end of the red wire you just removed to terminal 8.

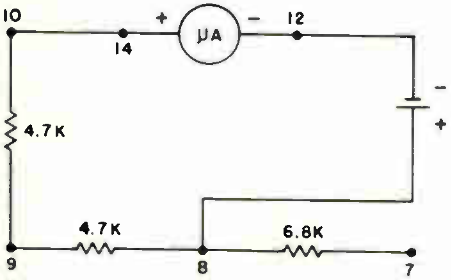

Fig. 5-6. Circuit you use for Step 3.

Touch the free end of the red wire to the positive terminal of the flashlight cell on the chassis. You now have a total of about 9,400 ohms in the circuit with a source voltage of 1.5 volts. Read the meter and record your readings in the space for Step 3 in Fig. 5-3.

Discussion: In this experiment, you have seen what happens in a series circuit when the voltage or resistance is changed. You should have a reading of something less than 15 for Step 1. When you doubled the voltage in the circuit by adding a second flashlight cell, you should have obtained a reading of about two times the original reading. In other words, when you double the voltage supplied to the circuit, the current in the circuit doubles. From this, you can see that there is a definite relationship between voltage and current in a series circuit.

In Step 3, when you reduced the resistance in the circuit, you should have found that the current was greater than in Step 1. This shows that if you reduce the resistance in a series circuit, the current will increase. We could have shown that increasing the resistance will cause the current to decrease, but this should have been obvious from the steps that you have already carried out in this experiment.

Instructions For Statement No. 5: In order to complete this statement you must obtain one additional reading. You will find the current through a resistance of approximately 7,500 ohms connected across a voltage of 1.5 volts. To get this reading, wire the circuit shown in the schematic in Fig. 5-7. Connect a short length of hookup wire from terminal 7 to terminal 9. Solder both connections. Fig.

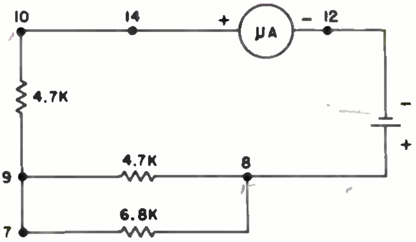

Fig. 5-7. Connect the free end of the resistors to the junction of the first and second resistors to get Statement answers.

5-8 shows the chassis wired according to Fig. 5-7. This places a 4,700-ohm resistor in parallel with the 6,800-ohm resistor. This combination is in series with the other 4,700-ohm resistor. Next, touch the red wire from terminal 8 to the positive terminal of the flashlight cell on the chassis.

Observe the meter reading on the 30-volt scale and answer the statement.

Remove the three resistors connected to terminals 7, 8, 9 and 10 and clean their leads so they will be ready for reuse. Also, disconnect and remove the short length of wire connecting terminals 7 and 9 and remove the 10″ length of red wire from terminal 8. Do not discard this wire as you can reuse it in later experiments. Do not remove any of the other wires.

Statement No. 5: When I touched the free end of the lead from terminal 8 to the 1.5-volt cell, I obtained a reading of approximately

(1) 15
(2) 30
(3) 10

EXPERIMENT 6

Purpose: To show how to connect resistors in parallel; and to show that the net resistance of a group of parallel-connected resistors is less than that of the smallest resistor in the group.

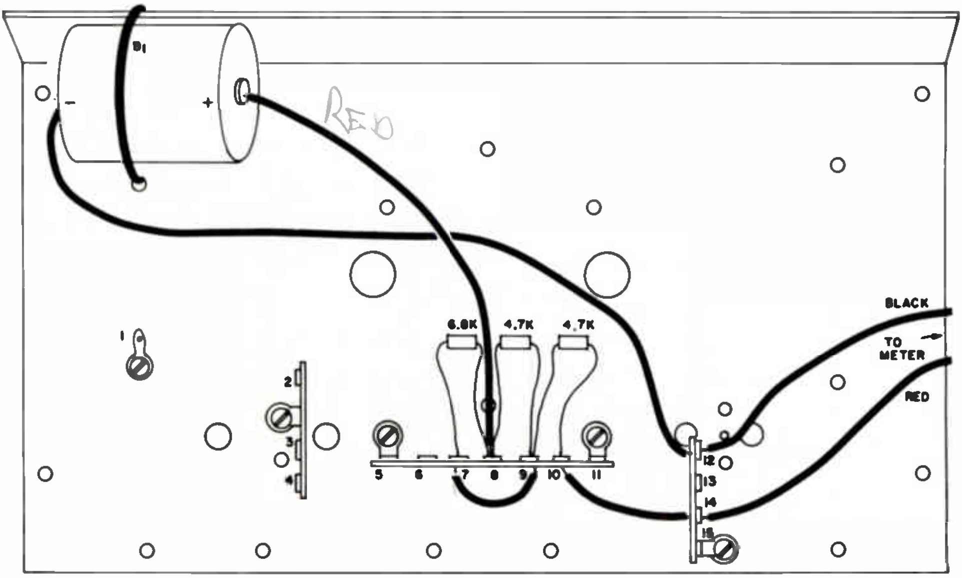

Fig. 5-8. Chassis arrangement for Statement 5.

Introductory Discussion: In the last experiment, you learned how to connect resistors in series with a source of voltage. When resistors or any other parts are connected across a voltage source, they are called a load. In a circuit of this type, each resistance, including that of the meter, can be considered as part of the total load resistance. Thus, the total load resistance is the sum of the individual resistances.

In this experiment we will show that loads can also be connected to the source voltage so that the entire source voltage is connected to each load. We will also show that when loads are connected in this manner, the net resistance of the combined load is less than the resistance of the smallest resistance in the group.

Experimental Procedure: In making these tests, you will use the following parts:

- **2 100,000-ohm resistors**
- **1 82,000-ohm resistor**
- **2 Flashlight cells**
- **Red hookup wire**

Since good connections will be required, we will solder leads to the batteries. To do this, clean the battery terminals (that you have not yet used) with a piece of sandpaper and tin them, as you learned to do in the last experiment.

Remove 1/2" of insulation from each end of an 8" length of red hookup wire. Place one end of one wire on the tinned area of the positive terminal of the cell connected to terminal 12. Touch the soldering iron to the junction. The solder on the tinned areas should melt and run over the wire. If necessary, add solder to get a good connection. Remove the heat, and let the joint cool. Solder the other end of the wire lead to the tinned area on

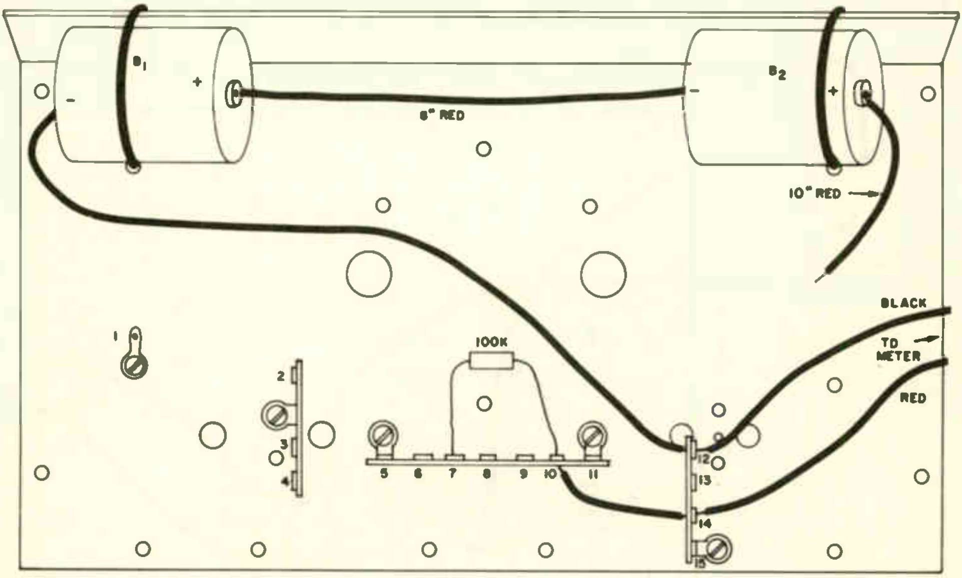

Fig. 6-1. Chassis wired for Step 1.

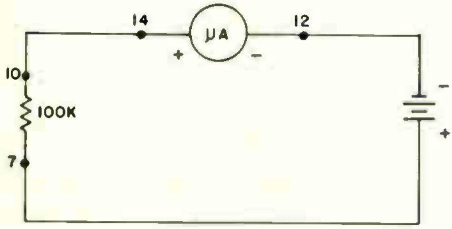

Fig. 6-2. Schematic diagram for Step 1.

the negative terminal of the second battery.

Secure the second battery to the right side of the chassis as shown in Fig. 6-1. You can pass a piece of string or hookup wire through the hole in the chassis and around the battery.

We will call the cell on the left side of the chassis B_1 and we will call the cell on the right B_2.

Locate the 10″ length of red hookup wire you used in the last experiment. Solder one end of this wire to the positive terminal of the flashlight cell, B_2. Leave the other end free.

You now have a 3-volt battery. The negative terminal of the 3-volt battery is the negative terminal of B_1 and is connected to terminal 12. The red wire connected to the positive terminal of B_2 is the "positive battery lead."

Complete the circuit shown in Figs. 6-1 and 6-2 by soldering a 100,000-ohm resistor between terminals 7 and 10.

Step 1: To get an indication of the current flowing with a 100,000-ohm resistor in the circuit.

Touch the free end of the positive battery lead, which is soldered to the positive terminal of B_2, to terminal 7. Read the meter indication on the 30-volt scale. The meter pointer should be in about the position shown in Fig. 6-3. Your reading may be somewhat higher or lower than the value shown in Fig. 6-3 because of normal tolerances in resistor values and the output voltages of different cells. Read the meter carefully and then remove the free end of the positive battery lead from terminal 7 to open the circuit. Record your reading in the space provided for Step 1 in Fig. 6-4.

Step 2: To connect a 100,000-ohm resistor in parallel with the resistor used in Step 1.

Clean the leads of the second 100,000-ohm resistor and connect it in parallel with the resistor used in the last

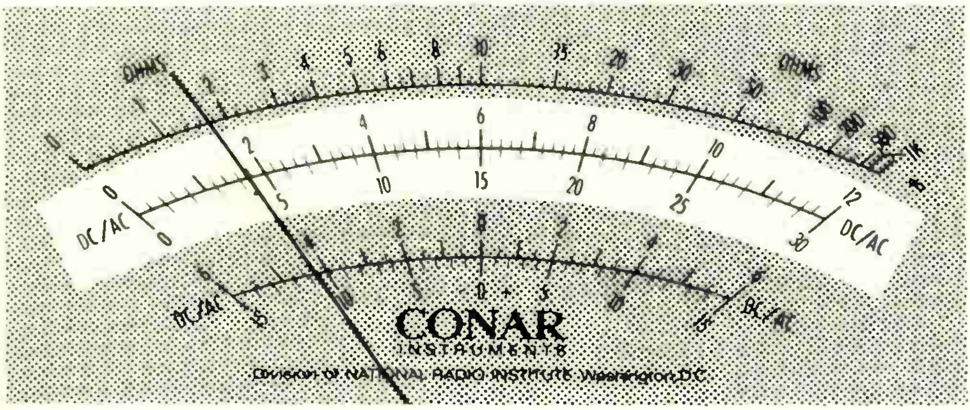

Fig. 6-3. Meter reading for Step 1.

STEP	READING
1	4.7
2	9.5
3	14.9

Fig. 6-4. Record your reading for Experiment 6 here.

step. You may solder the leads to terminal 7 and 10 or, if you prefer, you may solder the leads to the leads of the resistor already in the circuit. The circuit for this step is shown in Fig. 6-5.

Touch the positive battery lead to terminal 7 and read the meter on the 30-volt scale. Remove the positive battery lead after recording your reading in the chart in Fig. 6-4.

Step 3: To add an 82,000-ohm resistor to the parallel connected 100,000-ohm resistor.

Clean the leads of the 82,000-ohm resistor and solder it either to terminals 7 and 10 or to the leads of one of the resistors used in Step 2. The schematic diagram of the circuit for this step is shown in Fig. 6-6. Touch the positive battery lead to terminal 7 and note the reading on the meter. Open the connection after recording your reading in Fig. 6-4.

Discussion: In this experiment you have demonstrated what happens to the current in a circuit when resistors are connected in parallel. You should have discovered that as you added the second 100,000-ohm resistor to the circuit, your reading on the meter was about twice what it was with only one resistor in the circuit. When you added the third resistor, you should have found that the current increased still more.

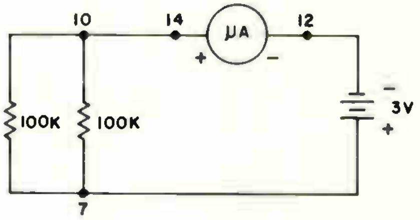

Fig. 6-5. Schematic diagram for Step 2.

You know from Ohm's Law that the amount of current that will flow in a circuit depends on the voltage applied to the circuit and the resistance in the circuit. In other words, I = E ÷ R. The value of E did not change; it was 3 volts throughout the entire experiment. Therefore, the change in current must have been entirely due to the change in resistance. In fact, the total resistance in the circuit decreased as you added more

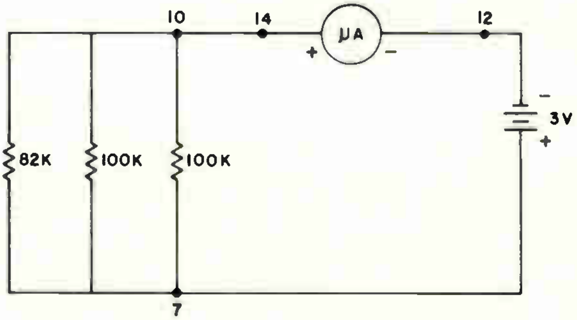

Fig. 6-6. Schematic diagram for Step 3.

resistors in parallel to produce the increase in the circuit current.

Of the three resistors used in this experiment, the 82,000-ohm resistor has the lowest resistance, and we will use this resistor by itself in the statement for this experiment.

Instructions for Statement No. 6: Remove all three resistors from terminals 7 and 10. Separate the resistors and reconnect the 82,000-ohm resistor to terminals 7 and 10.

Touch the positive battery lead to terminal 7 and note the reading on the meter. Open the circuit, and write the reading in the margin of this page. Answer the statement, and then disconnect the 82,000-ohm resistor. Clean and straighten its leads so that it will be ready for re-use. Leave all other connections alone as they will be used in the next experiment. Leave the two flashlight cells connected together and the lead from the negative terminal of the battery connected to terminal 12.

Statement No. 6: When I connected an 82,000-ohm resistor in place of the parallel group, the reading was:

(1) higher
[✓ *(2) lower*]

5.7

than the reading obtained in Step 3.

This indicates that the resistance of the parallel group was:

(1) more than
[✓ *(2) less than*]

that of the 82,000-ohm resistor by itself.

EXPERIMENT 7

Purpose: To show that the current is the same at every point in a series circuit.

Introductory Discussion: You already know that current in a circuit is the flow of electrons through the circuit. Electrons flow from the negative terminal of the voltage source, which is the battery in this experiment, through the load, and back to the positive terminal of the battery. Inside the battery, electrons flow from the positive terminal to the negative terminal.

In any series circuit, the current is the same throughout the entire circuit. In other words, if you connect a current-measuring instrument into the circuit to measure the current, it will not make any difference where you connect the instrument -- you will always get the same current reading. In this experiment you will demonstrate this. You will even show that the current flowing in the battery itself is the same as the current flowing in the external circuit.

Experimental Procedure: In this experiment, in addition to the meter, chassis and flashlight cells you will need the following parts:

1 100,000-ohm resistor
1 82,000-ohm resistor
1 22,000-ohm resistor
Hookup wire

Fig. 7-1 shows the circuit you will use for Step 1. This is the same setup used in

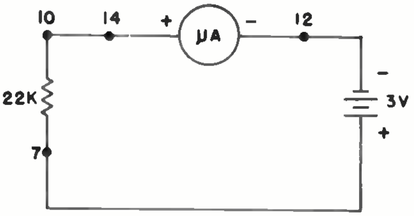

Fig. 7-1. Schematic of circuit for Step 1.

STEP	READING
1	20.5
2	20.5
3	20.5

Fig. 7-2. Record your reading for Experiment 7 here.

the last experiment. To construct the circuit, solder the leads of the 22,000-ohm resistor to terminals 7 and 10. When you have made these connections you should have:

(1) a wire from the negative battery terminal (negative terminal of B_1) to terminal 12,
(2) a wire connecting terminal 14 and terminal 10,
(3) a 22,000-ohm resistor connected from terminal 10 to terminal 7,
(4) a wire from the positive terminal of B_1 to the negative terminal of B_2, and
(5) a wire soldered to the positive battery terminal with the other end free. There should be no wire soldered to terminal 7.

If your circuit is properly wired, you may proceed with the first step.

Step 1: To measure the current leaving the battery.

Touch the free end of the positive battery lead to terminal 7. Read the meter on the 30-volt scale and record the reading in the space provided for Step 1 in Fig. 7-2. On the schematic in Fig. 7-1, you can see that the battery current flows from the negative battery terminal, through the meter to the resistor. It then flows through the resistor and back to the positive battery terminal.

Step 2: To measure the current returning to the battery.

Rewire the circuit as shown in Fig. 7-3. To do this, first unsolder and remove the red wire from terminal 10 to terminal 14. Unsolder the black negative battery lead from terminal 12. Solder the free end of the black wire to terminal 10. Connect and solder a length of hookup wire from terminal 7 to terminal 12.

Notice on the schematic in Fig. 7-3 that the meter is now between the resistor and the positive battery terminal.

Touch the free end of the positive battery lead to terminal 14 to complete the circuit. Read the meter on the 30-volt scale. Open the circuit after recording the reading for Step 2 in Fig. 7-2.

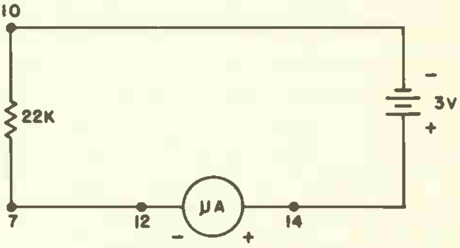

Fig. 7-3. Circuit for Step 2.

Step 3: To show that the current flowing inside the battery itself is the same as the current flowing in the external circuit.

The battery you are using in this experiment consists of two flashlight cells. Large batteries of the type used in earlier tube-type portable radios have voltages of 45 and 90 volts and are made up of groups of 1.5-volt cells, similar to flashlight cells. These are connected in series to get the required voltage. The more cells that are connected in series, the higher the voltage.

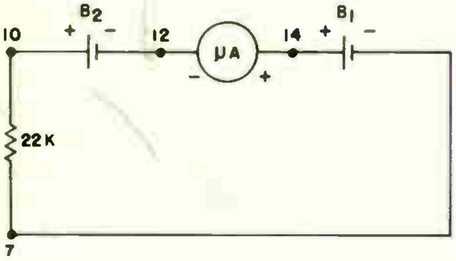

Fig. 7-4. Circuit for Step 3.

With an external circuit connected to the battery, you can measure the internal current in the battery by inserting a meter between any two adjacent cells.

To illustrate this in the experiment, wire the circuit shown in the schematic in Fig. 7-4. Fig. 7-5 shows a pictorial diagram of the wiring. Unsolder and remove the short length of hookup wire connected from terminal 7 to terminal 12.

Locate the wire connecting the two flashlight cells. Unsolder this wire from the positive terminal of B_1. Solder the free end of the wire to terminal 12.

Solder the negative battery lead to terminal 7.

Connect and solder a length of hookup wire from terminal 14 to the positive terminal of B_1. Check to see that your circuit is wired correctly.

Touch the positive battery lead (from B_2) to terminal 10 to complete the circuit. Read the meter carefully and open the circuit after recording your reading in the space provided for Step 3 in Fig. 7-2.

Discussion: In Step 3 of this experiment, the circuit is connected as shown in Fig. 7-4. Here the meter is actually placed between the two flashlight cells, and is measuring the current flowing from one cell into the second cell. Compare your readings for this step with your readings in Steps 1 and 2.

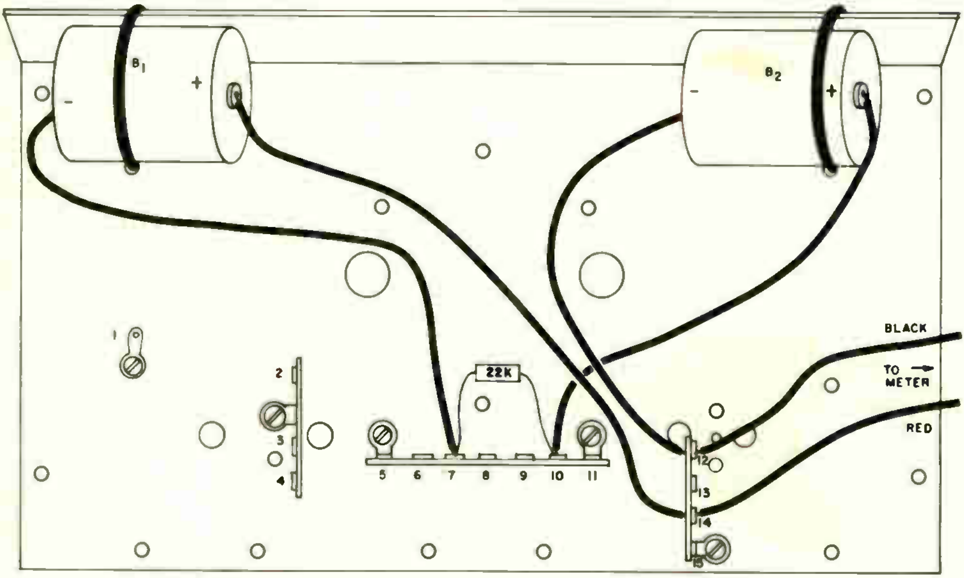

Fig. 7-5. Chassis wired for Step 3.

Notice that the readings are the same in all three steps. This demonstrates an extremely important fact. The value of the current is the same throughout the entire circuit. This means you can connect a meter at any point in a simple series circuit to measure the current; the reading will be the same regardless of where the meter is connected.

It is easy to see why the current in a series circuit is the same throughout the entire circuit. When you close the circuit by touching the battery wire to the circuit, electrons begin to leave the negative terminal of the battery. They strike other electrons and cause them to move. These electrons, in turn, strike additional electrons, and so on throughout the entire circuit. This, of course, occurs instantaneously; as soon as the circuit is completed, electrons start moving through the entire circuit.

At the same instant that electrons begin to leave the negative terminal of the battery, pushing other electrons before them, other electrons begin entering the positive terminal of the battery, because the electrons are attracted by the positive potential. The number of electrons moving in one part of the series circuit is exactly equal to the number of electrons moving in any other part of the series circuit.

Instructions for Statement No. 7: In the preceding experiment, you demonstrated that when resistors are connected in parallel, the total resistance of the combination is lowered. If the applied voltage does not change, this results in an increase in current. For this Report Statement, you will connect a low resistance in series with a high resistance. Then you will shunt each resistance with an 82,000-ohm resistor and note the effect on the total circuit current.

7

4

To carry out the experiment for this statement, you will need one 100,000-ohm resistor and one 82,000-ohm resistor. Wire the circuit as shown in Fig. 7-6. Connect a 100,000-ohm resistor from terminal 10 to terminal 13. Solder both connections. Check your circuit to see that it is wired according to Fig. 7-6. Solder the positive battery wire to terminal 13.

Note the reading on the meter on the 30-volt scale. Bend the leads of the 82,000-ohm resistor so that you can conveniently bridge the resistor across either the 100,000-ohm or the 22,000-ohm resistor. Bridge the 82,000-ohm resistor first across the 100,000-ohm resistor and note the meter reading on the margin. Next move the 82,000-ohm resistor over and bridge the 22,000-ohm resistor. Again, read the meter and note the reading in the margin.

Compare the two meter readings and answer the Report Statement.

Unsolder the positive battery lead from terminal 13. Unsolder and remove the 100,000-ohm resistor connected between terminals 10 and 13 and the 22,000-ohm resistor connected between terminals 7 and 10. Unsolder and remove the short red wire between the positive terminal of B_1 and terminal 14. Unsolder the red wire from terminal 12. (The other end of

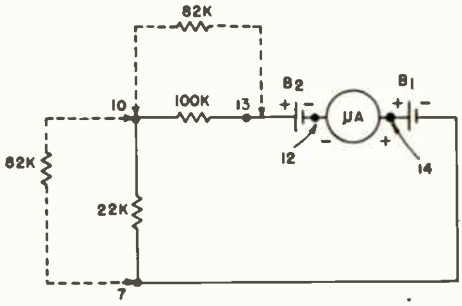

Fig. 7-6. Circuit for Statement 7.

this wire is soldered to the negative terminal of B_2.) Solder the free end of this wire to the positive terminal of B_1 to connect the two cells in series again. Clean and straighten the leads of the resistors you removed and clean all unused terminals.

Statement No. 7: When I shunted the 100K-ohm resistor with an 82K-ohm resistor, and then shunted the 22K-ohm resistor with the 82K-ohm resistor, I found that the effect on the current was:

(1) greater when the 22K-ohm resistor was shunted.
[✓ *(2) greater when the 100K-ohm resistor was shunted.*]
(3) the same in both cases.

EXPERIMENT 8

Purpose: To show that the total current flowing in a parallel circuit is the sum of the currents flowing in the branches.

Introductory Discussion: In any piece of electronic equipment, there are usually several tubes or transistors connected across a single power supply. Each circuit, or stage, as they are usually called, generally draws a different current. The total current that the power supply must provide is equal to the sum of the currents drawn by the individual stages. Each stage acts as a separate load connected across the power supply. If a defect develops in one stage so that the stage draws more current than it should, not only will that stage be overloaded, but also the total current that the power supply must furnish will increase. As a result, the power supply may be overloaded. It is important for you to remember this when you start doing repair work. If a power transformer overheats, it does not necessarily indicate that the transformer is defective; it often indicates

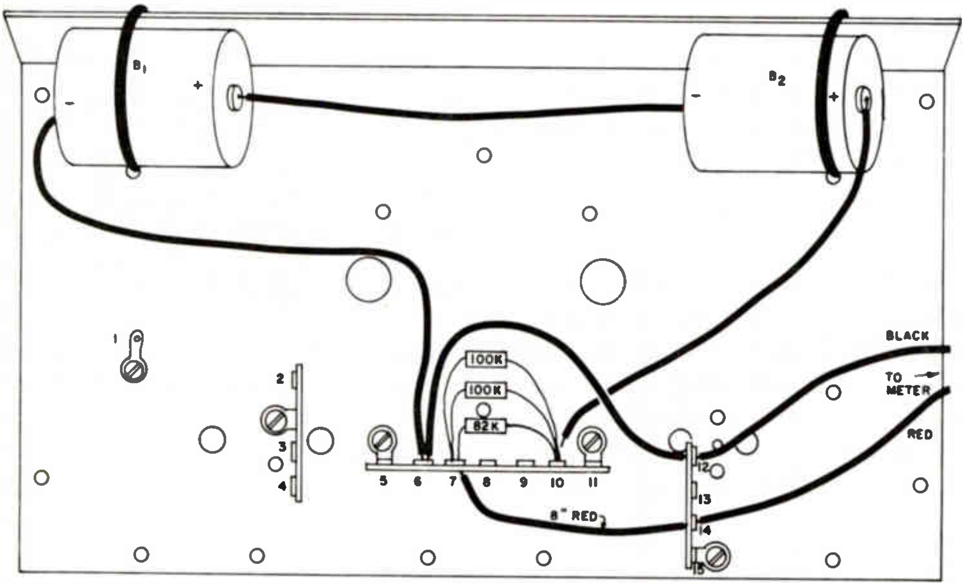

Fig. 8-1. Chassis for Step 1.

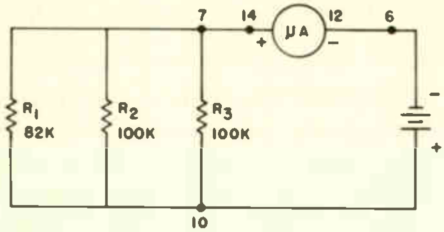

Fig. 8-2. Schematic of circuit for Step 1.

that a defect in some stage other than the power supply is causing the transformer to overheat.

In this experiment you will prove that the sum of the individual branch currents in a parallel circuit is equal to the total circuit current.

Experimental Procedure: In addition to the parts already on the experimental chassis you will need the following parts:

2 **100K-ohm resistors**
1 **82K-ohm resistor**
Hookup wire

1 9
4' 2/8

You should have the two flashlight cells connected to form a 3-volt battery on your chassis. For this experiment, you must wire your circuit as shown in Figs. 8-1 and 8-2.

Solder the two 100,000-ohm resistors and the 82,000-ohm resistor to terminals 10 and 7. You should then have two 100,000-ohm resistors and the 82,000-ohm resistor connected in parallel. Connect the black wire from the negative terminal of B_1 to terminal 6. Next strip 1/4" of insulation from each end of a 5" length of black hookup wire and solder this wire to terminals 6 and 12 as indicated in Fig. 8-1.

Remove about 1/4" of insulation from each end of an 8" length of red hookup wire. Solder one end to terminal 14 and solder the other end to terminal 7. Do not connect the positive battery lead at this time.

Before you go to Step 1, carefully check your work with the schematic of Fig. 8-2 and the pictorial drawing of Fig. 8-1. Make sure you have made all of the connections correctly.

Step 1: To measure the total current flow in a parallel circuit.

Touch the positive battery lead (connected to the positive terminal of B_2) to terminal 10. Observe the readings on the 30-volt scale on your meter. Remove the positive battery lead from terminal 10 after recording your reading in the space provided for Step 1 in Fig. 8-3.

STEP	READING
1	14.9
2	4.9
3	4.9
4	6

Fig. 8-3. Record your reading for Experiment 8 here.

With the arrangement shown in Fig. 8-2, the three resistors are in parallel and the current which you measured is the total current flowing in the circuit.

Step 2: To measure the current through a 100,000-ohm resistor.

You will use the circuit shown in the schematic diagram in Fig. 8-4. To change your wiring to make this circuit, unsolder the lead of the 82,000-ohm resistor and the lead of one 100,000-ohm resistor from terminal 7. Solder these two leads to terminal 6.

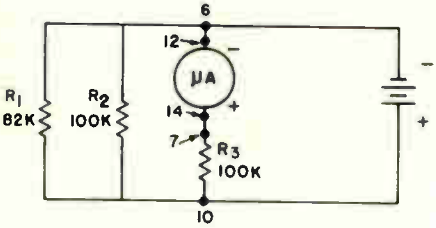

Fig. 8-4. Circuit for Step 2.

As you can see in the schematic, when the circuit is completed, current will flow through all three resistors. However, only the current through R_3 the 100,000-ohm resistor connected to terminal 7 will flow through the meter.

Touch the positive battery lead to terminal 10. Read the meter on the 30-volt scale and record your reading for Step 2 in Fig. 8-3.

Step 3: To measure the current through the second 100,000-ohm resistor, R_2.

Fig. 8-5 shows the circuit. To make the necessary changes, unsolder the 100,000-ohm resistor lead from terminal 7 and resolder it to terminal 6. Then unsolder the lead of the other 100,000-ohm resistor from terminal 6 and resolder it to terminal 7.

Touch the positive battery lead to terminal 10 and observe the meter indication on the 30-volt scale. Remove the battery lead from terminal 10 after recording your reading in the space for Step 3 in Fig. 8-3.

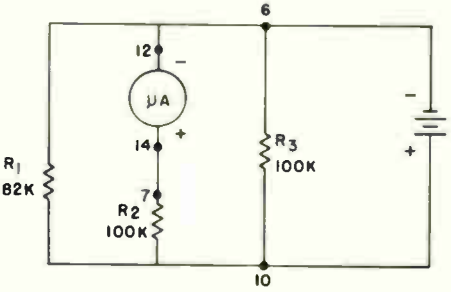

Fig. 8-5. Circuit for Step 3.

Step 4: To measure the current through the 82,000-ohm resistor.

Modify the circuit as shown in the schematic in Fig. 8-6. Unsolder the 100,000-ohm resistor lead from terminal 7 and resolder it to terminal 6. Unsolder the lead of the 82,000-ohm resistor from terminal 6 and resolder it to terminal 7. This places the meter in the 82,000-ohm resistor circuit only.

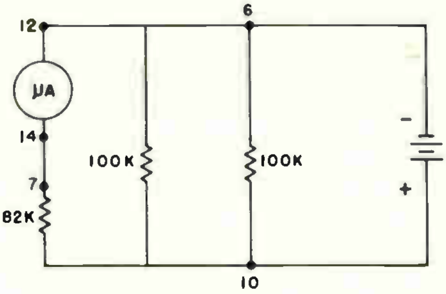

Fig. 8-6. Circuit for measuring the current through the 82K-ohm resistor.

Touch the positive battery lead to terminal 10. Read the meter on the 30-volt scale. Remove the positive battery lead from terminal 10 after recording your reading in the space provided for Step 4 in Fig. 8-3.

Discussion: In this experiment, you have measured the total current flowing in a circuit, and also the current flowing in the individual branch circuits. Since you used two 100,000-ohm resistors, you should have found that the current flowing through these resistors was the same.

In other words, the readings you obtained in Steps 2 and 3 should have been equal.

In actually taking this measurement, you may have found a slight variation because the resistors have a tolerance of 10%. Even though we call the resistor a 100K-ohm resistor, its actual resistance may be as much as 10,000 ohms more or less than 100,000 ohms. The resistance in series with the meter, therefore, may be any value between 90,000 and 110,000 ohms, which would account for the variation in your measurements. The 82,000-ohm resistor can have any value between 73,800 ohms and 90,200 ohms. Therefore, it is actually possible to have little or no difference in reading between the 82,000-ohm resistor and one or both of the 100,000-ohm resistors. In most electronics work, resistor values are not critical, and it is much more economical to use a resistor having a 10% tolerance, than it is to use a resistor having a 1% tolerance.

To show that the total current flowing in the circuit is equal to that in the individual branch circuits, add your readings for Steps 2, 3, and 4, and compare the result with the readings for Step 1. The sum of the readings recorded in Steps 2, 3, and 4 should be approximately equal to the reading you have recorded in Step 1.

Instructions for Statement No. 8: For this Statement, you do not need to take any additional measurements. You can use the readings you took in the experiment to answer the statement.

Answer the statement and unsolder and remove the two 100,000-ohm resistors and the 82,000-ohm resistor from terminals 6, 7, and 10. Remove the red wire from terminals 7 and 14 and remove the black wire from terminals 6 and 12.

Statement No. 8: When I measured the individual branch currents flowing in the circuit consisting of two 100K-ohm resistors and one 82K-ohm resistor, I found that the current was greatest

(1) through one of the 100K-ohm resistors.
[✓ *(2) through the 82K-ohm resistor.*]

This shows that maximum current will flow through the branch in the parallel circuit having

[✓ *(1) the lowest resistance.*]
(2) the highest resistance.

EXPERIMENT 9

Purpose: To show that a microammeter can be used as a voltmeter if a suitable resistor is placed in series with the meter.

Introductory Discussion: You have seen how a microammeter can be used to indicate the presence of current and to show if the current increases, decreases, or remains constant when circuit conditions are changed. We have not been able to measure the current in microamperes or milliamperes because the meter is not calibrated to read in microamperes. It would be possible to calculate the current from your scale readings, but since we are not interested in exact values, it is not necessary.

Your meter is a 0-200 microammeter. This means that a current of 200 microamperes must flow through the meter to give a full-scale deflection. In other words, when the pointer is at 30 on the 30-volt scale, the current flowing through the meter is 200 microamperes. (Microamperes is abbreviated μa.)

If your meter had a 200 microampere (200 μa) scale printed on it, and we inserted a resistance in series with the meter, and then connected the combination across a voltage source, you could read the current through the meter. The current would depend upon two things: the voltage of the source, and the resistance we placed in series with the meter. If we knew what the resistance was, we could read the current from the meter, and then calculate the voltage by using Ohm's Law. Ohm's Law states that $E = I \times R$. So we would multiply the current in amperes by the resistance in ohms to get the voltage of the source.

This arrangement has one drawback, however. It takes quite a bit of time to make the mathematical calculations. Actually, it is not necessary to do this, because as long as the resistance remains unchanged, the current will depend only on the voltage. Therefore, we can calibrate the meter to read directly in voltage. Now let us see how we can find out what resistor we need in order to use the 3-volt range on the meter.

To do this, we again turn to Ohm's Law. One form of Ohm's Law states that the resistance is equal to the amount of voltage divided by the amount of current. In other words, $R = E \div I$. We want the meter to read full scale when the voltage applied is 3 volts; therefore E will be equal to 3. We know that the meter is a 200 microampere meter; it takes 200 microamperes (200 μa) of current to make the meter read full scale. Converting this value to amperes, we get .0002 ampere. Now, to get the value of resistance needed, we divide 3 by .0002. This will give us 15,000. Therefore, the resistance value that should be added to the circuit is 15,000 ohms.

If we want to build an accurate meter, we will have to subtract the resistance of the meter itself from the resistance to be placed in series with the meter. However, the resistance of your microammeter is small compared to 15,000 ohms, so we will simply connect the 15,000-ohm resistor in series with the meter to give us a voltmeter that will read 3 volts on full scale. The error introduced by disregarding the meter resistance will be unimportant in this experiment.

As mentioned earlier, the scales on the meter are labeled 0 to 12 and 0 to 30. For the 3-volt scale, read the 0 to 30 volt scale but mentally divide the reading by 10, or place a decimal point before the last digit. For example, for a full scale reading, the pointer will point to 30. Dividing this by 10 gives us 3.0. Similarly, a reading of 20 is actually 2.0 on the 3-volt scale, just as 15 is 1.5 volts, 5 is 0.5 volts and so on.

Experimental Procedure: In this experiment, in addition to your meter and chassis with parts mounted, you will need the following parts:

1 15,000-ohm resistor
Hookup wire

Prepare 1′ lengths of red and black hookup wire. Remove about 1/2″ of insulation from each end of the wires.

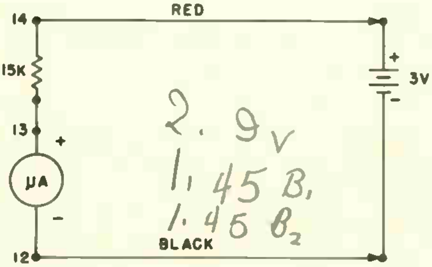
Step 1: To convert your microammeter to a voltmeter.

Unsolder the red meter lead from terminal 14 and reconnect to terminal 13. Connect the 15,000-ohm resistor from terminal 13 to terminal 14. Solder terminal 13. Solder one end of the 1′ length of red wire to terminal 14. Leave the other end free.

Solder one end of the 1′ length of black hookup wire to terminal 12. The meter can now be used as a 0 to 3 volt voltmeter. The black wire connected to terminal 12 is your *negative voltmeter lead* and the red wire connected to terminal 14 is your *positive voltmeter lead.*

Step 2: To measure the voltage of the two flashlight cells connected in series.

The cells should still be connected in series as they were in the last experiment. Touch the negative meter lead (the black wire connected to terminal 12) to the negative terminal of the 3-volt battery, and touch the positive meter lead to the positive terminal of the 3-volt battery. Fig. 9-1 shows the circuit used in this step. Note the reading on the 3-volt scale on your meter. The reading should be approximately full scale, indicating a voltage of about 3 volts. The reading might be a little higher or lower than full scale, depending upon the tolerance of the 15,000-ohm resistor and the actual voltage of your battery. In general, new flashlight cells have a terminal voltage of 1.55 volts which drops to about 1.5 volts when the cells are heavily loaded (are supplying large current). In this circuit there is hardly any load so the battery voltage should be 2 times 1.55 volts or about 3.1 volts which would make your meter read slightly above full scale.



2.9v
1,45 B_1
1.46 B_2

Fig. 9-1. Circuit to measure battery voltage.

Step 3: To measure the voltage of a single flashlight cell.

Touch the positive voltmeter lead to the positive terminal of one cell, and touch the negative meter lead to the negative terminal of the same flashlight cell. Note the reading on the meter. The reading should be about center scale, indicating a voltage of approximately 1.5 volts. Check the voltage of the other flashlight cell in the same way.

Discussion: The meter that you constructed in this experiment is often referred to as a 5,000-ohms per volt voltmeter. We usually write this as 5,000 ohms/volt. Notice that to convert the meter to a 3-volt voltmeter, we use a 15,000-ohm resistor. If we wanted to convert the meter to a 12-volt meter, we would have used a 60,000-ohm resistor. If we wanted to convert the meter to a 30-volt meter, we would have used a 150,000-ohm resistor. In all cases, to find the resistance needed, we multiply the required full scale voltage by 5,000.

In the early days of electronics, meters with sensitivities of 1,000 ohms/volt and 5000 ohms/volt were the only types available. Today most meters have sensitivities of 20,000 ohms/volt to 150,000 ohms/volt.

The sensitivity of the meter used in service work is important. If the meter has a sensitivity of only 5,000 ohms per volt, it is quite possible that you will not get an accurate indication of the voltage in a circuit. In the next experiment we will show you exactly how this can happen and why the sensitivity of the meter is important to the serviceman.

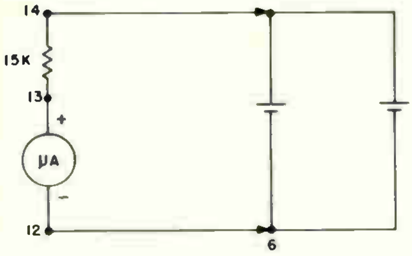


Fig. 9-2. Circuit for Statement 9.

Another type of meter, the vacuum tube voltmeter or the transistor voltmeter, has an even higher sensitivity than the meters previously discussed. For this reason most electronics technicians prefer this type to the simple voltmeter of the type you have just constructed. You will build a sensitive transistor voltmeter in the next Training Kit.

Instructions for Statement No. 9: In this statement, you are to measure the voltage of the two flashlight cells when they are connected in parallel. To do this, unsolder the red wire from the positive terminal of cell B_1 which is on the left side of your chassis. This wire should still be attached to the negative terminal of cell B_2. Solder the free end of this wire to terminal 6. Solder the free end of the positive battery lead (the wire soldered to the positive terminal of B_2) to the positive terminal of B_1. Check your work against Figs. 9-2 and 9-3.

Touch the positive voltmeter lead to the positive terminal of battery B_1 or B_2 and the negative meter lead to terminal 6. Note the reading on your meter, and answer the statement.

Unsolder the red wire from the positive terminal of battery B_1 and push the free end out of the way. Unsolder the red wire from terminal 6 and solder the free end to the positive terminal of flashlight cell B_1. Leave the 15,000-ohm resistor connected to terminals 13 and 14, and the

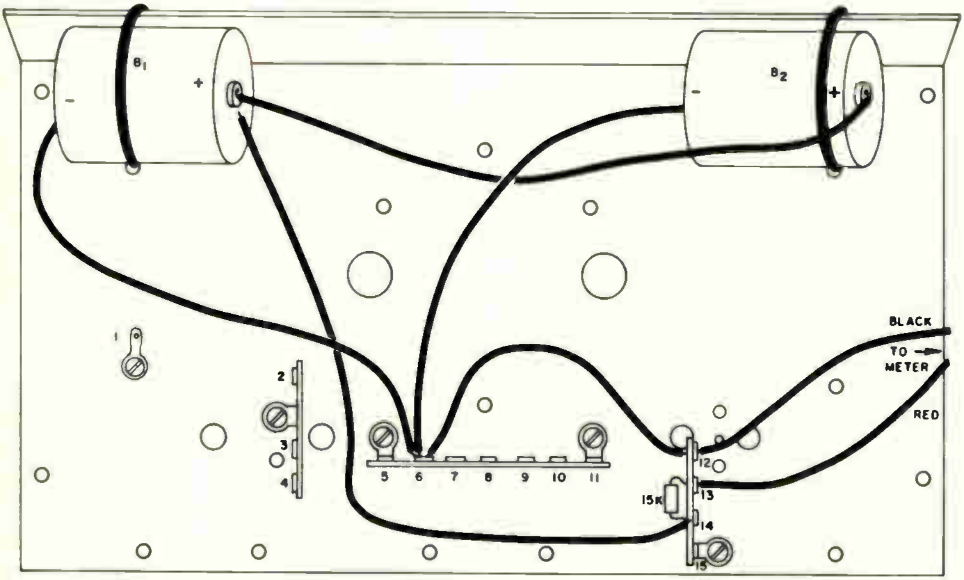

Fig. 9-3. Chassis used for Statement 9.

red and black voltmeter leads connected to terminals 12 and 13.

Statement No. 9: When I measured the voltage of the two parallel-connected flashlight cells, I found that it was approximately

(1) 3 volts.
[✓ *(2) 1.5 volts.*]
(3) 0.

EXPERIMENT 10

Purpose: To show that in a series circuit, there is a voltage across each part, that the sum of the voltages is equal to the source voltage, and that a voltmeter can upset the voltage division.

Introductory Discussion: You already know that if you connect your voltmeter across the battery, you get an indication of the voltage produced by the battery.

When the battery is connected to a series circuit, the battery voltage drives electrons through the circuit. The electrons, in moving through each part of the circuit, set up a voltage across each part. If you accurately measure the voltage across each part and add these voltages, you will find that the sum of these voltages is equal to the source voltage.

In this experiment, you will construct a simple circuit and measure the voltage across each of the individual parts in the circuit to prove that the sum of the voltages is equal to the battery voltage.

Experimental Procedure: In this experiment, in addition to the meter and chassis, you will need:

1 470-ohm resistor
1 680-ohm resistor
1 1,000-ohm resistor
2 100,000-ohm resistors
1 82,000-ohm resistor
2 Flashlight cells

Your flashlight cells should still be connected in series to form a 3-volt battery.

Construct the circuit shown in Fig. 10-1. Solder one lead of a 1,000-ohm resistor to terminal 6. Push the free lead through the slot in terminal 4. Connect the 680-ohm resistor between terminals 3 and 4 and solder terminal 4. Connect the 470-ohm resistor between terminals 2 and 3. Solder terminal 3. Solder the resistor lead and the free end of the positive battery lead to terminal 2.

Step 1: To measure voltages in a low-resistance series circuit.

You will use your 3-volt meter to measure the voltages in the circuit shown in Fig. 10-1.

To measure the source voltage, hold the negative voltmeter lead on terminal 6, and touch the positive meter lead to terminal 2. Observe the meter on the 3-volt scale and place your reading in the space for the source voltage in Fig. 10-2.

Next, while holding the negative voltmeter lead on terminal 6, touch the positive lead to terminal 4 and measure

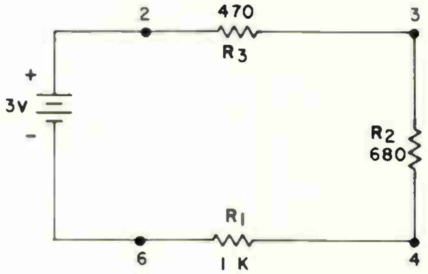

Fig. 10-1. Circuit for Experiment 10.

	READINGS

SOURCE	2.9

Fig. 10-2. Record your reading for Step 1 here.

the voltage across resistor R_1. Record this voltage in the space provided for R_1 in Fig. 10-2.

Move the positive meter lead to terminal 3 and the negative meter lead to terminal 4 and measure the voltage across resistor R_2. Record your reading in the space provided for R_2 in Fig. 10-2.

To measure the voltage across resistor R_3, touch the positive meter lead to terminal 2 and the negative meter lead to terminal 3. Read the voltage on the 3-volt scale on your meter and record your reading in the space provided for resistor R_3, in Fig. 10-2. Now add together the three voltages you recorded for R_1, R_2, and R_3 and put this value in place labeled $R_1 + R_2 + R_3$ in Fig. 10-2.

Unsolder the positive battery lead from terminal 2, to open the circuit. Unsolder and remove the 470-ohm, the 680-ohm and the 1,000-ohm resistors.

Step 2: To measure voltage in a higher resistance series circuit.

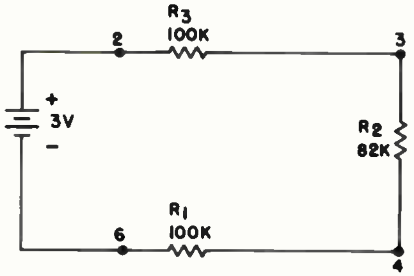

Fig. 10-3. Circuit used in Step 2.

1.35
.85
2.20
.65
2.85

Construct the circuit shown in Fig. 10-3. Solder one lead of a 100,000-ohm resistor, R_1, to terminal 6. Connect the other lead to terminal 4. Connect one lead of the 82,000-ohm resistor to terminal 4 and solder. Connect the other lead of this resistor to terminal 3. Connect and solder the other 100,000-ohm resistor, R_3, from terminal 3 to terminal 2. To complete the circuit, solder the positive battery lead to terminal 2.

Measure the voltage applied to the circuit by holding the positive voltmeter lead on terminal 2 and touching the negative voltmeter lead to terminal 6. Read your meter on the 3-volt scale and record your reading in the space reserved for the source voltage in Fig. 10-4.

	READINGS
R_1	.25
R_2	.2
R_3	.25
$R_1+R_2+R_3$	.75
SOURCE	2.9

Fig. 10-4. Record your readings for Step 2 here.

Using the same technique you used in Step 1, measure the voltages across each of the three resistors. Record these voltages in the spaces provided for it in Fig. 10-4. Now add together the three voltages you recorded for R_1, R_2, and R_3 and put this value in the place labeled $R_1 + R_2 + R_3$ in Fig. 10-4.

When you have made your readings, disconnect the positive battery lead from terminal 2.

Discussion: In Step 1, you measured the source voltage applied to the circuit and you measured the voltage across each resistor. You found that the source voltage was about 3 volts. This is the voltage across the three series-connected resistors.

The voltage drop across R_1 was about 1.4 volts, across R_2 it was about .95 volts and across R_3 about .7 volts. When you added the voltage drops across resistors R_1, R_2 and R_3, you should have found the sum to be approximately equal to the source voltage.

The voltage across a resistor is determined by the current in the resistor and the value or resistance of the resistor. As you would expect from Ohm's Law, the largest resistor has the largest voltage across it while the smallest resistor has the smallest voltage.

Another important point that you should learn from the experiment is how to connect the voltmeter to measure voltage. A voltmeter is always placed in parallel with or across the voltage you are interested in measuring.

To measure the battery voltage in the circuit in Fig. 10-1, you measure between terminals 2 and 6, which are directly across the battery. To measure the voltage across resistor R_1, you measure the voltage between terminals 4 and 6. In every case, the positive meter lead is connected to a more positive point than is the negative meter lead. The negative battery terminal is the most negative point in the circuit. In Fig. 10-1, the voltage at terminal 4 is more positive than the voltage at terminal 6. Similarly, the voltage at terminal 3 is more positive than the voltage at terminal 4 and the voltage at terminal 2 is more positive than the voltage at terminal 3.

You must always connect your voltmeter so the positive lead is connected to the more positive terminal. Otherwise, your meter will read backwards and may be damaged.

In Step 2, you also found that the supply voltage is about 3 volts. However, when you add the three readings taken for Step 2, you will find that the three voltage drops do not add up to 3 volts. At first glance, you might think that something is wrong.

Actually, the error is due to your meter resistance. The circuit you have when you connect the meter across R_1 is shown in Fig. 10-5.

Since the resistance of the voltmeter, which consists of the 15,000-ohm resistor and the resistance of the 0 to 200 microammeter, is only slightly more than

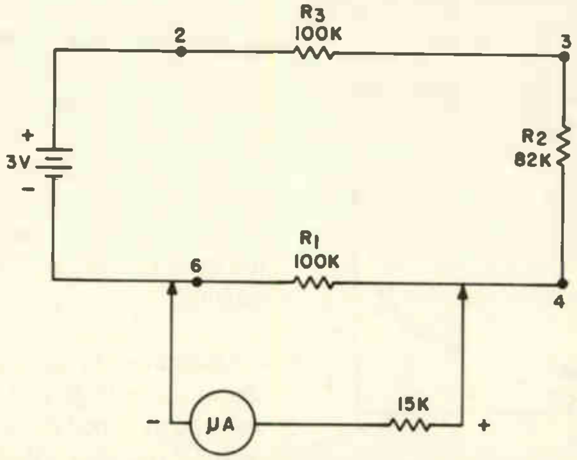

Fig. 10-5. Circuit for Experiment 10 with meter connected across R_1.

15,000 ohms, the total resistance of R_1 and the meter in parallel with it is much less than the 100,000-ohm value of R_1 alone. The resistance of the combination is very close to 15,000 ohms. Therefore, most of the voltage will be dropped across resistor R_2 and R_3, and very little will appear across the combination of R_1 and the meter circuit in parallel with it.

The same thing is true when you connect your meter across R_2 and R_3. Each time you connect the meter across a high resistance, the parallel combination of the meter and the resistor across which you are measuring voltage forms a resistance that is much lower than the original resistor value. The entire circuit, therefore, is upset and the voltage you measure is not the true voltage that is across the resistor when the meter is not connected to it.

To prevent such erroneous readings, you need a meter with a very high resistance. If your meter had a sensitivity of 100,000 ohms per volt on the 3-volt scale, you would have a total resistance of 300,000 ohms in the voltmeter circuit. Then, when you make your measurements, you would be placing 300,000 ohms in parallel with 100,000 ohms. Although the meter resistance is still low enough to upset the circuit you used in this experiment, it would not upset the circuit nearly as much as the 15,000-ohm resistance did.

The resistor values used in the first step were much less than the combined value of the meter and its series resistor. For this reason, the meter resistance has very little effect on the readings you made in the circuit in Step 1.

In your next set of experiments, you will build a transistorized voltmeter. This meter has a resistance of several megohms. Thus, when you use this meter to measure the voltage in high resistance circuits, you will get a more accurate voltage indication than you would using a simple voltmeter such as that which you used in this experiment.

Instructions for Statement 10: For this statement, you are to measure the voltage drop across two resistors. R_1 and R_2 in Fig. 10-3. Solder the positive battery lead to terminal 2. Touch your negative meter lead to terminal 6 and the positive meter lead to terminal 3. Observe your meter indication on the 3-volt scale and write the reading in the margin on this page. .4

Statement No. 10: When I measured the voltage across resistors R_1 and R_2, I found that the voltage was

[✓ *(1) less than 1 volt.*]
(2) approximately 1.5 volts.
(3) approximately 3 volts.

After you have answered the statement, unsolder the positive battery lead from terminal 2 and push it out of the way. Unsolder and remove the red and black meter leads and all other parts and wires connected to terminals 12, 13, and 14. Straighten and clean the leads of the 15,000-ohm resistor and set it aside.

You should still have the two flashlight cells connected in series and attached to the chassis. You should also have the two 100K-ohm and one 82K-ohm resistors soldered to terminals 2, 3, 4 and 6. These resistors and the 3 volt battery will be used in the first experiment of the next training kit.

Looking Ahead

This completes the experiments in Kit 1T. One of the most important things you should have learned is how to solder correctly. As we pointed out, you will make soldered connections in all your electronics work, and one poorly soldered connection can cause you hours of unnecessary work.

In later kits you will have further experience in reading the meter. Of course, you will use the meter throughout your Practical Demonstration Course. You should have learned how to read the 0 to 30 volt and 0 to 12 volt scales in this group of experiments; in the next kit, you will learn how to read the ohmmeter scale. You also demonstrated a number of important basic circuit actions. It is much easier to study and understand the more advanced circuits that you will encounter later if you understand how the simple circuits work, and what changes in the circuit will do to voltage distribution and current flowing in the circuit.

In the next kit, you will build a transistorized voltmeter (tvom). You will find this work extremely interesting, and at the same time you will be building an instrument that will be useful to you in the rest of your experiments, and later when you start work in any branch of the electronics field. In addition to building the tvom you will continue with your studies of basic circuits.

Check to see that your training Kit Report sheet is completed and send it to NRI for grading.

While waiting for the return of this Report and for your next kit, prepare the parts you have left over for use in later kits. The parts left over are shown in Table I. *Remove the meter from its box and unsolder and remove the diodes and wires from the meter terminals.* Also, remove the solder lugs. Clean the meter terminals, and place the meter back in its box. Since the meter is a delicate instrument, be sure to put it in a safe place.

TABLE I

1	Pot mtg. bracket	2	4700-ohm resistors
1	Chassis plate	1	6800-ohm resistor
1	Etched circuit board with tube socket	1	15,000-ohm resistor
1	Marking crayon	1	22,000-ohm resistor
1	Meter	1	1/4" X 6-32 machine screw
1	6-32 hex nut	2	1/4" X 4-40 machine screws
2	4-40 hex nuts	2	Large solder lugs
1	1000-ohm potentiometer	2	Silicon diodes
1	470-ohm resistor		Hookup wire
1	680-phm resistor		Solder
3	1000-ohm resistors		

IMPORTANT: Be sure to save ALL PARTS from this Kit, including screws and nuts, because you will need them later. Keep small parts in individual envelopes or boxes.

The following parts are attached to the chassis plate:

2	Flashlight cells
1	3-lug terminal strip
1	4-lug terminal strip
1	7-lug terminal strip
1	Small solder lug
5	1/4" × 6-32 machine screws
5	6-32 hex nuts
2	100,000-ohm resistors
1	82,000-ohm resistor

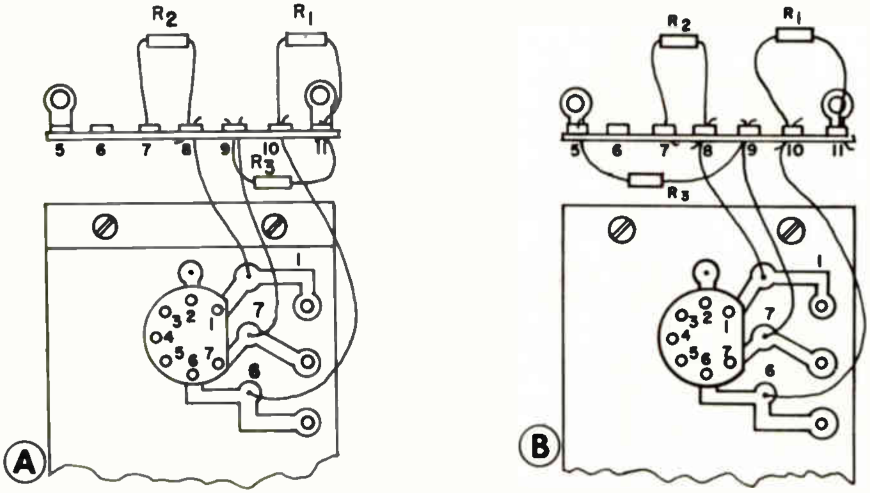

Fig. 4-6. Examples of how you could have wired the circuit used in Experiment 4.

Important Notice

As you use your soldering iron, a scale will accumulate on it. Eventually this scale will keep the iron from heating properly, and you will have to remove it. To do so, remove the tip from the barrel. Remove the scale from the tip and tap the end of the barrel against the workbench to loosen and remove the scale in the barrel. Refile the tip, if necessary, and put it back in the barrel.

If you have a soldering gun, poor contact may develop between the tip and the metal terminals of the gun. This can be eliminated by loosening and then tightening the nuts holding the tip in place. Make sure the nuts are tightened securely. Clean and re-tin the tip when it gets dirty, and replace it when it gets pitted.

Warning

You are expected to make a grade of A, B, C, or D for each group of ten experiments in this Practical Demonstration Course. If any of your reports come back to you marked "Low," you are to repeat the experiments and report statements marked "X" and then send in a complete new set of answers, using the new report blank we will send you. Since this procedure may mean that you will have to dismantle equipment that is to be used as a unit in succeeding experiments, do not begin work on the next Kit until you have received a grade of A, B, C, or D.

Each Day Counts . . .

Each day of our life offers its own reward for work well done, its own chance for happiness. These rewards may seem small, and these chances may seem petty in comparison with the big things we see ahead.

As a result, many of us pass by these daily rewards and daily opportunities, never recognizing that the final goal, the shining prize in the distance, is just a sum of all these little rewards we must win as we go along.

PRACTICAL DEMONSTRATIONS
IN BASIC ELECTRONICS

A Plan For Studying The Experiments

As you know, these Experimental Kits are intended to come to you on a definite schedule. This arrangement is so that you will study the necessary theory in your regular lessons before you carry out any corresponding experiments. This permits you to adopt either of the following plans of study:

1. You may wish to complete one or two experiments in a kit, do a lesson, and then return to the kit for one or two more experiments. This plan permits the experiments in one kit to be finished about the time the next kit is due. Thus, the lessons and experiments run along together, and provide you with a varied program of study.
2. You may prefer to break away from your lessons and to complete all the experiments in a kit at one time before going back to your lessons. This plan has the advantage that you do not waste any time getting out and putting away materials, but it can be followed only if you can leave your equipment set up long enough to finish.

Whichever plan you follow, you can begin NOW with the experiments in this kit. However, be sure to read the preliminary information on pages one through sixteen before you begin, so you will know just how the experiments are to be carried out. In a similar manner, begin on future kits as soon as you receive them.

NOTICE

NRI has set up the CONAR Division of the National Radio Institute to handle the sale of professional test equipment and other electronic equipment. NRI has had unsurpassed experience in the design of quality kits. All CONAR kits are designed and produced by the National Radio Institute. The transistorized volt-ohmmeter you will build as part of your training is the CONAR Model 212. This is the same professional tvom you will see advertised nationwide. Several of the parts you received in this kit, including the meter, will be used in the assembly of your tvom.

INSTRUCTIONS FOR PERFORMING EXPERIMENTS 1 THROUGH 10

LECTURE-ROOM DEMONSTRATIONS YOU PERFORM IN YOUR OWN HOME

How many times have you heard the expression, "Seeing is believing"? Probably many times, because it is human nature to doubt something you cannot see or touch.

Although you can learn how a piece of equipment works from pictures and words, the average person understands better if he can actually set up equipment and make tests himself to see how it works.

You must have a knowledge of theory before you can work successfully in the radio-TV-electronics field. However, unless you know how to apply theory and make tests, your knowledge is useless. Theory and practical application must go hand-in-hand.

The NRI Course of training is a well-balanced combination of theory and practical instruction. Practical demonstrations and experiments are given in this manual and the following manuals.

Doing these experiments will give you actual experience in handling parts and making measurements, and will help you understand explanations of more advanced circuit actions. This type of experience is more valuable to you than class or lecture-room demonstrations by an instructor in which you take no active part, and you can do the experiments at your own convenience.

This practical work with experimental equipment will help you develop confidence in your own ability and will provide what you need to become a practical technician.

The experiments will help you to solve technical problems you will encounter in your work. You will see for yourself what happens when a particular part is defective, and you will learn how to detect and correct errors and how to adjust circuits.

Every experiment in every manual is important, because it is an actual working demonstration. Do not pass over any of them hurriedly, even though you may feel that you already know the results.

If you look underneath the chassis of any modern piece of electronic equipment, you will see that the connections are soldered. A soldered connection is the most reliable type of connection to make in commercial production because it will not deteriorate much during the entire life of the electronic equipment.

When you repair defective equipment, you must be able to find the defective stage and then the defective part. However, the ability to find what is wrong is of little use unless you also know how to take out the defective part and how to solder the connections for a new part. Furthermore, you may often have to unsolder one or more connections during your tests in order to find the defective part.

In the first section of this manual, you will study the fundamentals of soldering and learn how to make a good soldered connection using actual electronic parts. You will make these connections in ex-

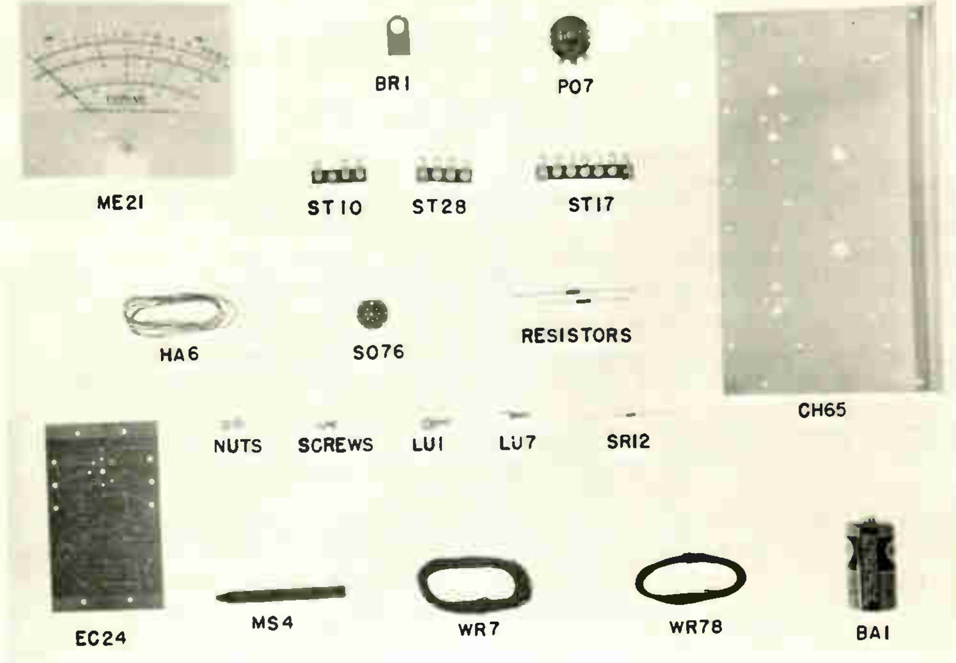

Fig. 1. Parts used in this Experimental Manual are shown here and listed below.

*All resistors are 1/2-watt, 10% tolerance unless otherwise specified.

actly the same way that you would in working on commercial equipment. The solder, hookup wire, and other parts that are included in this kit are standard items, just like those that you might use in working on any piece of electronic equipment. In later experiments, you will have practice in working from schematic diagrams. You will also assemble a number of simple circuits to demonstrate some basic electrical laws.

HOW THE MANUALS ARE ARRANGED

The manual for each kit in your Practical Demonstration Course contains the instructions for performing ten experiments. These experiments are numbered consecutively throughout the whole series; Experiments 1-10 are in the first manual, 11-20 in the second, etc. At the end of each experiment is a Statement that you are to complete, so that you can check your work as you go along. When the ten statements have been answered, be sure to submit the training Kit Report to NRI for grading.

In each manual, the figures are numbered to correspond to each experiment. Each figure number has two parts. The first part is the number of the experiment in which it appears, and the second part is the number of the figure within the experiment. For example, Fig. 1-3 would be the third figure in Experiment 1; Fig. 6-2 would be the second figure in Experiment 6. If there are any figures that do not apply to one particular experiment, they will be numbered consecutively in each manual, starting with Fig. 1.

CONTENTS OF THIS KIT

The parts included in your first kit are pictured in Fig. 1 and listed below. Each part that you receive in your kits is assigned a part number. The part number and description appears below Fig. 1. When you need a part for the experiments, you will be given the part value, a description, and in some cases the part number.

Now check the parts that you receive against this list to make certain that you have all of the parts. *Do not lose or discard any of these parts because you will use many of them again in later experiments.*

For your convenience, most of the parts are packed on cardboard under a clear plastic film. This protects the parts during shipment and also makes it easy to inventory your parts. To remove the parts, cut around them with a sharp knife or a razor blade.

IMPORTANT: If any part of this kit is obviously defective or has been damaged during shipment, please return the defective part to NRI for replacement, following the procedure given on the "Packing and Returned Material Slip" enclosed in this kit.

Preparing For The Experiments

Before you start the experiments, there are several things you will need to do. You will need a place to work and tools to work with.

You do not need an elaborate workbench. A folding card table set up near an electrical outlet will be satisfactory. Do not use a metal-top table, because it could cause short circuits that might damage the equipment. If you have to use a metal-top table, cover the top with a nonconductor, such as cardboard or linoleum.

TOOLS YOU WILL NEED

The tools you need to do these experiments are the same as those you will use in all kinds of electronic work. They are pictured in Fig. 2, and listed under the figure. None of these tools are supplied with this kit. Probably you already have some of these tools, since the average home usually does have a few tools for simple repair work.

You can get those tools you do not have from hardware stores, radio-supply

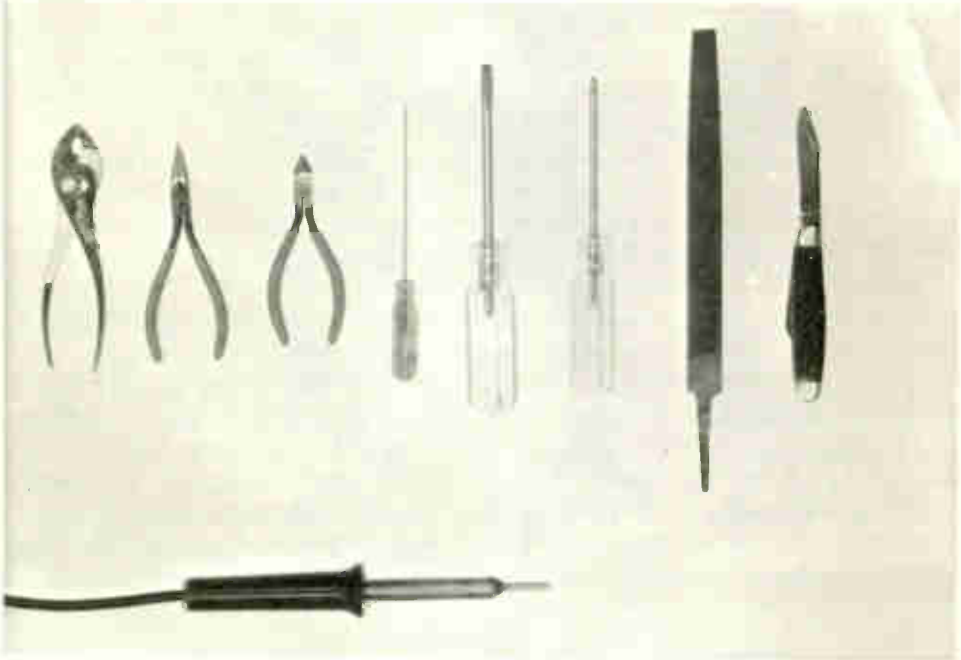

Fig. 2. These are the tools you will need to do these experiments. You probably already have many of them. Get the best ones you can afford; you will be using them throughout your course as well as when you do service work. These tools are not supplied with your kits. From left to right, all-purpose pliers, longnose pliers, diagonal cutters, small screwdriver, medium size screwdriver, Phillips screwdriver, metal-cutting file, and pocket knife. Below the tools is a soldering iron.

houses, or mail-order firms. Since you will use the tools in all of your electronic work, they are a worthwhile investment. Select good quality tools that "feel right" in your hand.

Pliers. The technician needs three types of pliers: longnose pliers, diagonal cutters, and ordinary slip-joint pliers. Each type has its own purpose and should be used for that purpose only. Pliers are designed primarily for holding, bending, and cutting. Many people use them for other purposes so they often ruin them or mar the material on which they are working.

Perhaps the pliers most often used in electronics are the longnose type. Although you may use longnose pliers to hold a nut in position so that it can be started on a screw, you should never use them to tighten nuts. You may spring the jaws so the points will not meet or you could actually break one of the jaws. Use your longnose pliers to hold wires in position for soldering, to remove wires, or for hard-to-reach places.

Diagonal cutting pliers, or "side cutters" as they are often called, are used for most cutting operations. Because the cutting jaws are at an angle, these pliers are ideal for cutting wires close to terminals.

Combination slip-joint pliers, often called "combination pliers," are also in common use. Because of the slip joint, the jaws can be opened wider at the hinge pin so that larger diameters can be gripped. These pliers come in 5, 6, 8, and 10-inch sizes. The thin-type, 6-inch size is best for electronics work.

Screwdrivers. Practically everyone is familiar with the standard screwdriver. The screwdriver is intended for one principal purpose - to loosen or tighten screws. Because the average person uses a screwdriver as a can opener, a pry or pinch bar, and even as a chisel, the screwdriver is one of the most abused tools.

The technician needs three screwdrivers - one with a small blade for loosening setscrews in dial and control knobs and one with a medium blade for general purpose work. He also needs a Phillips screwdriver because screws with a special head known as a "Phillips head" are often used in electronic equipment. Screwdrivers with plastic handles are best because the plastic is a good insulator. Later on you will need a special type of screwdriver, known as an "alignment tool." This is a non-metallic tool for special uses, but you won't need it now.

Files. There are more than twenty types of files. Each type comes in sizes from three to eighteen inches. They may be either single or double cut and are classified according to the different grades of coarseness or fineness, depending upon the size and spacing of the teeth.

The type most often used in electronics is a 10-inch second-cut mill file. It is used to keep the tip of the soldering iron in good condition by removing small amounts of metal, leaving the filed surface smooth. This type of file is also useful in brightening lugs for easier soldering.

Knife. A good knife is useful when preparing wires for connection to other parts; a sturdy pocket knife is fine.

Soldering Iron. The soldering iron is used more often by servicemen than any other tool. Since you will use it often and it is so important, you should choose it carefully. A number of soldering irons suitable for electronics work are shown in

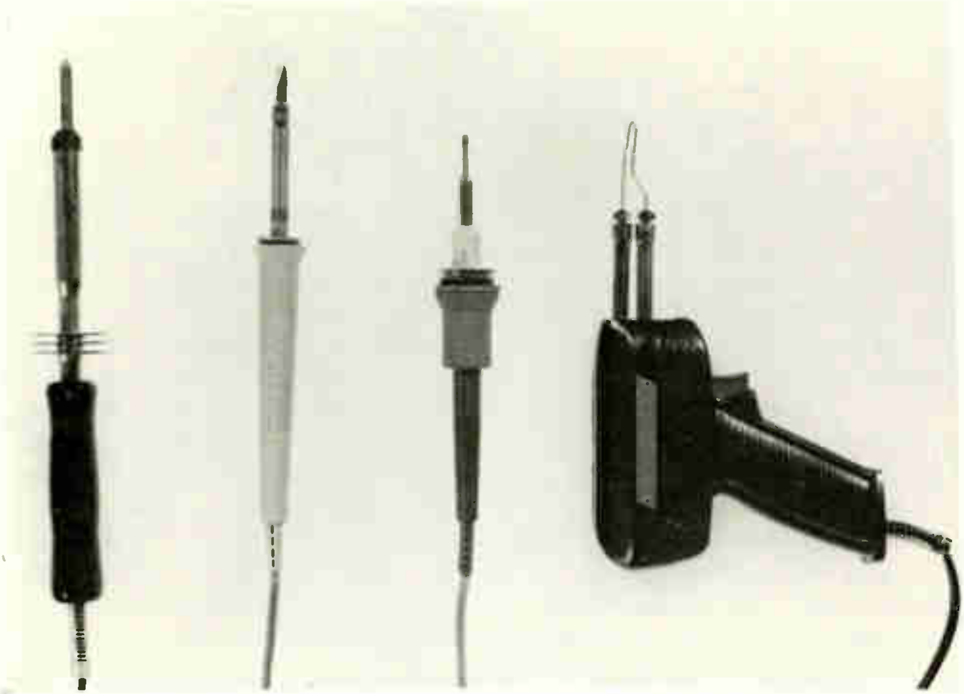

Fig. 3. Several soldering irons suitable for electronics work.

Fig. 3. It is best to buy a soldering iron from a firm that specializes in electronics parts. You should obtain your iron from your local wholesaler, from a mail-order wholesaler, or from the CONAR Instruments Division of NRI.

Hardware stores sometimes carry soldering irons in stock, but they may have only the large type that is used for heavy work, such as automobile radiator repair or roofing work. These irons are too heavy for easy handling and too big to be used where small parts are crowded together.

From left to right in Fig. 3, the first iron is called a medium duty iron. This type of iron generally has a rating of from 50 to 150 watts and is used where a relatively large amount of heat is needed, such as when soldering to the chassis.

The two irons in the center are "pencil" type irons. These types have replaceable heating elements and tips. They are available with various wattage ratings, usually 25 to 40 watts, suitable for general electronic soldering, and 40 to 50 watts, for heavier duty work. These "pencil" irons are the types most suitable for the beginner as they are lightweight and easy to handle. Perhaps the most suitable iron for the beginner would be one like the third iron from the left in Fig. 3. A 37-1/2 element and a chisel-shaped tip make an ideal choice of element and tip.

At the right in the photo is a soldering gun. A gun of this type has the advantage over the iron in that it heats and cools very quickly. Thus, it is excellent for a serviceman making house calls or a technician working on equipment in a plant. He plugs the gun in when he arrives at the job and it is ready for use immediately. Everyone going into electronics, whether on a part-time or full-time basis, will find a gun useful. However, it is not quite as easy to turn out well-soldered connections with a gun as it is with an iron. Therefore, the beginner should start with a conventional soldering iron and learn to use it correctly and later, if he so desires, he can use a soldering gun.

As mentioned previously, the most suitable single iron for general service work and for use in your kits is an electric iron with a tip about an inch long and 1/8" to 1/4" in diameter. The tip should be of the chisel type with two flat surfaces. The wattage rating should not be more than 50 watts, because a high-wattage iron is bulky, and if its barrel touches parts, it may damage them.

When you buy an iron, be sure you get a soldering iron stand with it, to rest the hot iron on when it is not in use. Or get an iron that is designed so that the handle is heavier than the tip end. Then the iron will balance when it is laid down with the tip off the bench.

The average electric soldering iron will operate on ac or dc at 117 volts. Power-line voltages may vary between 110 and 120 volts; an iron designed for 117-volt operation may be used on any voltage between 105 volts and 130 volts.

Although the modern soldering iron is a rugged tool, it should never be abused. Do not use it as a hammer, drop it, or attempt to cool it quickly by plunging it into water. When properly cared for, an iron will last for years.

Although some irons have pre-tinned tips, most tips must be tinned before use. If your iron has a bright, shiny tip or a dull gray tip, it has been pre-tinned, and it is ready for use. If the tip is a natural copper color, you must tin it before using it.

TINNING A SOLDERING IRON

You cannot solder properly unless your soldering iron is properly tinned. Therefore, your first step in learning how to solder is to learn how to tin a soldering iron.

The tip of the soldering iron is made of copper. When an untinned soldering iron is heated, the copper combines with the oxygen in the air, forming a dark coating of copper oxide on the tip of the iron. If you try to use an untinned iron, the copper oxide coating will act as a heat insulator and keep the heat of the iron from the parts you are trying to solder. It will be practically impossible to heat the part sufficiently to melt the solder properly.

You can prevent this by covering the tip of the iron with solder. This is called "tinning" the iron. The solder will form a protective layer over the copper tip so that the oxygen cannot get at the copper and corrode it. The tinned tip will be a good conductor of heat, and you will be able to heat the parts enough to solder them properly.

Preparing the Tip. The first step in tinning a soldering iron is to examine the tip. A photograph of the tip of a new soldering iron that has not been tinned is shown in Fig. 4A, and a photograph of a soldering iron that has been used and needs re-tinning is shown in Fig. 4B. Notice that the tip of the new iron is reasonably smooth, whereas the tip of the iron that has been used is pitted, dirty, and uneven.

If your soldering iron is in good condi-

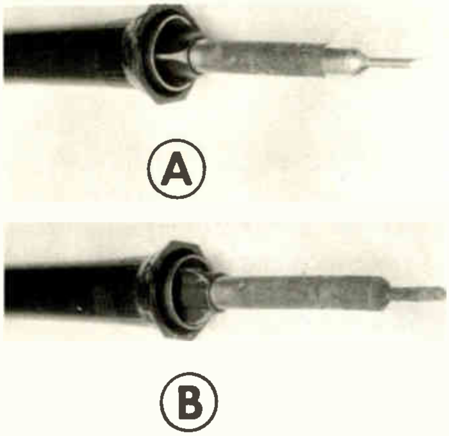

Fig. 4. If your soldering iron is new and has not been tinned as at (A), or if it has been used and is pitted as at (B), it will need tinning.

tion, like the one shown in Fig. 4A, you can plug it into an electrical outlet and start heating it. On the other hand, if you have an iron that has been used and looks like Fig. 4B, you should file the tip smooth before you start to heat it. Even though your iron may be in good condition, read the following instructions carefully, because after your iron has been used for some time, it will become pitted like the one shown in Fig. 4B. You will have to go through this procedure to re-tin it.

To file the tip of the iron, rest the iron on a vise or a similar metal support, as shown in Fig. 5. Grasp the iron in one hand and proceed to file one of the surfaces flat as shown. Try to file the surface at approximately the same angle as that of the original tip. Do not remove any more metal than is necessary, but make sure that you file the surface until all of the dark spots and holes in the surface are gone. When you have completed the operation, the tip of the iron should look as it does in Fig. 6.

After you have filed one surface of the tip, turn the iron over. In other words, rotate the iron 180°, and file the surface flat on the opposite side of the tip. Again, remove no more metal than is necessary, but make sure you file the surface until it is clean. Try to file at the same angle as the first surface, as shown in Fig. 7.

If your iron has a pyramid-shaped tip, turn the iron a quarter turn and file one of the other surfaces. Then turn the iron over and file the last surface. When you

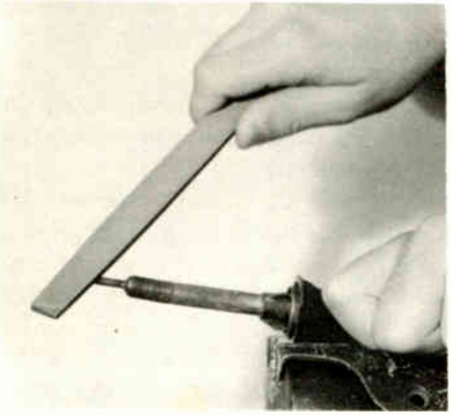

Fig. 5. To file the tip of your iron, hold it against a vise as shown here.

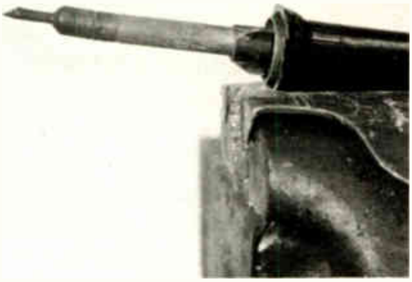

Fig. 6. When you have filed one surface, your iron should look like this.

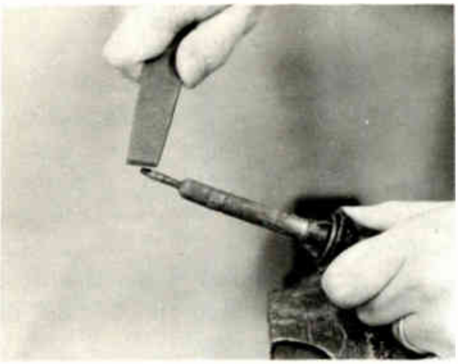

Fig. 7. File the opposite surface at the same angle as the first surface, as shown.

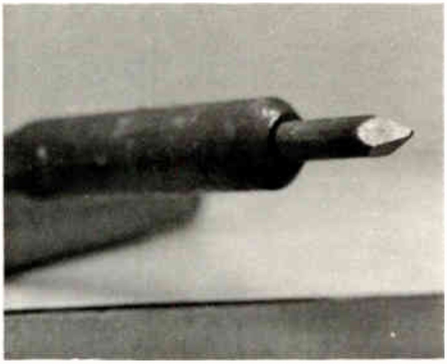

Fig. 8. Your iron should look like this after filing all four surfaces on its tip.

have filed all tip surfaces, the tip of the iron should look like the one shown in Fig. 8. Notice that the sides are approximately even.

Before you start to heat the iron, examine the edges of the flat surfaces on the tip. If the edges are rough, smooth them by careful rubbing with a piece of sandpaper.

Tinning the Iron. After you have prepared the surface for tinning, or if you are tinning a new iron that is in good condition, plug the iron in and wait for it to heat. As the iron heats, periodically touch the end of the solder to the tip so you will know when the iron is hot enough to melt the solder. You should tin it as soon as it reaches a high enough temperature, because the longer an untinned iron is heated, the more copper oxide will form on the tip.

When the iron has reached operating temperature, again rest it on a vise and lightly file one surface as shown in Fig. 5. Once you have filed the surface lightly so that it is shiny, quickly set the file down, pick up the roll of solder, and touch the end of the solder to the tip of the iron. Move the solder around the tip until the entire surface is tinned, as shown in Fig. 9. After you have tinned one surface of the tip, turn the iron and go through the same procedure of lightly filing the other surfaces, and then applying solder.

After you have tinned the surfaces of the tip, use a clean cloth to wipe off any excess solder. Hold the cloth loosely as shown in Fig. 10 to avoid burning your hand. When you have your iron tinned, it is ready for use. Unplug it, and set it aside until you are ready to start soldering.

Fig. 9. How to apply solder to tin the tip of the iron.

Fig. 10. Wiping excess solder from the iron with a piece of cloth.

Notice that the solder you received in this kit contains a rosin core that acts as a cleaning agent and prepares the metal surface to receive the solder. It is difficult to make a good soldered connection using plain solder alone; another material called flux must be applied along with the solder. Rosin flux is used in this case. Only rosin core solder should be used in soldering electronic equipment.

Hardware and other stores sell some solder with an acid core. Acid flux in any form should never be used in electronic equipment. The acid will corrode the leads and terminals and may damage some of the parts. Use only rosin core solder in electronics work; do not use liquid or paste flux. Solder similar to that which we have supplied in this kit should be used in all your electronics work.

IMPORTANT NOTICE

In checking students' problems, NRI has found that poor soldering is more frequently the cause of failure to get proper results than all other troubles combined. Therefore, be sure to perform every step in each experiment to learn all you can about soldering.

DO NOT SKIP ANY STEPS

MOUNTING THE PARTS

Most of your experiments will be carried out on your experimental chassis plate which is shown in the parts photo, Fig. 1. You will mount several parts on the chassis plate before you begin the experiments.

The parts supplied with this kit are shown in Fig. 1 and identified in the list below the photograph.

Gather the following parts and place them on your worktable. Then they will be handy when you are ready to use them:

1 Chassis plate (CH65)
1 7-lug terminal strip (ST17)
1 3-lug terminal strip (ST10)
1 4-lug terminal strip (ST28)
1 Potentiometer mounting bracket (BR1)
1 1K-ohm potentiometer (PO7)
1 Solder lug (LU1)
6 1/4" X 6-32 screws (SC1)
6 6-32 hex nuts (NU1)
1 Marking crayon (MS4)

Notice that we have supplied two sizes of screws and nuts. The size of a machine screw is given by its diameter and the number of threads per inch. The first number is the diameter. Thus, the 6-32 screws (SC1) are larger in diameter than the 4-40 screws (SC6), but the 4-40 screws have a finer thread. The length of a screw is given in fractions of an inch.

Follow the instructions as you mount the parts on your chassis and do not attach any parts until instructed to do so.

Place the chassis upright on your worktable so that the holes are positioned as shown in Fig. 11. The bent lip should be away from you and pointing upward. To

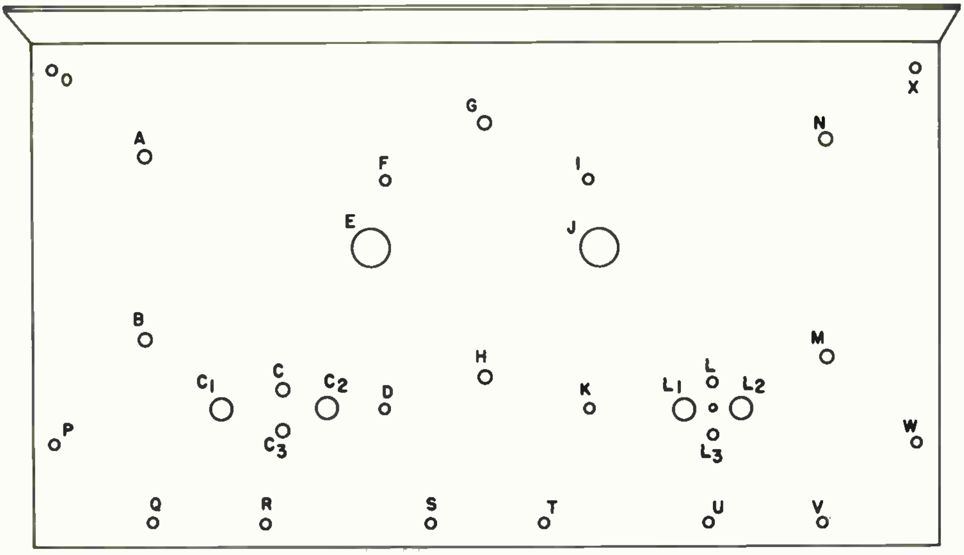

Fig. 11. Chassis hole identification.

help you locate the parts correctly, we have given the holes identifying letters. You can use the marking crayon to label these holes on the chassis. If you prefer, you can put small pieces of tape near these holes and mark on the tape with a pen.

Fig. 12 shows the chassis with the parts

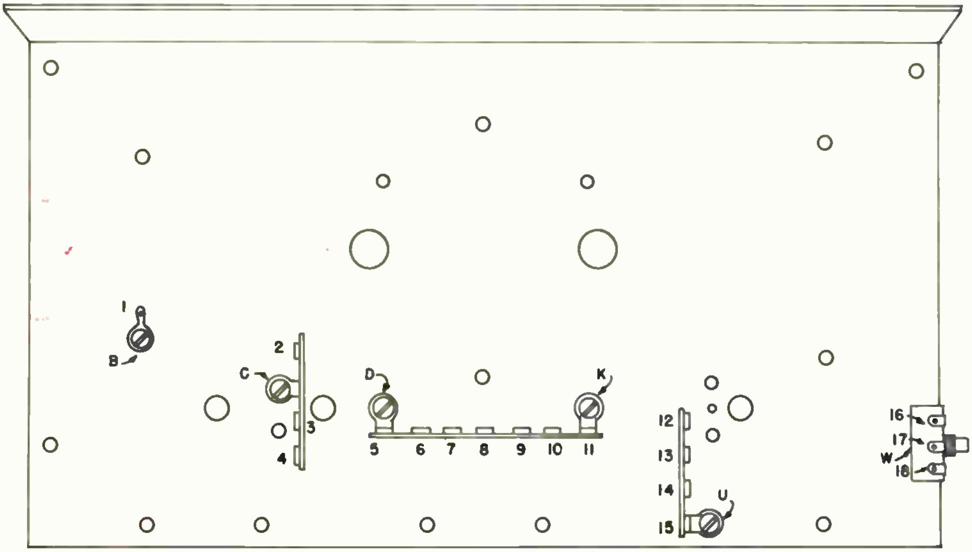

Fig. 12. Parts mounted on the chassis and the terminal identification number.

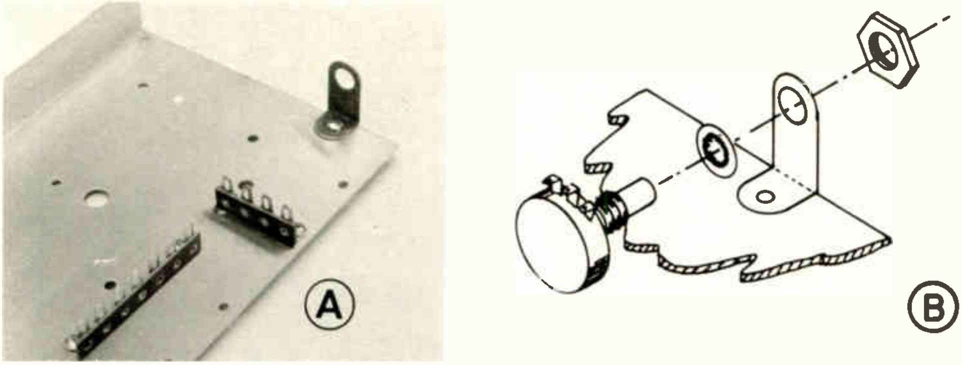

Fig. 13. (A) Mounting the potentiometer bracket; (B) mounting the potentiometer.

mounted on it. Be sure to mount the parts at the correct location and position them as shown in the drawing.

Mount the 3-lug terminal strip at hole C, as shown in Fig. 12. Pass a 1/4" X 6-32 screw down through the mounting foot in the terminal strip and through hole C in the chassis. Attach a 6-32 hex nut. Position the terminal strip as shown and tighten the screw. Hold the nut with pliers as you tighten the screw.

Install the 7-lug terminal strip at holes D and K. Use 1/4" X 6-32 screws and nuts. Position the strip exactly as shown in Fig. 12. Pass a screw down through the left mounting foot and hole D and attach a nut. Pass a screw through the other mounting foot and through hole K. Attach a nut and tighten both screws.

Mount the 4-lug terminal strip at hole U. Use a 1/4" X 6-32 screw and nut. Position the terminal strip as shown in Fig. 12 and tighten the screw.

Install the potentiometer mounting bracket at hole W. See Fig. 13A. Use a 1/4" X 6-32 screw and nut. Pass the screw down through the small mounting hole in the bracket and through hole W in the chassis. Attach the nut and tighten the screw.

Install the potentiometer in the potentiometer mounting bracket. As shown in Fig. 13B, slip the large lockwasher over the shaft and bushing of the potentiometer and slip the bushing through the hole in the bracket mounted on the chassis. Attach the large control nut, turn the potentiometer so its terminals are upward; then tighten the control nut.

Bend the solder lug at about a 45° angle, as shown in Fig. 14. Mount the solder lug at hole B, using a 1/4" X 6-32 screw and nut. Tighten the screw.

The numbers appearing in Fig. 12 are the terminal identification numbers. They will be used throughout this kit for identifying the terminals when making connections.

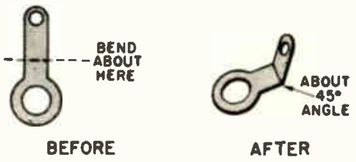

Fig. 14. Before you mount the solder lug, bend it as shown here.

Learning To Solder

Our experience in teaching students has shown that over 75% of the troubles encountered by students and technicians is due to poor soldering! You might think from this that good soldering is difficult, but this is not true. If you watch an experienced man work with a soldering iron, it looks quite simple. The experienced technician follows the two basic rules given below to make good soldering easy.

First: Have the materials to be joined and the tip of the iron clean and free from grease. If the terminals or wires are not bright, scrape them with a knife or with a piece of fine sandpaper until they are clean and bright.

Second: Have the sections to be joined hot enough to melt the solder so that it will run freely to all parts of the connection and form a good bond.

If you follow these two basic rules, you will never have soldering trouble. If you ignore them, you may spend hours looking for defective parts when the trouble is simply a poorly soldered connection.

SOLDERING TECHNIQUES

Perhaps the most important step in making a good soldered connection is to make sure that the parts you are attempting to solder together are clean. For example, if you try to solder a capacitor lead to a terminal strip, and the capacitor lead is not clean, you will find it practically impossible to get the solder to stick to the lead.

All leads, whether they are resistor or capacitor leads or merely wires to be soldered, should be tinned before you attempt to solder them. Most of the resistors and capacitors that you will receive in your kits have been tinned by the manufacturer. However, in the manufacturing processes, the tinned surface sometimes becomes covered with wax or other impurities. These leads should be cleaned and retinned whenever necessary.

You can use approximately the same procedure to tin a lead as you used to tin the tip of your soldering iron. The first step is to clean the lead. You can either scrape the lead carefully with a knife, as

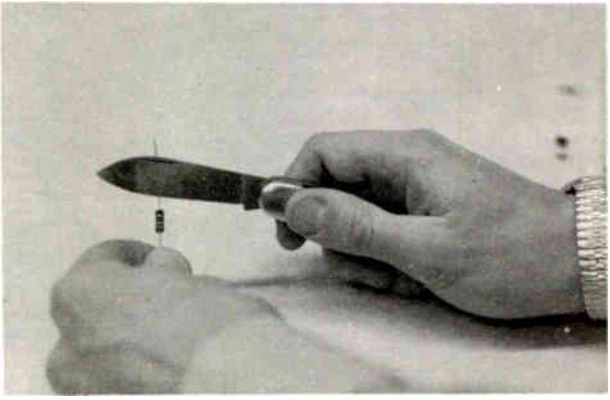

Fig. 15. How to use a knife to clean a resistor lead.

Fig. 16. Using sandpaper to clean a lead.

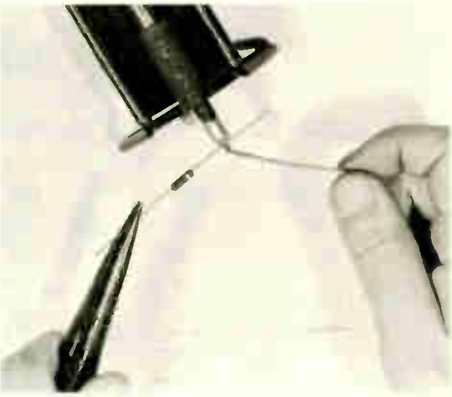

Fig. 17. How to tin a resistor lead.

shown in Fig. 15, or you can use a small piece of fine sandpaper. Hold the lead in the sandpaper, as shown in Fig. 16, and draw the sandpaper over the lead several times.

After you have cleaned the lead, hold the part with your longnose pliers and touch it to the tip of your soldering iron, as shown in Fig. 17. Then touch the solder to the lead. Allow a small amount of solder to melt onto the lead and onto the tip of the iron. Move the lead back and forth through the solder to tin the entire lead. If you apply enough heat to melt the solder thoroughly, the solder will flow smoothly over the lead, as shown in Fig. 18. Tin the other lead in the same way.

Lugs on terminal strips also should be cleaned and tinned before you attempt to solder a wire or a lead to the lug. Usually, brushing over the terminal quickly with a piece of sandpaper will remove any dirt or grease that may be on the terminal. Sometimes it will be necessary to scrape the terminal with a knife or file.

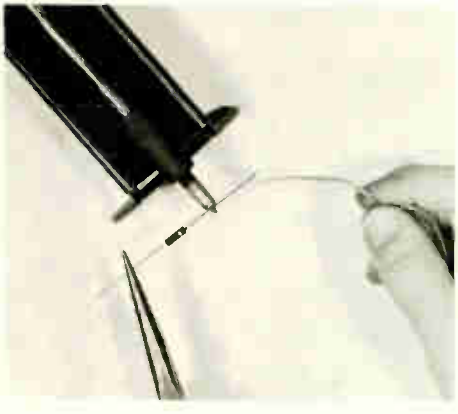

Fig. 18. A tinned resistor lead.

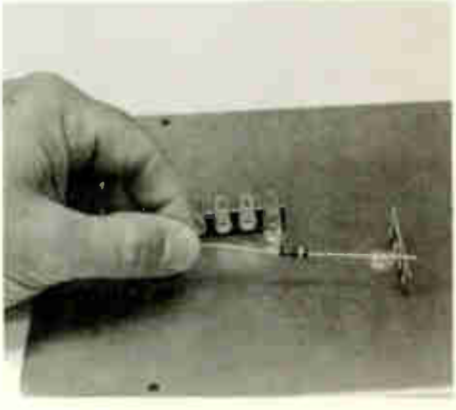

Fig. 19. Making a connection to terminal.

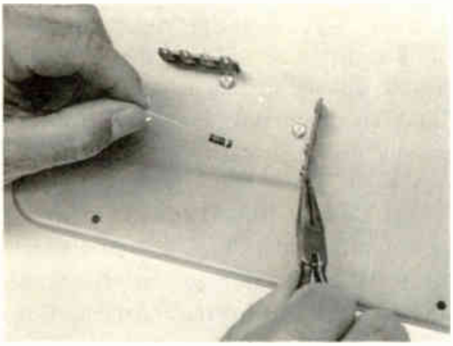

Fig. 20. Bending the lead.

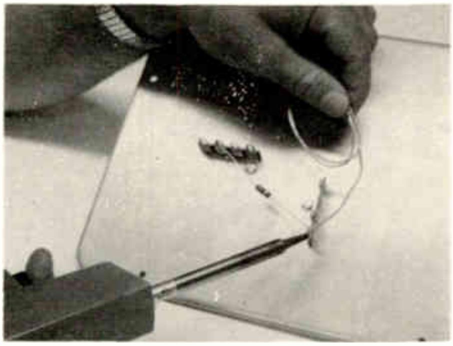

Fig. 21. Soldering a connection.

The tube socket pins and lugs on the terminal strips that you will receive in your kits have been tinned. You should have no trouble in soldering to these terminals. However, before soldering to them, carefully examine them to be sure they are clean. If they are not, clean and tin them to avoid soldering difficulties later.

To solder a lead to a terminal strip or solder lug, place the lead through the opening in the terminal lug, as shown in Fig. 19. Bend the end of the lead slightly as in Fig. 20 so that the lead can be placed in contact with the metal part of the lug. Do not wrap the lead around the terminal strip lug unless you are told to do so. This type of connection is too difficult to remove. Later, when you begin wiring equipment that you will leave assembled permanently, you will wrap the leads around the various terminals in order to insure strong mechanical and electrical connections.

When you have the lead in place, hold your soldering iron against the terminal and against the lead, as shown in Fig. 21, to heat both of them to the solder-melting point. Unless you heat them both, you will not make a good connection.

After they are hot enough, touch the end of the solder to the terminal and lead, so that the solder will flow freely over the resistor lead and the terminal. Do not use too much solder. You want only enough to cover the resistor lead and hold it to the terminal. If you use too much, the solder will flow down the terminal strip and may short to the chassis. A properly soldered connection showing the correct amount of solder is shown in Fig. 22, and a connection with an excessive amount of solder is shown in Fig. 23.

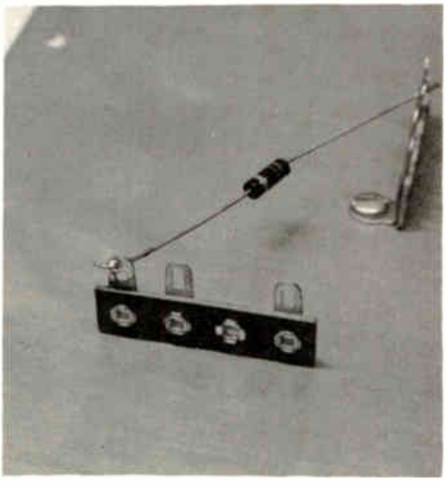

Fig. 22. Good solder connection.

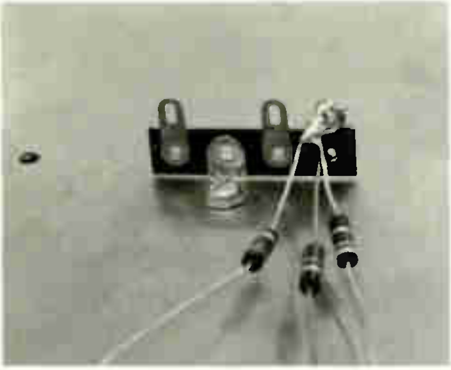

Fig. 23. Poor solder connection (too much solder).

When soldering a connection, do not be in a hurry to get the soldering iron off the connection. In most cases, it is better to hold the iron on the connection a little too long than it is not to hold the iron on long enough. When you are starting to solder, watch each connection carefully. Hold the iron on the connection long enough to allow the solder to flow freely. Solder should melt and flow in, around, and over all the leads you are attempting to solder to a terminal. The solder should also flow freely over the terminal. If you hold the iron on the terminal only long enough to melt the solder and have it start to flow, you will find that you have a rough-looking joint, and the chances are that if you apply pressure to the leads, they will pull loose. On the other hand, if you hold the iron on the joint long enough to allow the solder to melt completely and flow freely over the joint, you will have a smooth-looking connection that will be mechanically strong. This is extremely important - make sure that the solder flows freely over each connection you make.

Using Too Much Solder. Avoid using too much solder. It takes very little solder to make a good electrical connection. Usually, if you heat the terminal and lead sufficiently, you will find that a drop of solder will be all that is needed. Do not hold the soldering iron in place and simply melt more and more solder onto the joint. Once you have one drop of solder flowing around the joint, lift the solder off the terminal, but continue to heat the connection so that the solder that you have on the terminal flows around the leads and over the terminal. This may be all the solder you need. If not, add more solder and allow it to flow into the joint. If you use too much, the solder will flow between the pins and the chassis, and between the chassis and terminal strip lugs.

It is particularly important that you heat large wires thoroughly. You will often find in your radio, TV, or electronics work that you must solder transformer leads in place. Usually the leads from a transformer, particularly the leads from the filament winding on a TV replacement power transformer, will be of a fairly large size. In addition, they are made of copper, which is a good heat conductor. As a result, they can carry away a substantial amount of heat. You will have to be sure that you have the iron in good contact with the lead when making this type of connection.

Etched Circuit Wiring. Etched or "printed" circuit boards are used in many radio and TV receivers as well as in other types of electronic equipment. You can expect to have to wire and to repair circuit boards. Therefore, you should know how to do so.

Examine the etched circuit board included in your kit (NRI part EC24). This is fairly typical of the boards used in commercial equipment. The board consists of a sheet of phenolic, which is an insulating material, with a pattern of copper foil strips bonded to one side. Notice that the copper foil connects together holes in the circuit board. When parts are mounted on the board with their leads extending through these holes and soldered to the copper, the copper foil provides the electrical paths which connect the parts together to form circuitry.

We call them "etched" circuit boards because of the way the boards are made. Each board is cut from a large sheet of phenolic to which a sheet of copper foil has been bonded. The desired copper foil pattern is transferred to the board by a photographic process. The board is then placed in a highly corrosive solution which etches away the unwanted copper foil, leaving the desired foil pattern.

After the etching is completed, the board is cleaned and the holes are drilled or punched and the lettering and other markings are printed on the phenolic.

Parts are usually mounted on the phenolic side of the board and they are supported by their leads, as shown in Fig. 24. The leads are passed through the holes in the board and soldered to the foil. When you install a part, bend the lead outward slightly to hold the part until you can solder the leads. Place the tip of your iron in contact with the lead and the foil and apply solder. Allow a small amount of solder to melt and flow into and around the joint. After the solder cools, cut off the lead flush with the top of the soldered connection. Fig. 25 shows an etched circuit board with good soldered connections.

As you go through these experiments, pay particular attention to each soldered connection you make. Tin the part leads before attempting to solder them; heat each connection thoroughly; inspect each connection and wiggle the leads after it is soldered to make sure that it is a good solid connection. Try to develop sound soldering habits; they will save you a great deal of time and difficulty, not only in your experiments, but all through your electronics career.

Performing the Experiments. To get the most benefit from the experimental course, you should follow a logical, planned procedure in each experiment. When you start a new manual, always study first the introduction at the beginning of the book. Then perform the experiments one at a time, in the correct order, by observing the following procedures:

1. Read through the instructions and discussions for the entire experiment once very slowly, and study any parts that are not immediately clear to you. Do not touch a single tool or part until you make this preliminary study.
2. Lay out on your worktable the

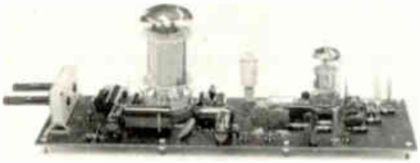

Fig. 24. Phenolic side of an etched circuit board with the parts installed.

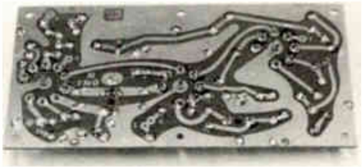

Fig. 25. Foil side of an etched circuit board, showing the parts installed.

parts and tools needed for the experiment to be performed.

3. Carry out the experiments one step at a time. Record your results whenever spaces are provided in the manual for this purpose. Additional observations and comments can be written in the margins of the pages for future reference.

4. Study the discussion at the end of the experiment very carefully, and analyze your results. After finishing an experiment, you should be able to tell in your own words exactly what you proved and how you did it.

5. Complete the Report Statement by writing the Statement Number on your Training Kit Report sheet in the space provided. Then enter the number of your choice for completing the Statement in the next column. Use the additional columns to the right for Statements that have more than one part.

6. When you have completed all ten experiments in the manual and have answered all of the statements, send in your Report Sheet for grading. Do not send in the manual.

EXPERIMENT 1

Purpose: To mount parts in a circuit; and to make soldered connections to these parts.

Introductory Discussion: Solder will hold parts together mechanically and fuse parts together so that they are, in effect, a single unit. A good soldered joint has little or no resistance and protects the surfaces of the parts from oxidation. Good soldered connections are a clue to the technician's ability. A man with an average knowledge of theory who can make good soldered connections will have less trouble than an expert on theory who cannot solder! In this experiment, you will mount parts and make several soldered connections. This experiment may seem simple, but do not pass over it quickly. The points that will be brought out are all very important.

Soldering ability is not hard to acquire and you should make this your first goal.

Experimental Procedure: Before you start the experiment, make sure your workbench is cleared so you will not lose any parts or have anything in your way. Gather your tools and the parts you will need in the experiment. At this time you should have a potentiometer, a solder lug and three terminal strips mounted on the chassis.

In the experiment, you will need the chassis with the parts mounted on it and the following parts:

3 **1000-ohm resistors (RE30; brown-black-red-silver)**
Rosin-core solder

Step 1: To prepare the parts to be soldered.

If you have the parts mounted on the chassis correctly, you are ready to wire the circuit by soldering resistors to various terminals. Plug in your soldering iron so that it can be heating.

Tin each lead of the three resistors until they are bright and shiny.

As you were instructed previously, you can use a knife or a small piece of sandpaper folded and held between the thumb and forefinger to clean the leads if they will not tin easily.

Test the iron by touching the end of the solder to the tinned tip of the iron. If the solder melts readily, the iron is ready for use.

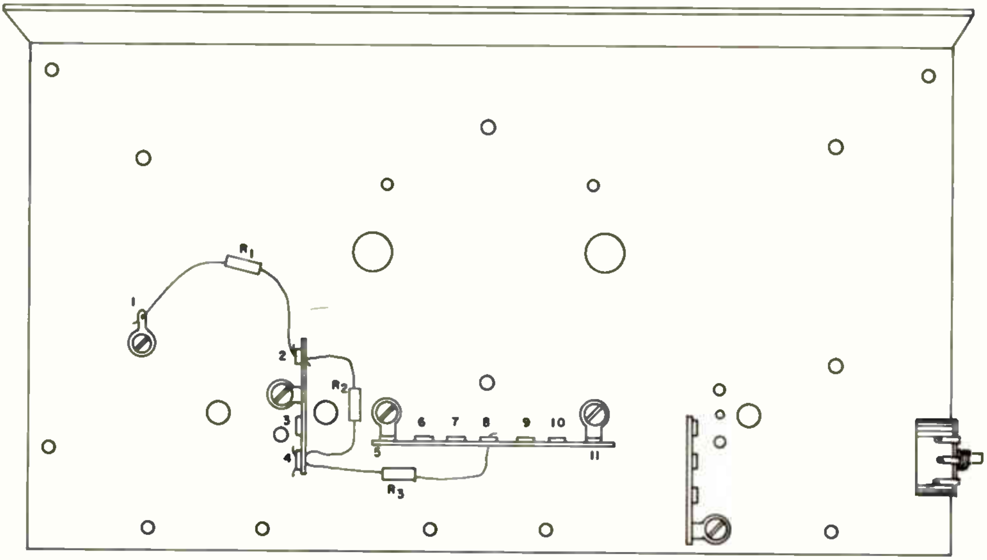

Fig. 1-1. Top view of the chassis, showing the resistors you will install in this experiment.

IMPORTANT: Do not cut the leads of any parts you received in this kit unless you are instructed to do so in the experiment. You will use most of the parts again in future experiments.

Fig. 1-1 shows you where you are to connect the resistors. The resistors are to be mounted so that the resistors and the leads are to be at least 1/2" above the chassis. As we mentioned earlier, we have given each terminal an identifying number. We will use these terminal numbers in this kit to indicate where the connections are to be made so as to simplify the instructions.

Connect the lead of one of the resistors to terminal 1, which is the solder lug mounted at hole B. Push the end of the lead through the hole in the solder lug and solder, as shown in Fig. 1-2.

Bring the tip of your soldering iron into contact with both the solder lug and the resistor lead, as in Fig. 1-2. Position the iron so that one flat surface of the tip is against the terminal. This permits maximum transfer of heat from the tip of the iron to the connection.

Touch the solder to the point where the terminal and the lead meet, and allow the solder to melt. Notice that the rosin flux flows out of the solder as the solder

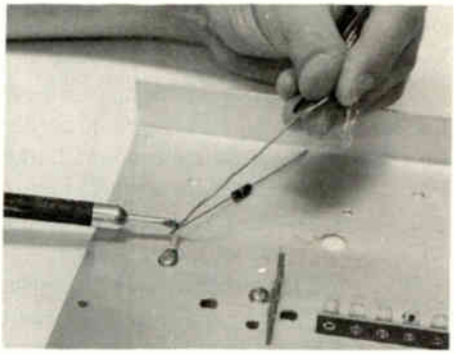

Fig. 1-2. Soldering the resistor lead to the terminal.

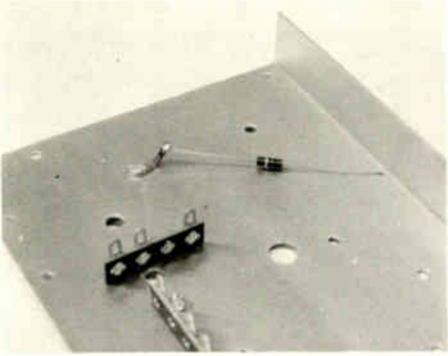

Fig. 1-3. Resistor R_1 soldered to terminal 1.

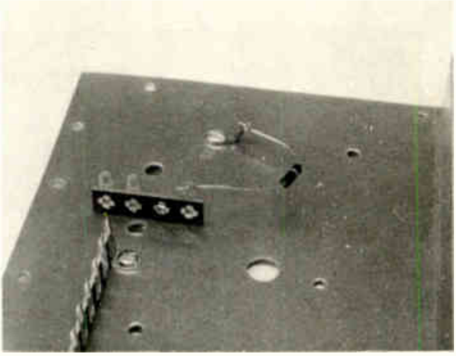

Fig. 1-4. Resistor R_1 in place on chassis.

melts. Remove the roll of solder and continue to heat the joint.

After the solder flows into the connection and coats the terminal and lead, remove the heat and allow the joint to cool and harden. Do not disturb the connection until the solder hardens.

If your solder joint is made correctly, the lead will be covered with solder where it touches the terminal and the solder should have a clean smooth appearance. Fig. 1-3 shows a good solder connection. The space between the resistor lead and the terminal is filled with solder and the solder also seals the connection.

It is a good idea to test each connection after it has cooled. To do this, grasp the resistor lead you have just soldered between the connection and the resistor body with your longnose pliers. Twist the lead gently and move it back and forth. If the lead does not move, you probably have a good soldered connection. If the lead breaks loose, or if the connection has a brown crust on it, re-melt the solder with your iron and let it cool again.

If you did make a poor solder connection, it may have been due to insufficient heat or to dirt on the lead or terminal. A poor joint can also result from your moving the lead before the joint has cooled.

Another problem which you might encounter is the "rosin" joint. This is a connection having a layer of rosin between the wire and the terminal. A rosin joint is indicated by a brown crusty appearance on the connection. You can correct a rosin joint by reheating the connection and allowing the rosin to boil out. As you heat the joint, you will see the vapor from the rosin rising from it.

With your longnose pliers, grasp the free lead of the resistor and slip it through the slot in terminal 2. Position the resistor as shown in Fig. 1-1. Twist the resistor slightly so the lead stays near the top of the slot in the terminal. Bend the end of the lead passing through the terminal so the lead touches the terminal, as shown in Fig. 1-4. Do not solder the connection at this time.

Step 2: To mount resistor R_2.

Now take another resistor and push the end of one lead about 1/8" through the slot in terminal 2. Bend the end slightly to bring it into contact with the terminal. Solder both leads to terminal 2. Place the tip of your soldering iron in contact with both leads and the terminal, with a flat surface against the terminal. Touch your solder to the connection and allow a small amount of the solder to melt. Remove the roll of solder and allow the molten solder to flow into the connection. Remove the heat and let the joint cool.

Test each connection by twisting and trying to move each lead. If the joint does not break loose, and the solder looks smooth, you probably have an acceptable connection. If not, reheat the connection, remelt the solder and allow it to cool and test the connections again.

Bend the leads of resistor R_2 at a right angle about 1/2″ from the body of the resistor and position the resistor as shown in Fig. 1-1. Connect the free lead of resistor R_2 to terminal 4. Do not solder it at this time, since another lead will be connected to the same terminal.

Step 3: To mount resistor R_3.

Connect another resistor, R_3, from terminal 4 to terminal 8. This time make the connection without detailed instructions. Bend the leads as required and position the resistor as shown in Fig. 1-1. Note that the body of the resistor should be about 1/2″ to 3/4″ from the 7-lug terminal strip. Solder and test both connections.

If you have done your work correctly, your chassis should look like Fig. 1-1. You should have a total of three resistors and four temporary soldered connections. We call them "temporary" because they can be disconnected easily, as you will see later. The solder provides both the mechanical strength and the electrical path between the leads and the terminals.

By contrast, a permanent connection does not rely on the solder for physical strength. Usually the wire is twisted or wrapped around the terminal for physical strength before the connection is soldered.

You will make only temporary soldered connections in the experiments in this manual. However, you will make permanent connections in later experiments. The instructions on how to make them will be given at that time.

Look over the connections you have made and examine them critically. Check to see if any solder has run down the terminal where it may make contact with the chassis and cause a short circuit. This condition is illustrated in Fig. 1-5. Also, look at each connection to see if solder has flowed to all parts of the joints. Look for big lumps of solder on the terminal. They indicate too little heat or too much solder.

Excess solder will do no harm, provided it does not short terminals together, short a terminal to the chassis, or contain excessive rosin. However, it looks messy and is a waste of solder. Too little heat means a poor connection; the cure is to hold the lead in position and reheat the joint.

Next you will unsolder the connections in order to learn the proper techniques for doing this.

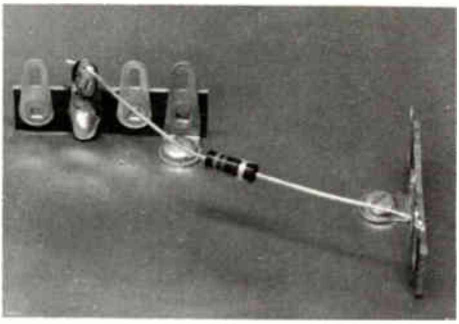

Fig. 1-5. A terminal shorted to the chassis by excessive solder.

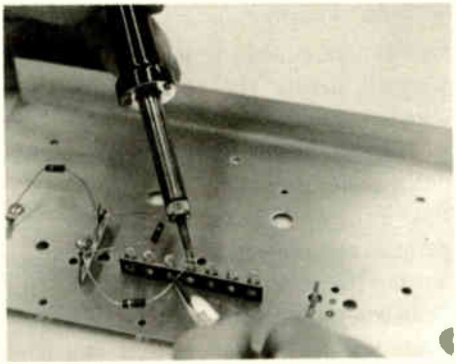

Fig. 1-6. Removing R_3 from terminal 8.

Step 4: To learn to unsolder connections.

Grasp the lead of R_3 connected to terminal 8 with your longnose pliers. See Fig. 1-6. Then touch the tip of your soldering iron to the connection. As soon as the solder melts, pull the lead out of the terminal. Wipe the tip of your iron with a cloth to remove the excess solder, and then touch the tip of the iron to the connections to terminal 4. Grasp the lead of resistor R_3 with your longnose pliers and, as soon as the solder melts, pull that lead free. Lay the resistor on your workbench. Grasp the lead of resistor R_2 connected to terminal 4. Apply heat to the terminal, and when the solder melts, pull the lead free. Wipe the excess solder from your iron with a cloth and then apply heat to the second lead of resistor R_2 which is connected to terminal 2. Remove the resistor and lay it on your work surface.

Use the procedure which we have outlined to unsolder the remaining connections and to remove resistor R_1.

Step 5: To clean parts so they will be ready for reuse.

Whenever you remove parts, clean the leads, lugs, and terminals so that you can use the parts again and connect other parts to the same lugs and terminals.

To practice this technique, first use your longnose pliers to straighten the resistor leads. Then, wipe any excess solder from the tip of your iron with a piece of cloth, and place the iron on the holder so that you can get to the tip easily. In one hand, hold a piece of cloth so that there are several thicknesses between your thumb and forefinger. With your longnose pliers in your other hand, grasp a resistor lead close to the body of the resistor. Hold the end of the lead against the tip of the iron until the solder on the lead melts, and quickly pull the hot lead through the cloth, as shown in Fig. 1-7. This will remove all excess solder and leave the lead surface clean and bright. Do this on all resistor leads that have been used in this experiment.

There are several methods of removing the solder from terminal and solder lugs. Probably the easiest and most efficient method to use on small pieces of elec-

Fig. 1-7. Removing the excessive solder from a resistor lead.

tronic equipment, such as the experimental chassis you received in this kit, is to turn the chassis upside down so that the terminals are pointing downward. Apply the tip of the iron to the end of the terminal, and when the solder melts most of it will run onto the tinned surface of the iron. Wipe the excess solder from the tip and repeat the procedure on the other lugs on the terminal strip. If a thin film of solder remains in the terminal holes, wipe the excess solder from the tip of the iron and reheat the lug. Push a resistor lead through the hole to remove the solder.

In addition to removing the solder from the terminals, this method will remove any excess solder that may be on the terminal strip lugs near the chassis.

Removing excess solder from terminals, tube socket pins and other types of solder lugs in large pieces of electronic equipment that you cannot pick up and turn upside down requires a slightly different procedure. In this case, with the terminals pointing upward, wipe the excess solder from the tip of your iron and keep the cloth in one hand while you work. Touch the tip of the iron to the side of the lug; when the solder melts, some of it will run onto the tinned surface of the iron. Wipe off the solder and keep repeating the process until all surplus solder has been removed. If you have trouble getting the solder out of the hole in a lug, heat the lug and push a resistor lead through the hole. The solder that accumulates on the resistor lead can then be easily removed.

The same procedure should be used to remove solder from tube socket pins and terminal strip lugs.

Discussion: In this first experiment, you began acquiring one of the most important skills a technician must have -- the ability to make good soldered connections. You have had practice in mounting actual electronics parts and soldering them into place. You have been able to see how solder looks as it cools and hardens. You should not expect to be an expert at soldering at this time; it takes considerable practice. However, if you carefully follow the procedures discussed in this experiment, you should have no trouble making good soldered connections and you will soon become an expert with a soldering iron.

You have also had practice in the equally important task of unsoldering, and you have learned how to clean the parts so they will be ready for reuse. This is important because often the serviceman must disconnect one part in order to check another. When you disconnect a part or lead, you should carefully prepare it and the terminal from which you removed it before resoldering the lead back into position.

Instructions for Statement No. 1: In this statement, there are two sentences to be completed, each having several choices preceded by numbers. Only one of the choices in each group correctly completes a sentence in the statement. Read the first sentence, and put a circle around the number preceding the choice that completes it. Do the same for the second sentence.

Statement No. 1: In this experiment, I used

[✓ *(1) temporary*]
(2) permanent

connections; and I found that as molten solder becomes hard, its appearance is

(1) a copper color.
[✓ *(2) a shiny gray color.*]
(3) a dull black color.

SOLDERING TIPS

Always use a clean, hot, well-tinned iron.

Always heat the junction to be soldered enough to melt the solder.

Always use a rosin-core solder.

Always tin part leads to be soldered.

Always test all leads in each joint after solder cools.

Always keep iron on joint until the rosin has boiled out of the joint.

Never try to solder dirty or untinned leads or terminals.

Never melt solder on the iron tip and carry it to the junction.

Never use acid-core solder or pastes for radio and electronic work.

Never drip solder off iron on to joint.

Never let leads move while solder is setting.

Turn now to the enclosed Training Kit Report sheet. Fill in the top part with your name, address, student number and Kit number, 1T. Write the number 1 in the first box of the column with the heading, "Statement No." This statement is in two parts. Therefore, place the number of your choice for the first part in the second column and place the number of your choice for the second part of the statement in the third column. As an example, assume that the first statement was:

San Francisco is located in the

(1) East
(2) South
(3) West

And it is in the state of

(1) Nebraska.
(2) California.
(3) New York.

The correct answers are (3) for the first part and (2) for the second part. Therefore, you would place the Statement number in the first column, the number 3 as your answer for the first part is the second column, and the number 2 in the third column.

EXPERIMENT 2

Purpose: To learn how to wire and repair etched circuit boards.

Introductory Discussion: Etched circuit boards are often used where compactness, ease of wiring or freedom from circuit variations are important. The vast majority of radio and TV receivers use etched circuit boards. Thus, it is likely that when you repair a receiver you will have to make repairs on etched circuit boards.

Etched circuit boards are fragile. They can be damaged by rough handling or poor workmanship. The phenolic will crack or break when subjected to excessive pressure. This results in breaks in the copper foil strips and produces open circuits.

The copper foil is glued to the circuit board. When overheated, the glue will weaken and the copper foil strips will pull loose from the board. However, the board will withstand a surprisingly large amount of heat before either the phenolic or the foil becomes damaged.

In performing this experiment, you will develop skill in working on etched circuit boards. This will prepare you for work on your future experimental kits and for practical work as a technician.

Experimental Procedure: In this experiment, in addition to your chassis, soldering iron and solder, you will need the following:

1 Etched circuit board (EC24)
2 22,000-ohm resistors (RE33; red-red-orange-silver)
1 7-pin tube socket (SO76)
Red hookup wire
Solder

Plug in your soldering iron so that it can be heating. Inspect the tip. If the tip is not clean, wipe it with a cloth and apply a thin coating of solder. If you wipe the tip frequently, it will last longer. Also, you will seldom have to file and retin the tip.

In this experiment, you will practice soldering to the etched circuit board and you will make repairs on the copper foil. The foil near holes A through H is for practice only. Do not be concerned if you damage it in performing this experiment. However, the remainder of the board will be used in later experiments. Therefore, you should exercise reasonable care in working on the board.

Step 1: To wire a circuit on the etched circuit board.

In order to become proficient at working on circuit boards, you will have to develop a feel for soldering to the copper foil. Before mounting any parts, you will determine how much heat the foil can withstand.

Place your etched board on your worktable with the foil side up. Touch the tip of your soldering iron to the foil near hole B. Hold the soldering iron nearly straight up with the tip at the edge of the hole, as shown in Fig. 2-1. Touch the end of your solder to a point where the tip touches the foil. Allow about 1/4" of solder to melt and flow onto the foil. When the solder spreads out smoothly on the foil, remove the heat and allow the foil to cool. Do not be concerned if the hole is covered with solder.

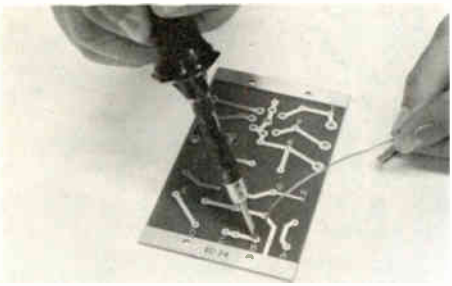

Fig. 2-1. Applying heat and solder to the foil.

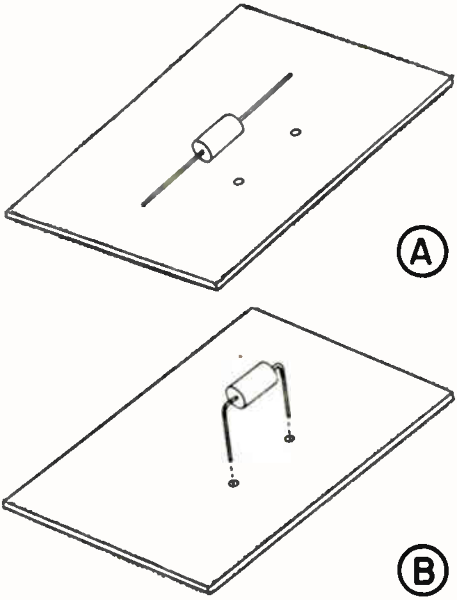

Fig. 2-2. (A) Measuring the resistor against the mounting holes; (B) resistor leads bent to correct spacing.

In a similar manner, apply heat to the foil surrounding hole A. Touch your solder to the iron and the foil and melt about 1/4" of the solder. Continue to heat the foil until the foil begins to loosen. This may take up to 15 seconds, depending upon the wattage rating of your iron and the condition of the tip. Remove the heat from the foil.

Notice that the phenolic around the overheated foil is charred slightly. Use a knife or your longnose pliers to peel the damaged foil off the board.

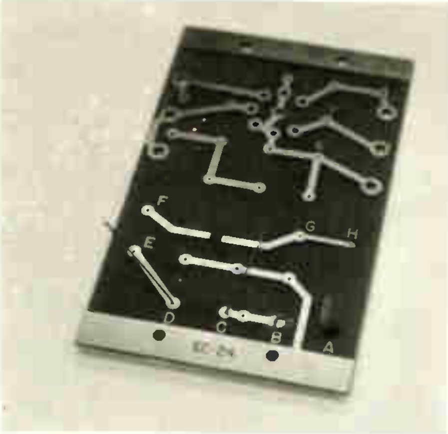

Fig. 2-3. Leads are bent outward to hold the resistor in place.

The brief experience which you have gained will give you some idea of how long it takes to make a connection and how long it takes to damage the circuit board. Next, you will mount and solder parts to the circuit board.

Install one of the 22,000-ohm resistors (red-red-orange-silver) on the phenolic side of the circuit board at holes C and D. Use the following procedure: First, "measure" the resistor against the spacing between the holes, as shown in Fig. 2-2A. In this case, the spacing between the holes is about 1/4" greater than the length of the body of the resistor, so bend both leads at right angles about 1/8" from the body of the resistor. Fig. 2-2B shows the leads ready for insertion in the holes.

Next, slip the leads through holes C and D and push the resistor down against the board. Bend the leads outward slightly, as shown in Fig. 2-3, to hold the resistor in place.

Turn the foil side of the circuit board up to solder the connections. Position the soldering iron so that the tip is in contact with both the foil and the lead. Touch the end of your solder to the point where the tip, lead and foil meet and allow about 1/4" of the solder to melt. Continue to heat the connection until the solder flows smoothly and completely surrounds the lead. Then, remove the iron and allow the connection to cool.

Finally, use your diagonal cutters to cut off the lead flush with the top of the solder connection.

Use the procedure outlined here to solder the other resistor lead to the foil.

Fig. 2-4 shows typical poorly soldered

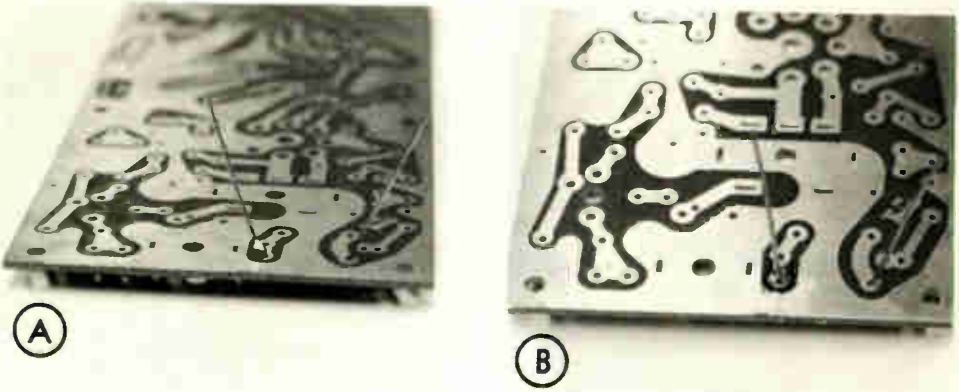

Fig. 2-4. Typical examples of poorly soldered connections.

connections. At A, too little heat was used; the solder adheres to the lead, but not to the foil. This connection could be improved by simply applying more heat. In Fig. 2-4B, too little solder was used, resulting in a minimum of strength and reliability. To improve this connection, you would apply both heat and solder.

Step 2: To demonstrate methods for removing components from etched circuit boards.

Wedge the blade of your small screwdriver between the board and the body of the resistor near hole C. (If the resistor is flat against the board, slip the screwdriver blade under the lead at hole C.) Heat the solder at hole C and lift the resistor enough to pull the lead from the hole.

Stand the circuit board on edge on your worktable. On the phenolic side of the board, grasp the lead of the resistor connected at hole D. With your forefinger and thumb pressing against the board, apply a lifting pressure to the resistor lead. Heat the connection at hole D on the foil side and when the solder melts, pull the resistor from the board and discard it.

Now you should clean the holes so that a new resistor can be installed. Heat the solder at one of the holes. While the solder is molten, insert a toothpick into the hole from the foil side of the board. Remove the soldering iron and let the foil and solder cool. When you remove the toothpick, the hole will be left clear.

Step 3: To demonstrate techniques for repairing etched circuit boards.

Cut through the foil between holes D and E to simulate a crack in the foil. You can use your pocket knife. Fig. 2-5 shows how to make a clean cut safely.

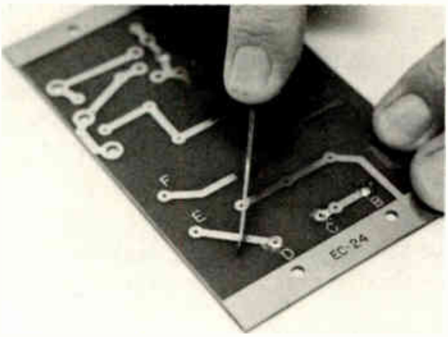

Fig. 2-5. Cutting the foil to simulate a crack in the board.

Heat the foil near the cut and melt a small amount of solder onto the foil. Use the tip of your iron to "run" the solder across the crack. The solder should adhere to the foil on both sides and bridge the narrow gap. If necessary, apply a little more solder to make a reliable repair.

A wider break, such as the one between holes F and G, requires a slightly different repair. You solder a short piece of bare wire across the break in the foil.

Remove about 2″ of insulation from a length of red hookup wire. There are several ways of removing the insulation. You can peel the insulation off with a knife, or you can cut the insulation with your diagonal cutters, knife or wire strippers and simply pull off the unwanted piece. Another technique is to crush the insulation with pliers and then peel off the pieces. When stripping the insulation off wire, it is important to avoid nicking or cutting the wire because this will weaken the wire and make it break easily.

As you did previously for the narrow break, heat the foil on both sides of the break and tin the foil with solder. Lay the bare wire across the break in the foil and solder the wire to the foil. Run solder along the wire and foil for about 1/2" on each side of the break. Using your diagonal cutters, cut off the wire beyond the solder. This should leave about 1" of wire bridging the break in the foil.

Step 4: To install parts on the foil side of the circuit board.

Bend the leads of a 22,000-ohm resistor (red-red-orange-silver) at right angles close to the body of the resistor, and insert the leads through holes C and D from the foil side of the board. Position the resistor about 1/16" to 1/8" from the board. This will leave room for soldering the connections. Bend the leads outward slightly to hold the resistor in place.

Solder one lead of the resistor to the foil. Apply heat to both the foil and the lead and apply solder. Allow the solder to flow freely over the connection. Remove the heat and let the joint cool. In a similar manner, solder the other resistor lead to the foil. You will use this resistor in later experiments, so do not cut off the leads! (Normally, after installing a part from the foil side as you have just done, you would clip off the excess lead length on the other side of the board.)

Locate the 7-pin tube socket. The socket has 7 pin connections and a center locating pin. You will install the tube socket on the *foil* side of the circuit board instead of from the phenolic side. Align the pins over the holes on the circuit board. Notice that there is an open space between the pins. Install the socket on the board by pushing firmly. When the socket is properly installed, the pins project about 1/16" on the phenolic side of the board.

With the socket in position, you are ready to solder. Since the tube socket pins on the phenolic side of the board will become quite hot as you solder them to the board, it would be a good idea to lay the board on a newspaper to protect your worktable. Hold the soldering iron so the tip is at the junction of the foil and a pin of the tube socket.

The flat surface of the soldering iron tip should be turned toward the pin. Apply solder to the foil and to the pin. Melt about 1/4" of solder and let it flow around the pin. Solder should adhere to one half or more of the perimeter of the pin and to the foil. Remove the heat and let the solder cool. In the same manner, solder the six remaining pins of the tube socket. Do not try to solder the center locating pin. Fig. 2-6 shows the socket soldered in place.

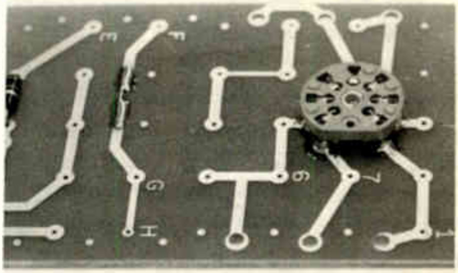

Fig. 2-6. Tube socket mounted on the etched circuit board.

Discussion: In this experiment, you have experienced working on a typical etched circuit board. You learned that you can solder to the circuit board with a moderate amount of heat. If the iron is clean and tinned, a connection can be soldered in a matter of seconds; it takes a considerable length of time to overheat and damage the circuit board.

In Step 2, you learned how to install components on the circuit board. First, you determined the lead spacing and bent the leads so you could insert the leads in the holes; then you pushed the part down against the circuit board and bent the lead to hold the part in place. Then you soldered the connection, allowed it to cool, and cut off the excess lead length, close to the soldered connection. In a good solder connection, the solder adheres to both the lead and to the foil and the solder has a smooth appearance.

You also learned how to remove parts from the etched circuit board. This is important because frequently you will have to disconnect a part to make tests and when you determine which part is bad, you will have to replace it. Before replacing a lead, clean the hole in the board. Otherwise, you may break the foil loose when you try to insert the lead.

In Step 4, you learned how to install parts on the foil side of the board. This is useful because you will sometimes find it easier to replace a part on the foil side of the board. Also, interconnecting jumper wires are sometimes connected on the foil side of the board in some pieces of equipment.

The circuit board with the tube socket attached will be used in later experiments.

Instructions for Statement No. 2: In order to answer the Report Statement for this experiment, you will have to make a few connections on your etched circuit board and trace the connections. You will need your red hookup wire.

Cut a 2" length of hookup wire and remove about 1/4" of insulation from each end. Push one end through hole E from the phenolic side of your circuit board. The holes are identified on the foil side of the board. Bend the wire and push the other end through hole F from the same side of the board. Solder both connections.

Cut a 3" length of hookup wire and remove about 1/4" insulation from each end. Push one end of the wire through hole G and push the other end through the hole identified by the number 7 from the phenolic side of the board. Solder both connections.

Trace the connections on the circuit board and answer the Report Statement. After you have completed the Report Statement, unsolder and remove the resistor and the pieces of hookup wire. Clean the holes which you used on your circuit board and clean and straighten the resistor leads.

Statement No. 2: When I traced the wiring, I found that the resistor

[✓ *(1) was*]
(2) was not

electrically connected to the tube socket.

Using Schematic Diagrams

To service any type of electronic equipment, the technician must know how the parts are connected in the circuit.

The electrical connections in a circuit can be shown by means of a schematic diagram. In a schematic diagram, symbols are used to indicate the various parts, and the connections between the parts are shown by lines.

You have already seen many of the symbols used in schematic diagrams in your lesson texts. You have also seen some simple schematic diagrams. It is extremely important for you to become familiar with the various symbols used, and also to learn how to read schematic diagrams. You will have to use this type of diagram throughout your career, because manufacturers of electronic equipment seldom supply pictorial wiring diagrams. Even if you have a pictorial diagram, it is far easier to work from a schematic once you learn how to use it.

In your experiments, you will start first with simple schematics, and gradually work up to more complex ones. In time, you will be as much at ease reading a complex schematic diagram as you are reading your evening newspaper. You will soon learn the value of this type of diagram and see how much easier it is to use than the pictorial type.

SYMBOLS USED

Before you can read schematic diagrams, you must be able to recognize the symbols used in them. Fig. 26 shows the symbols commonly used to represent resistors, capacitors, and ground connections. Study these symbols so that you will be sure to recognize them the next time you see them. You will use them in these experiments.

Fig. 26. Symbols often used in schematics.

Connections and Crossovers. Often in a schematic diagram, one lead crosses over another. In some cases, there will be a connection between the two leads; in other cases, there will be no connection. There are three different systems in use to indicate whether or not there is a connection; the one that is used in any particular diagram depends on the preferences of the person making the diagram. You might think that this would be confusing, but it is usually very simple to see which system has been used.

Fig. 27 shows the three systems. Notice that in System 1 when there is a dot used on some crossovers and no dot used on the others, the dot indicates a connection, and the crossover without the dot indicates that there is no connection.

In System 2, a straight crossover is used to show a connection, and a loop is used to show no connection. You can easily tell when this system has been used. If you notice some crossovers with the loop, and some without the loop, you know that the straight crossovers represent connections, and the crossovers with the loop indicate no connection. Similarly, if you see some crossovers with dots and others without, you will know that System 1 has been used.

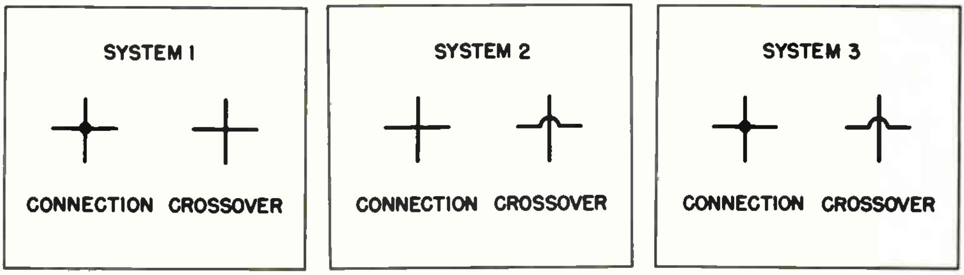

Fig. 27. Three systems used on schematics to show connections and crossovers on wires.

System 3 is a combination of the first two. We will use this system in the drawings in the experiments. The crossover with a dot indicates a connection. The crossover with a loop indicates no connection. Study these three systems - become familiar with them now, and you will have no trouble later.

Tubes. The various symbols used to represent the elements in a tube are shown in Fig. 28. The symbol for the heater is shown at A, the symbol for the cathode at B, for the grid at C, for the plate at D, and for the whole tube at E. This tube is called a triode - it has three elements plus a heater. Notice the little numbers beside each of the elements. These tell you which pin each element is connected to inside the tube. The tube we have shown is a 6C4. In this particular tube, the plate is connected to pins 5 and 1; the grid to pin 6, the cathode to pin 7, and the heater to pins 3 and 4. Nothing is connected to pin 2.

Diodes. The symbol for a semiconductor diode is shown in Fig. 29. The two elements of a diode are the cathode and the anode. The "arrow" in the symbol points toward the cathode terminal.

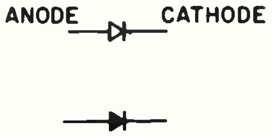

Fig. 29. Schematic symbols for a semiconductor diode.

Transistors. There are several types of transistors in wide usage. The symbols for two types are shown in Fig. 30. At A and B, we have bipolar transistors. As you can see, the only difference between the NPN and PNP symbols is the direction of the arrow. The e, b, and c labels identify the emitter, base and collector of both transistors.

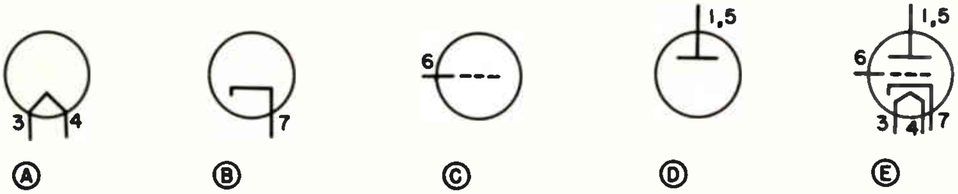

Fig. 28. Symbols used to represent the elements in a tube. Shown is tube type 6C4.

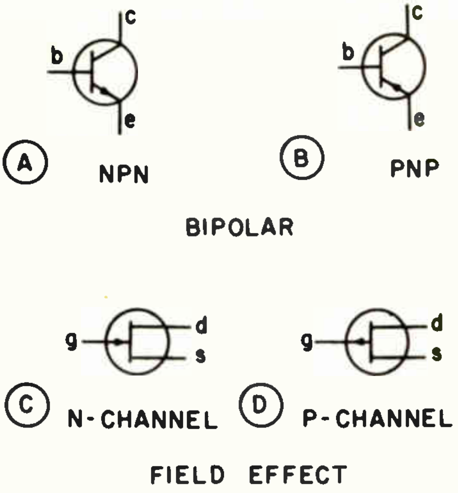

Fig. 30. Schematic symbols for transistors.

The symbols for junction field-effect transistors (FET's) are shown in Figs. 30C and 30D. You can see that the direction of the arrow is toward the junction for the N-channel and away from the junction for the P-channel FET's. In both cases, the s, g and d represent the source, gate and drain terminals. You will learn other transistor symbols later in your course.

Meters. Fig. 31 shows symbols used to represent meters on schematic diagrams. In the symbols in Fig. 31A, the letters inside the circle indicate the type of meter: V for voltmeter, μa for microammeter, ma for milliammeter, and ohm for ohmmeter. Fig. 31B shows semipictorial symbols that are sometimes used.

READING A SCHEMATIC

When working with schematic diagrams, you must remember that the schematic diagram shows the electrical connections, not the actual physical connections. An example of this can be seen in Fig. 32A. The schematic diagram shows the capacitor C_1 connected on the left to resistor R_1. From the junction of these two components there is a line going to the plate of the tube V_1.

In your work you will be interested only in the electrical connections. It will be unimportant to know whether the capacitor and resistor are first connected together and a lead run from the junction of the two to the tube socket, or whether the two are connected directly to the tube socket. Electrically both connections are the same.

The other side of capacitor C_1 is connected to the grid of the tube marked V_2. The schematic diagram shows C_1 connected to R_2 and then a line going from the junction over to the grid. The pictorial wiring diagram shows that both the capacitor and the resistor are connected directly to the grid terminal on the socket.

Notice on the schematic diagram that the lower end of resistor R_2 is connected to ground. In the wiring diagram, we see

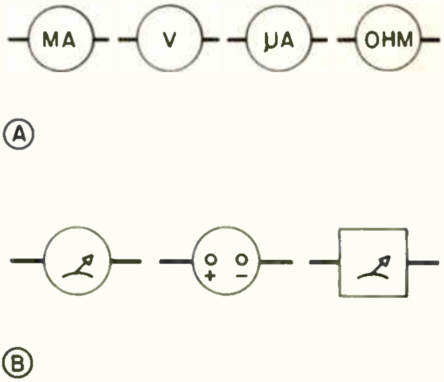

Fig. 31. Symbols used on schematics to represent meters.

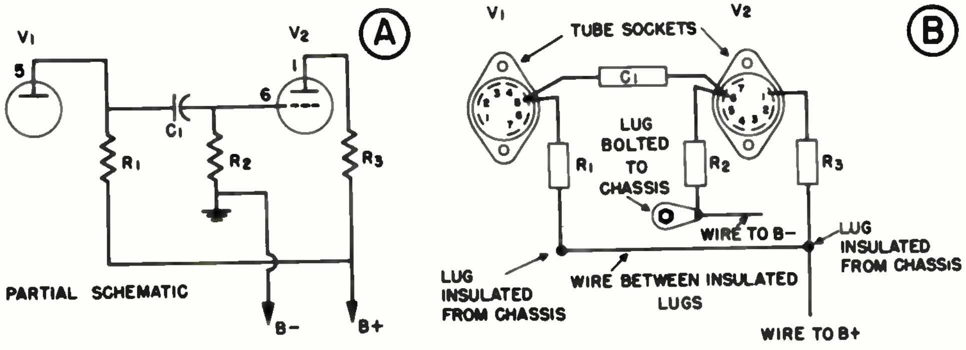

Fig. 32. (A) A schematic diagram; (B), actual wiring diagram of the same circuit.

that R_2 connects to a lug that is bolted to the chassis. Any number of ground connections can be made in this way to the chassis. When this is done, the chassis is used as part of the circuit; the chassis connects directly to B-. In some equipment the chassis is not used as part of the circuit. You will see later how to tell from a schematic diagram whether or not the chassis is part of the circuit. This information will be given to you on the schematic diagram.

Study Fig. 32 carefully. Find an electrical circuit on the schematic diagram, and then trace out the circuit on the pictorial wiring diagram. This will be valuable practical experience for you and will help you to become familiar with schematic diagrams.

EXPERIMENT 3

Purpose: To obtain practical experience in wiring from a schematic diagram.

Introductory Discussion: Fig. 3-1 is a pictorial diagram showing the actual physical location of the parts in the circuit you will wire in this experiment.

Fig. 3-2 shows the same circuit in schematic form. The circuit is that of a simple power supply. If an ac voltage were connected between terminals 1 and 2, a variable positive dc voltage would be available between terminals 17 and 15.

In a simple circuit of this type a pictorial diagram may seem easier to follow than a schematic diagram. However, a glance under the chassis of any electronic device will show how complex the pictorial diagram would become. In fact, it would be practically impossible to show how the parts are connected with a photograph or pictorial drawing. On the other hand, it is easy to show the connections with a schematic diagram.

Experimental Procedure: In this experiment, in addition to the chassis with the terminal strips and potentiometer mounted on it, you will need:

3 1000-ohm resistors (RE30; brown-black-red-silver)
1 Silicon diode (SR12)
Hookup wire
Solder

As you can see in Fig. 3-1, the diode appears similar to a resistor and is somewhat smaller. The diode is a semiconductor device which passes current in one direction only. Current can pass from cathode to anode but not from anode to

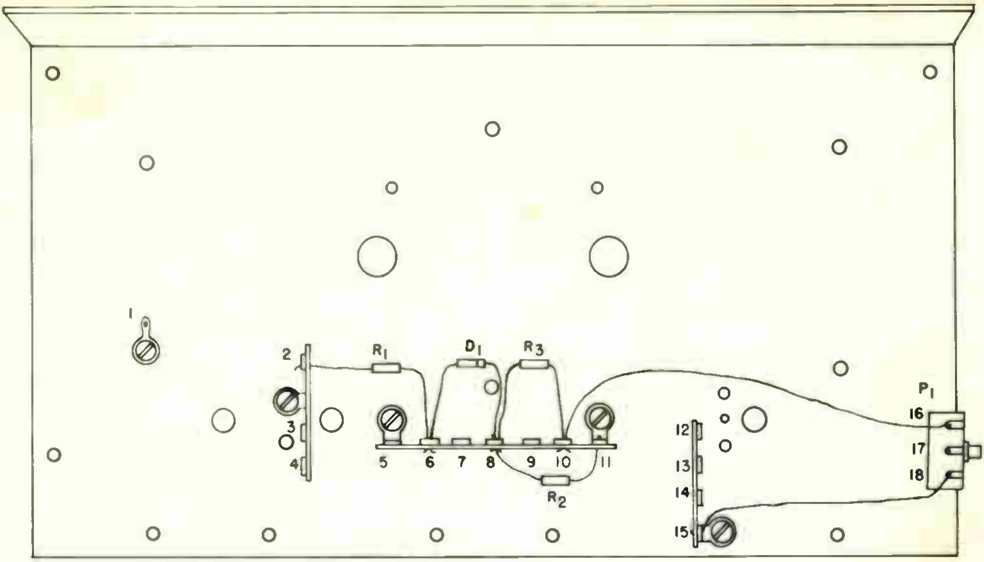

Fig. 3-1. Pictorial diagram of the circuit used in Step 1.

cathode. Thus, the diode is capable of rectifying an ac voltage.

The cathode and anode terminals of a diode are identified in one of several ways. You will usually find colored bands or a plus sign near one end of the diode, or one end of the diode may be tapered. The band, taper or other markings indicate the cathode lead of the diode as shown in Fig. 3-3.

Step 1: To determine what connections are to be made.

First, carefully study Fig. 3-2. Resistor R_1 is connected between terminal 2, which is the "input" terminal, or the terminal to which the ac voltage would be applied, and the diode D_1. The cathode lead of diode D_1 is connected to resistors R_2 and R_3. One lead of R_2 is grounded.

Resistor R_3 is connected between the junction of diode D_1 and resistor R_2 and the potentiometer, **P_1**. Potentiometer **P_1** is connected between R_3 and ground.

Notice the ground symbols on the diagram. The metal chassis forms the common connection between the ground points.

Where possible, leads of the parts which are wired together are connected to a common terminal. For example, the cathode lead of D_1, one lead of R_2 and one lead of R_3 can all be soldered to the same terminal.

When instructed to use hookup wire, cut a length of your red wire and remove about 1/4" of insulation from each end before making the connection. See that the insulation is about 1/16" back from the actual solder connection. Never try to solder to the insulation.

When we instruct you to use a short length of bare wire, use your wire strippers, diagonal cutters or longnose pliers to remove the insulation from a short length of hookup wire.

In the next step, you will perform the actual wiring.

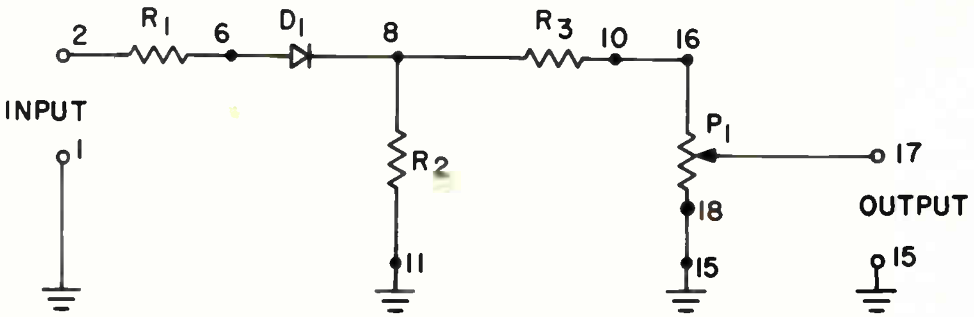

Fig. 3-2. Circuit used in Experiment 3.

Step 2: To wire the circuits from the schematic diagram.

In this step, you will mount the parts and connect wires between them to form the circuit shown in the schematic diagram in Fig. 3-2.

Connect resistor R_1 to terminals 2 and 6 as shown in Fig. 3-2. You can choose any of the three resistors since they are all the same value. Bend the leads so that the ends are spaced properly to slip through the slots in terminals 2 and 6. Slip the leads through the terminals and solder terminal 2.

Connect the diode to terminals 6 and 8 with the proper polarity. The cathode and anode leads are identified in Fig. 3-3. The cathode lead of each diode is on the right. Connect the cathode lead to terminal 8 and connect the anode lead to terminal 6. Solder terminal 6.

On the schematic diagram, notice that the cathode lead of the diode and one lead of resistor R_2 are connected together. Also, R_2 is connected from the junction with the diode lead to ground. Therefore, connect R_2 between terminals 8 and 11 as shown in Fig. 3-1. Solder terminal 11.

Next connect resistor R_3. On the schematic, this resistor is connected between the junction of diode D_1 and resistor R_2 and terminal 16 of the potentiometer. For convenience, we connect the resistor between terminals 8 and 10 and use hookup wire to complete the connection.

Install the resistor and solder terminal 8. Connect a length of hookup wire from

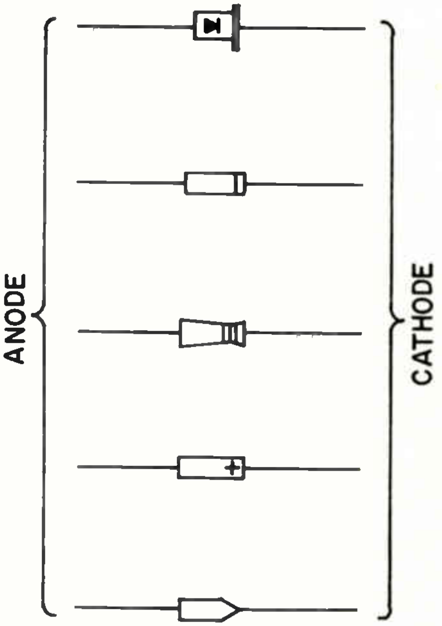

Fig. 3-3. Methods used to identify the leads of semiconductor diodes.

terminal 10 to terminal 16 and solder both connections.

The potentiometer is connected between resistor R_3 and ground. Thus, we must ground terminal 18. Again, we choose a convenient grounded terminal, which is terminal 15. Connect a length of hookup wire from terminal 18 to terminal 15 to complete the wiring. The center terminal of the potentiometer, terminal 17, is the "output" terminal.

This completes your wiring. You should have made all of the connections shown in Fig. 3-1. To make certain, check your wiring as follows:

1. There should be a resistor, R_1, between terminals 2 and 6.
2. Diode D_1 should be connected between terminals 6 and 8, with the cathode lead to terminal 8.
3. Resistor R_2 should be connected between terminals 8 and 11.
4. Resistor R_3 should be connected between terminals 8 and 10.
5. There should be hookup wire from terminal 10 to terminal 16 on the potentiometer.
6. There should be a length of hookup wire from terminal 18 on the potentiometer to terminal 15.

You should make a habit of checking your connections in this way each time you finish wiring a circuit. By checking your work, you may find and correct errors that could be serious or difficult to find later. When you check your work, pay particular attention to the soldered connections. Be sure that all connections are soldered properly. If not, resolder them.

When you are satisfied with your work, unsolder all of the connections and remove the parts. Straighten the resistor and diode leads and remove the excess solder from all terminals. Use the techniques you learned in Experiment 1.

Remove the 1000-ohm potentiometer from the mounting bracket and carefully clean the terminals. Remove the potentiometer mounting bracket and put it with the potentiometer. You will use these in a later Training Kit.

Discussion: In this experiment, we have taken you step-by-step through the wiring of a circuit from a schematic diagram. You have checked your work by comparing the actual parts layout with a list of the connections and with a pictorial diagram. This layout is not the only one that could be made from the schematic of Fig. 3-1. The same electrical circuit could have been made with the leads routed along different paths.

You should practice drawing schematic diagrams because such practice will help you to become more familiar with schematic symbols and will aid you later in tracing circuits. You need not start with elaborate diagrams; simple circuits like those shown in this experiment will be satisfactory.

The schematic diagram shows electrical connections only. Therefore, additional information is needed in order to wire more complex circuits. Experienced technicians usually sketch a layout before wiring. However, once a circuit is wired, it is easy to trace the circuit by following the schematic diagram.

Instructions for Statement No. 3: This statement is a test of your ability to relate a physical parts layout to a schematic diagram of that layout. Fig. 3-4 shows a circuit wired on your experimental chassis using resistors, a diode and a potentiometer.

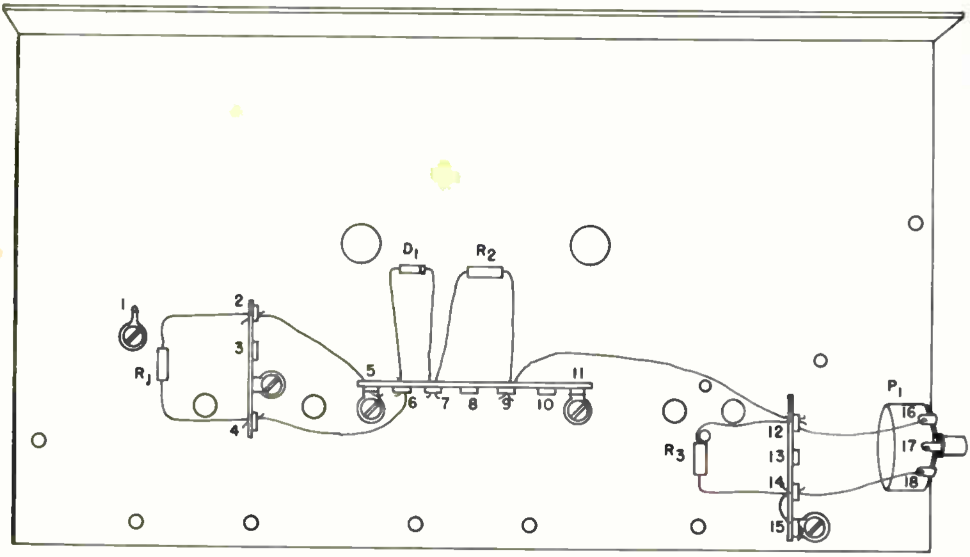

Fig. 3-4. Pictorial diagram of the circuit shown in Statement 3.

Study this circuit carefully and compare the arrangement with the four schematics in Fig. 3-5. When you are certain you have the schematic which corresponds to the circuit of Fig. 3-4, complete the statement here and on your Report Sheet.

Statement No. 3: The schematic diagram of the circuit in Fig. 3-4 is Fig. 3-5:

[✓ *(1) A*]
(2) B
(3) C
(4) D

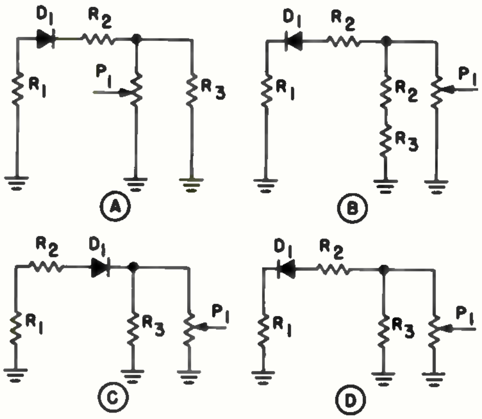

Fig. 3-5. Schematics for use with Statement No. 3.

IDENTIFYING RESISTORS

As you go ahead with your experiments, and when you work on your own, you will need to be able to identify the value of resistors.

Although the value is stamped on some resistors, on most 1/2-watt, 1-watt, and 2-watt resistors the value is indicated by means of colored bands on the resistor. You should learn to read this color code so that you can identify resistors quickly.

The colored bands on the resistor usually are nearer to one end than the other. Thus, to read the color code, turn the resistor so that the colored bands are toward the left end of the resistor as shown in Fig. 33.

Each color represents a number. These are given in Fig. 33. The first band, labeled A, gives the first figure in the value; the second band, labeled B, gives the second figure in the value; the third band, labeled C, gives the number of zeros after the second figure in the value, and the fourth band gives the tolerance of the resistor (silver for ±10% tolerance, gold for ±5% tolerance). If the tolerance is ±10%, it means that the actual value of the resistor may be as much as 10% higher or lower than the value indicated. If it is ±5%, the actual value may be up to 5% higher or lower than the value indicated.

COLOR C GIVES THE NUMBER OF CIPHERS FOLLOWING THE FIRST TWO FIGURES.

COLOR D GIVES THE TOLERANCE

GOLD BAND INDICATES ±5%
SILVER BAND INDICATES ±10%
NO BAND INDICATES ±20%

Fig. 33. Standard resistor color code.

Some resistors may have a fifth color band. This band will follow the tolerance band (to the right) and is used to indicate a military reliability level. The fifth band will be Brown, Red, Orange or Yellow which indicate increasing percent of reliability. In your work you can simply ignore the fifth band.

To find the value, you need to look only at the first three bands. For example, suppose you have a resistor color-coded red, red, and black. Referring to the chart, you see that red represents 2. Therefore, the first two figures in the value are both 2. As we have said, the third band indicates the number of zeros in the value. Since black represents 0, when the third band is black, there are no zeros in the value. So the value of the resistor is 22 ohms.

If the resistor had been color-coded red, red, and brown, the first two figures would again be 2. Brown represents 1, so there would be one zero, and the value would be 220 ohms. Red, red, and red would indicate a value of 2200 ohms (often written 2.2K ohms, where the K stands for 1000); red-red-orange, a value of 22,000 ohms (often written 22K-ohms); red-red-yellow, a value of 220,000 ohms (or 220K ohms or .22 meg; a megohm is 1,000,000 ohms); red-red-green, a value of 2,200,000 ohms (or 2.2 megohms); and red-red-blue, a value of 22,000,000 ohms (or 22 megohms).

Look over the resistors you have received, and practice reading the color codes on them. You can check the values by referring to the parts list given in Fig. 1. In the next experiment you will have some practice in picking out resistors of different values.

EXPERIMENT 4

Purpose: To construct a circuit using only a schematic diagram for guidance.

Introductory Discussion: If you read construction articles in any of the radio-TV-electronics magazines, you will see that step-by-step wiring instructions are rarely given; you work from a schematic diagram. Thus, if you wanted to build some of this equipment, you would have to work out the placement of the parts and other details for yourself.

We want you to become so familiar with schematic diagrams that you can look at one and picture the arrangement of the parts. That is not hard if you start with simple circuits like those you have built so far, and gradually work up to more complex circuits. The manufacturer's servicing information on any equipment usually has a complete schematic diagram and the parts values. If you are servicing the equipment, you will have to find the defective part, determine its value, and make the replacement.

Usually connections between parts are shown by a line that follows the shortest path between the two parts. However, this is not always true. The only sure way to find the part is to trace the circuit. Often it is more convenient to run a lead over a somewhat longer path to avoid crowding a section of the diagram. An example of this is given in Fig. 4-1. We could have drawn a horizontal line directly from pin 4 of V_1 to pin 3 of V_2 to show that they are connected. However, the line would have had to cross a number of other lines, thus crowding the diagram, and perhaps causing some confusion. Drawing the line as in Fig. 4-1 avoids confusion.

Tracing circuits on a schematic diagram is in many ways like tracing a road between your home and another city on a

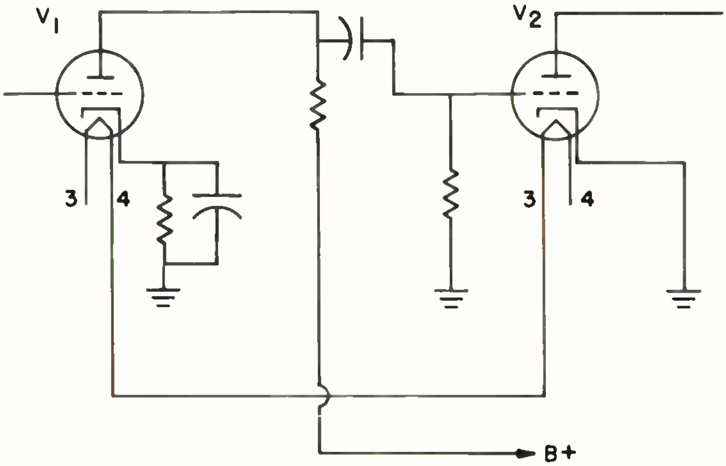

Fig. 4-1. Typical schematic diagram showing a two-stage tube circuit.

road map. You will seldom find a road that goes in a straight line from one place to another. Instead, the road will turn time and time again; you may have to go a certain distance on one road and then turn onto another. So it is in tracing the circuit on a schematic diagram. You start at one point in the circuit and trace toward another point. You may find a direct circuit between the two points, but more often you will find the circuits are connected by something other than a direct connection. In addition, you may find that to get from one point to the other you have to trace the circuit to some intermediate point, and then from that point on through an additional circuit to the point that you are interested in reaching.

Frequently in service work you will have to trace out the actual wiring in a receiver and compare the wiring with a schematic diagram. We cannot stress too strongly how important it is for you to learn to use this type of diagram. This is why we will concentrate on learning how to use diagrams.

When you work from a schematic diagram in the experiments, there may be several ways in which the various leads can be run. In general, try to use the shortest possible route. When we work on the more complicated circuits, we will give detailed instructions on exactly where to place each important lead; but during these early experiments, we will leave you on your own as much as possible to give you all the practical experience we can.

When you build equipment from a schematic diagram, you should carefully check each circuit you wire to make sure it is wired correctly. Also make sure that each connection is properly soldered. Even if you learn to work from a schematic, the equipment you build will not work properly unless all connections are properly soldered. Many people waste a great deal of time because of careless wiring and poorly soldered connections, which could easily have been spotted if a little extra time had been taken to check the work. Start right now by checking each circuit you wire against the schematic diagram and by checking each soldered connection you make. These are good habits, and the sooner you acquire them the better.

Experimental Procedure: For this experiment, in addition to the chassis with the solder lug and terminal strips, you will need the following:

1 1000-ohm resistor
1 22,000-ohm resistor
1 100,000-ohm resistor
2 1/4" × 4-40 screws
2 4-40 hex nuts
1 Etched circuit board (EC24)
Hookup wire
Solder

Use the resistor color code chart shown in Fig. 33 to help identify the three resistors used in this experiment.

Check your experimental chassis and make certain that the terminals are clean and all excess solder has been removed. At the same time, check the tip of your soldering iron to be sure it is clean and well-tinned.

For this experiment, you will use the tube socket on your circuit board and the terminals on your chassis. You will mount the circuit board along the edge of the chassis and connect "jumper" wires from the tube socket terminals in the copper foil to the 7-lug terminal strip on the chassis.

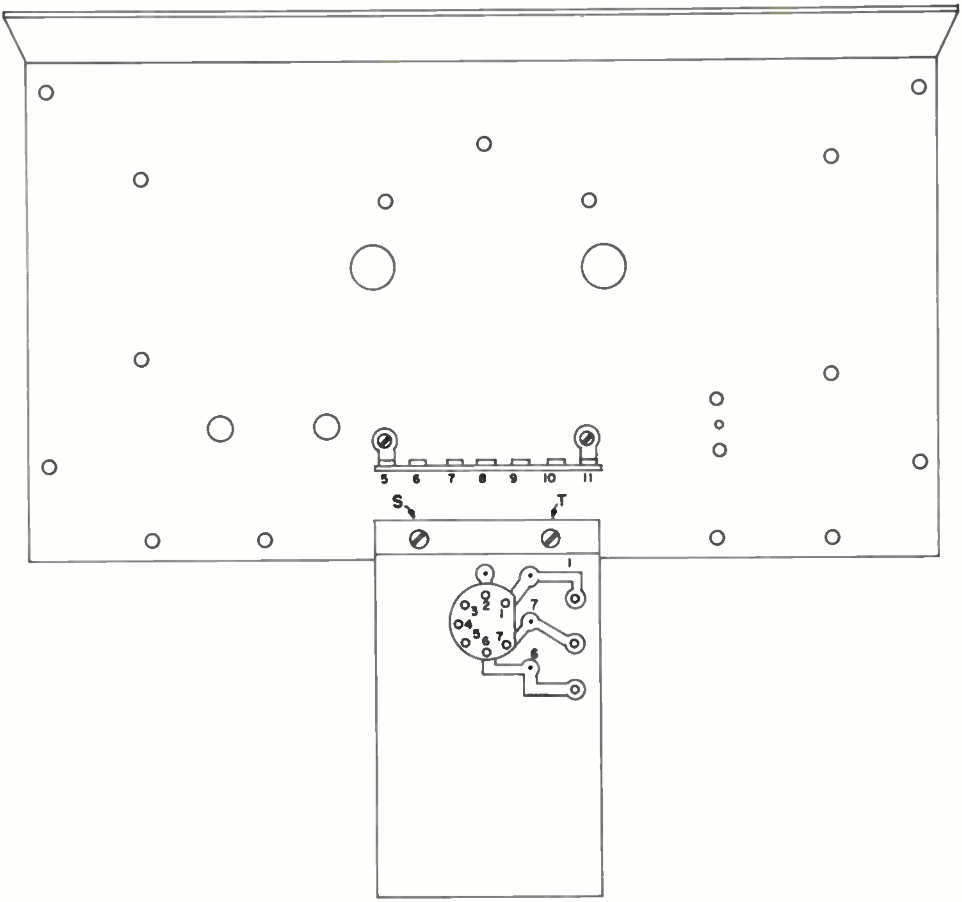

Fig. 4-2. Mounting the circuit board on the experimental chassis.

Mount the circuit board over holes S and T in the chassis (the holes are identified in Fig. 11 and Fig. 4-2). Position the circuit board over the edge of the chassis as shown in Fig. 4-2. Note that the tube socket is toward the chassis and the foil side of the board is turned upward. Attach the board with 1/4" X 4-40 screws through the mounting holes in the circuit board and chassis. Attach two 4-40 nuts and tighten.

The pins on the tube socket or tube are numbered from the blank space in a counterclockwise direction when viewed from the top. As shown in Fig. 4-3, pin 1 is at the right of the blank space, pin 2 is next, and so on. Pin 7 is to the left of the blank space. The pin in the center of the socket is not numbered. We will be primarily interested in pins 1, 6, and 7 of the socket. Connections to these holes are labeled on the foil side of EC24.

Refer to Fig. 4-4 as you make the following connections. Connect a short length of hookup wire from the hole in the foil which connects to pin 1 of the tube socket to terminal 8 on the 7-lug terminal strip. Remove about 1/4" insula-

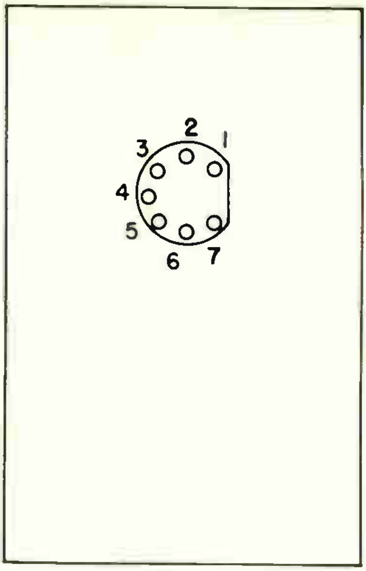

Fig. 4-3. Identifying the tube socket pins on the etched circuit board.

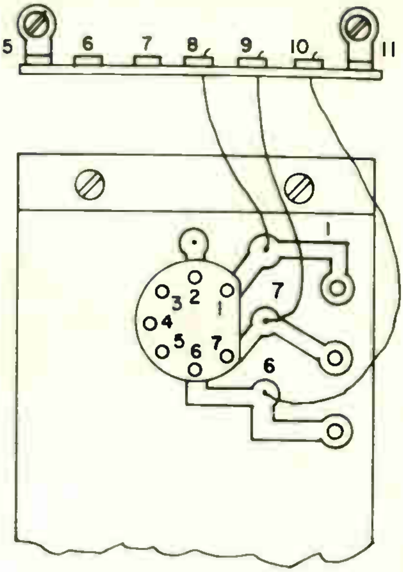

Fig. 4-4. Wiring connecting the tube socket to the terminal strip.

tion from each end of the wire. Slip the end of the wire through the hole in the circuit board from the foil side and solder to the foil.

Similarly, connect a short length of hookup wire from the hole in the foil at pin 7 to terminal 9.

In the same manner, connect a short length of hookup wire from the hole in the foil at pin 6 to terminal 10.

We often refer to a terminal or a conductor connected to a tube socket pin by the tube pin number or even by the element of the tube connected to that pin when a tube is inserted in the socket. Thus, the terminals on the chassis may be identified by the tube socket pin numbers, or as the grid, cathode and plate terminal of the 6C4 tube.

When working from schematic diagrams, remember that ground symbols indicate connections to the common return point (the chassis in this case) and that these connections can be made to anything that is connected to the chassis electrically. As your chassis is presently set up, you can use terminals 1, 5, 11, and 15 as ground connections.

If you are connecting two or more leads to a given point, do not solder until all leads are in position.

In this experiment, you are to wire a circuit directly from a schematic diagram. The diagram you are to use is shown in Fig. 4-5. The tube socket pins are indicated by the open circles nearest the tube symbol. All of the other terminals, which are shown by black dots, represent terminals on the terminal strip.

Before mounting a part, make a trial fit to determine where the part should be located. Sometimes this technique is used by experienced technicians in order to get a neat layout and prevent undue crowding of parts.

Step 1: To mount resistor R_1.

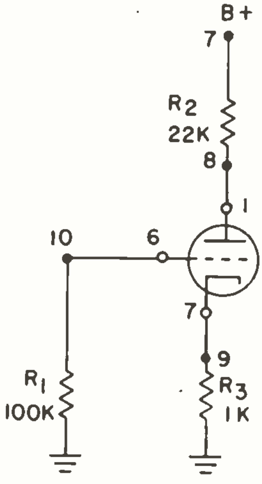

Fig. 4-5. Circuit used in Step 1.

First, find R_1 on the schematic diagram in Fig. 4-5. Notice that it is a 100,000-ohm resistor. Select a 100,000-ohm resistor from among the parts you have collected for this experiment.

From the schematic, you can see that R_1 is connected between pin 6 of the tube socket and ground. Because these connections will be made on the terminal strip, the connection will be made to terminal 10 and a ground terminal.

As stated earlier, there are four places where you can make your ground connection. The solder lug, terminal 1, and the mounting feet of the terminal strips, terminals 5, 11 and 15, are bolted directly to the chassis. Thus, they make electrical contact with the chassis and can be used for ground connections.

Connect one end of the 100,000-ohm resistor to terminal 10 and connect the other end to whichever ground point you find to be most convenient. Bend the resistor leads so that they do not touch the chassis. Also, they should not make contact with any other terminals. Solder terminal 10. Do not solder the ground terminal because you may want to make other connections to it.

Step 2: To mount resistor R_2.

Find resistor R_2 on the schematic diagram. You will see that it is a 22,000-ohm resistor (indicated by 22K on the diagram). You can also see that R_2 is connected from pin 1 of the tube socket, which is the same as terminal 8 on the terminal strip to terminal 7. Terminal 7 is marked "B+" on the schematic. Connect one lead of the 22,000-ohm resistor and solder these connections.

Step 3: To mount resistor R_3.

R_3 is a 1000-ohm resistor. On the schematic, R_3 is between pin 7 of the tube socket and ground.

Install the resistor between terminal 9 on the terminal strip (which is electrically the same as pin 7) and ground. You will have to choose a ground terminal. There are no more connections to be made. Thus, you can solder all connections which you have not yet soldered.

Step 4: To check your work.

After all wiring is in place, check your work against the schematic diagram. This check should now show:

1. A 100,000-ohm resistor between tube socket pin 6 and a ground terminal.
2. A 22,000-ohm resistor between tube socket pin 1 and terminal 7.
3. A 1000-ohm resistor between pin 7 of the tube socket and ground.

Discussion: In this experiment, you have gained experience in working from a schematic diagram. You have practiced reading resistor color codes, and you have again practiced making solder connections. You will use each of these skills every time you work on any electronic equipment.

After you have looked over your work to be sure that it is electrically equivalent to the circuit shown in Fig. 4-5, turn to the back of this manual. On page 77 you will see Fig. 4-6. This shows two ways in which you might have arranged your parts. However, these are not the only possible ways to mount the parts. As long as your arrangement is electrically the same as Fig. 4-5, you have done the experiment correctly.

Instructions For Statement No. 4: After carefully checking your work, answer the statement here and on your Report Sheet. Then unsolder the connections and remove the resistors. Disconnect the three jumper wires from the terminal strip and from the circuit board. Remove the circuit board from the chassis, clean the holes, and put the board aside. Finally, clean the resistor leads and terminals so that they will be ready for use in later experiments.

Statement No. 4: When I wired the circuit used in this experiment, I connected the 22,000-ohm resistor to the:

[✓ *(1) plate*]
(2) cathode
(3) grid

terminal of the tube socket.

Learning to Use A Meter

An electric current is invisible, odorless and tasteless. In other words, we cannot tell that a wire is carrying current unless we use some special means of detecting it.

Although a bell or light bulb can be used to show the presence of current, neither of these devices will indicate how much current is flowing. The current in the circuit must be at a certain level before the bell will ring or the bulb will light. For example, the light bulb will light to full brilliance when its greatest current is flowing through it. As the current is decreased, the light will grow dimmer. Finally, it will reach a point where the light will give no visual indication of current, even though current may still be present in the circuit. Something is needed that will show not only whether there is current flowing, but also how much current is flowing. A meter will do both of these jobs.

MEASURING CURRENT

A meter that is used to measure current is known as an ammeter. An ammeter indicates current in amperes. The ampere, however, is much too large a unit for most measurements in electronics, so we use a meter that indicates either milliamperes (ma) or microamperes (μa). A milliampere equals one-thousandth of an ampere and a microampere equals one-millionth of an ampere. Such meters are called milliammeters and microammeters. They are made the same and operate in the same manner as an ammeter. The only difference is that the milliammeter and microammeter are much more sensitive and will respond to much smaller currents.

The meter you will use in your experiments has a range of 0 to 200 microamperes. This means that a full scale reading on the meter indicates that 200 microamperes are flowing through the meter. When the meter pointer is at half scale, half of 200 microamperes or 100 microamperes are flowing through the meter. When the meter pointer is at 1/10th scale, 20 microamperes are flowing through the meter.

PREPARING THE METER

The meter supplied in this kit is an extremely delicate instrument. It contains a jewel movement similar to that of a fine watch. Therefore, the meter must be handled with care at all times. We cannot replace any meter that has been damaged through careless handling or improper usage. If you follow carefully the instructions given, you will have no trouble with the meter. However, if you fail to follow the instructions, you may damage your meter and have to replace it.

The meter case is plastic. It can easily be scratched with a screwdriver or similar tool, or by scraping it across your workbench. Also, the plastic can be permanently damaged by heat. Be sure that you do not accidentally touch the soldering iron to the meter case.

While you are performing these experiments, the meter will be left in its box. You will connect wires to the meter terminals so that you will have easy access to the meter.

You will need the following:

- 2 **Large solder lugs (LU7)**
- 1 **Meter (ME21)**
- 2 **Diodes (SR12)**
- **Hookup wire**
- **Solder**

Your meter is supplied with mounting hardware and two large nuts for each terminal. These parts are in an envelope in the meter box. Save all of the hardware as you will have need for it later.

To prepare the meter, place a soft pad or towel on your workbench. Next, remove the meter from the box and place the meter carefully on the pad or towel, face down, and with the top of the meter away from you.

Remove the wire from the meter terminals. The terminals were shorted together to prevent damage to the meter during shipment. If the meter is shaken or dropped, the physical movement will cause the meter pointer to move. A voltage is generated in the coil attached to the pointer. The short circuit across the meter terminals permits the current to flow through the terminals and back through the coil. This cancels the tendency of the coil to move and protects the meter from violent pointer swing.

You will now attach the large solder lugs to the meter terminals. First, attach a large nut to one of the terminals and run it all the way down. Then slip a large solder lug over the terminal and secure it with another nut. Position the solder lug so it points toward the bottom of the meter case and tighten the nut. Hold the lower nut with a small wrench or pliers and tighten the outer nut. Do not allow the terminal to turn, since this could damage the connection inside the meter case.

In a similar manner, attach two nuts and a solder lug to the other meter terminal and tighten the nuts.

Now you will identify the lugs on the back of the meter. The one on the left as you face the back of the meter is the positive, or plus terminal of the meter; the one on the right is the negative or minus terminal. The terminals may be further identified by plus or minus signs stamped on the plastic or on the ends of the screws or "POS" and "NEG" printed near the terminals.

Examine the two diodes supplied with this kit. Refer to Fig. 3-3 to help you identify the cathode leads.

Connect the lead at the cathode end of one diode to the positive terminal of the meter. This is diode D_1 in Fig. 34. Slip the end of the lead through the lug attached to the terminal. Do not solder at this time. Slip the anode lead of D_1 through the negative terminal lug.

Connect the second diode, D_2, to the meter terminals also, but with the opposite polarity. Slip the cathode lead through the negative terminal lug and the anode lead through the positive terminal lug. Do not solder at this time.

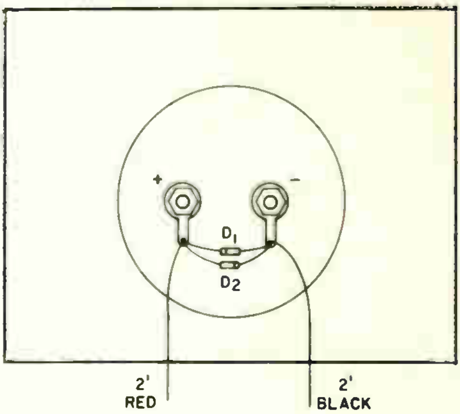

Fig. 34. Connections to the meter movement.

Prepare 2-foot lengths of red and black hookup wire. Remove about 1/4" of insulation from each end of each wire.

Connect the 2-foot length of red hookup wire to the positive meter terminal lug. Check to see that all three leads are through the hole in the terminal; then solder the connection. Be sure all three leads are soldered. After the solder cools, test the connection.

In a similar manner, connect and solder the length of black hookup wire to the negative meter terminal lug. Compare your wiring with Fig. 34 to see that you have done the work correctly.

Next, you will connect the meter leads to terminals on your chassis. Refer to Fig. 35. Connect the red lead from the meter to terminal 14. Connect the black lead from the meter to terminal 12.

Connect a 6" length of hookup wire from terminal 14 to terminal 10. Solder terminal 14.

In order to simplify the instructions, we will call terminal 10 the "positive meter terminal" and we will call terminal 12 the "negative meter terminal."

Put the meter in its box, face up. Do not attempt to make any measurements with your meter until instructed to do so.

The diodes, which you connected to the meter, are used to help protect the meter movement from excessive current. When a voltage of about .6 volt is present, one of the diodes will conduct and provide a low resistance path around the meter movement. We use two diodes connected with the opposite polarities to provide protection regardless of the polarity of the excessive voltage.

In normal operation, the voltage across the meter terminals will not exceed .15 volt. Therefore, the diodes have no significant effect on the operation of the meter unless excessive voltage is applied.

SETTING THE METER POINTER TO ZERO

The meter pointer should rest directly

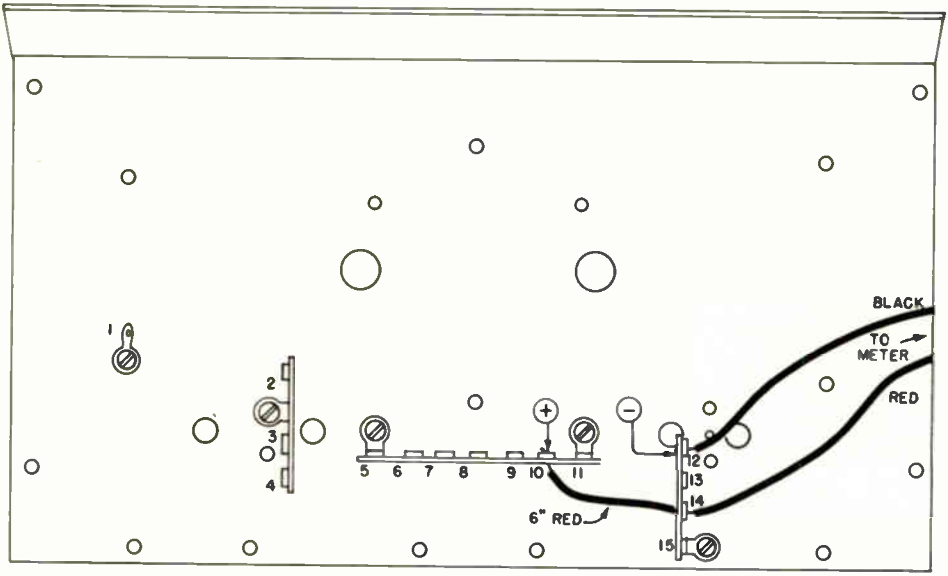

Fig. 35. The meter leads connected to terminals 12 and 14 with a jumper from 10 to 14.

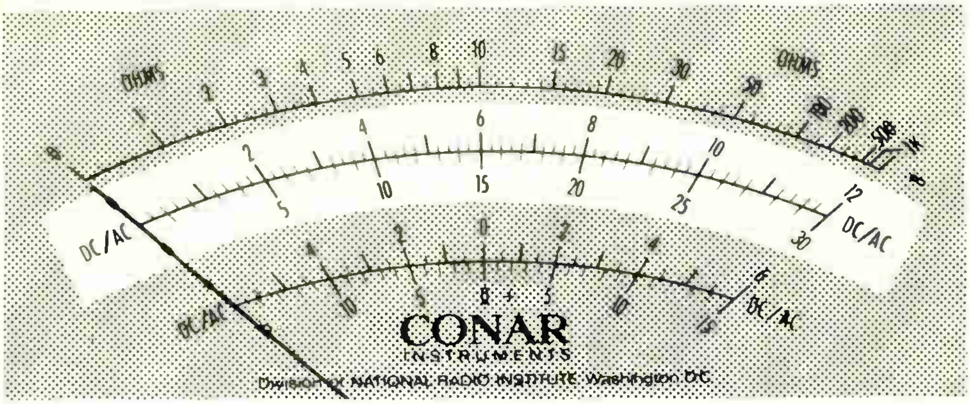

Fig. 36. The 0-12 and 0-30 volt scales on your meter.

over zero as shown in Fig. 36 when the meter is not in use. To set the pointer to zero, use a screwdriver blade that fits in the plastic screw slot on the meter face. Too small or too large a blade can damage the screw. Turn this screw, and notice that the meter pointer can be placed to the right or to the left of zero. Leave the screw adjusted so the meter pointer is over the zero mark. It is unlikely that you will have to make this adjustment again.

READING THE METER

The first time you look at the face of the meter you received in this kit, you may think that the meter is complicated and that it will be difficult to read. As a matter of fact, it is no more difficult to read a meter than it is to tell time on a clock. Of course, a meter may be something new to you, and it will take some practice to learn how to read it quickly. However, it will not be long before you will be able to read it at a glance.

At this time we will concentrate on the 0 to 12 and 0 to 30 volt scales. As you will see, the two scales may often be used together to help you obtain precise readings. These two scales are shown in white in Fig. 36. The 0 to 12 volt scale is the upper scale and has the numbers 0, 2, 4, 6, 8, 10 and 12 printed in black. The 0 to 30 volt scale is the lower scale and has the

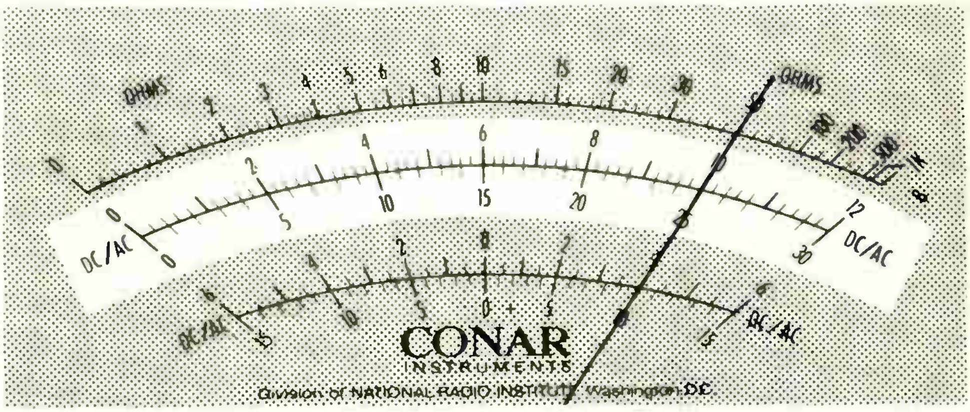

Fig. 37. A meter reading of 25 or 10.

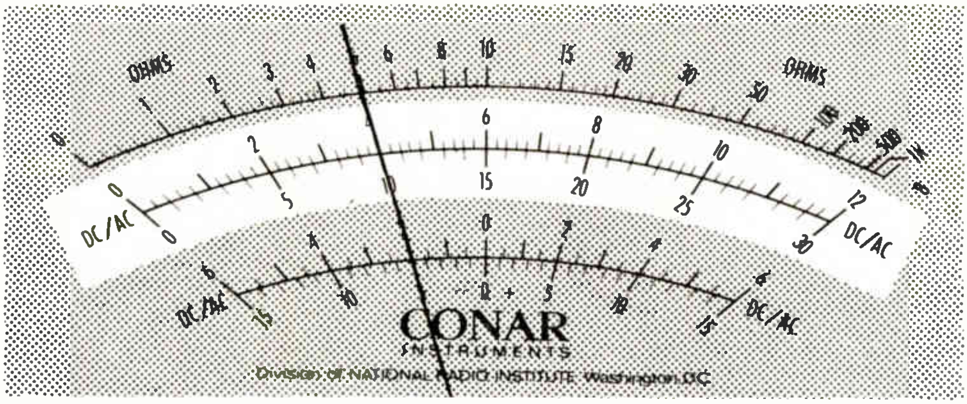

Fig. 38. A meter reading of 10 or 4.

numbers 0, 5, 10, 15, 20, 25 and 30 printed in black. Notice that the 0 to 12 volt scale has several short marks as well as some longer unnumbered marks. The 0 to 30 volt scale has four short unnumbered marks between each number.

Now look at the meter shown in Fig. 37. In this case the pointer is indicating 10 on the 0 to 12 volt scale and shows 25 on the 0 to 30 volt scale. If the pointer is as shown in Fig. 38, the reading would be 10 on the 0 to 30 volt scale and 4 on the 0 to 12 volt scale. These readings are quite easy to determine, as you can see, but what happens if the pointer is somewhere between the numbers on the scale?

Look at the scale shown in Fig. 39. Now the pointer is over one of the short marks of the 0 to 12 volt scale, but is between two short marks on the 0 to 30 volt scale! To read this value, note that on the 0 to 12 volt scale there are nine marks (or ten spaces) between 6 and 8; eight short marks and one long mark. The long mark represents 7 volts, and each short mark represents 0.2V. The pointer in Fig. 39 is on the third short mark following the 6 volt mark. Since each short mark is 0.2V, the pointer shows a reading of 6.6 volts.

Now, what is the reading of Fig. 39 on the 0 to 30 volt scale? First, notice that

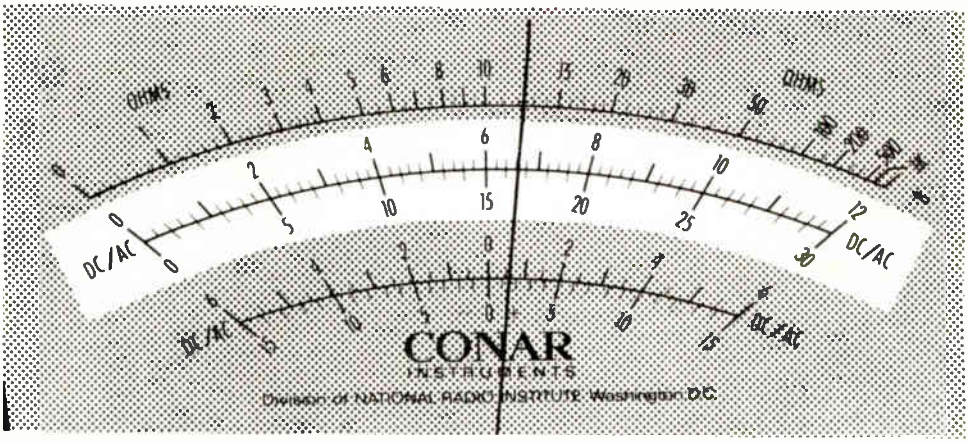

Fig. 39. Another sample meter reading.

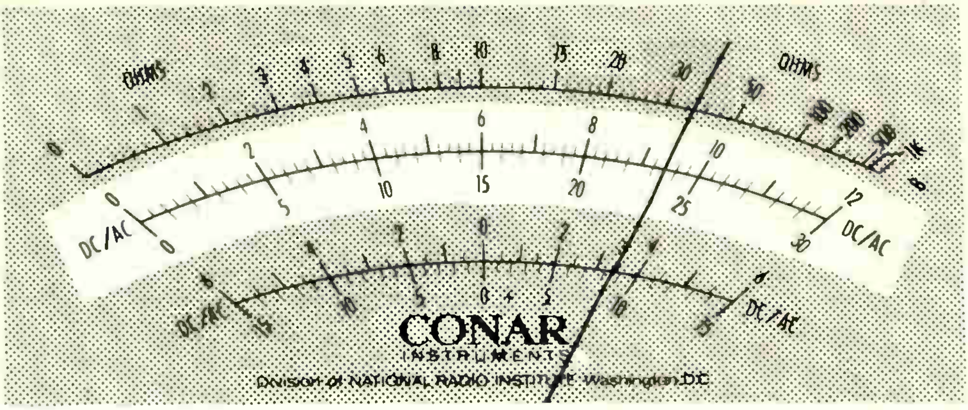

Fig. 40. Study this meter reading and see if you can tell what it is.

between 15 and 20 there are four short marks. Each mark, therefore, represents one volt. The pointer is halfway between the first and second marks following 15 so the reading is 16.5 volts. You can tell that the pointer is exactly halfway between the two marks by looking at the upper (0 to 12 volt) scale. On this scale, every other mark falls exactly halfway between the one volt marks on the 0 to 30 volt scale. This means that while the 0 to 30 volt scale is marked in one volt steps, you can determine readings to one half a volt by looking at the divisions on the 0 to 12 volt scale.

Let's look at another example. Take a look at the scale shown in Fig. 40. Using the reasoning that we applied in the previous examples, can you tell what the reading would be on the 0 to 12 and 0 to 30 volt scales? If you have trouble, go back and reread the material in the previous paragraphs. After careful study you should have no difficulty in seeing that the readings are 9.4 volts and 23.5 volts respectively on the 0 to 12 and 0 to 30 volt scales.

There is always the possibility that the pointer will not fall precisely on one of the short marks of the 0 to 12 volt scale. How are these values read? Take a look at Fig. 41. Notice here that the pointer is halfway between the second and third short marks after 4 on the 0 to 12 volt

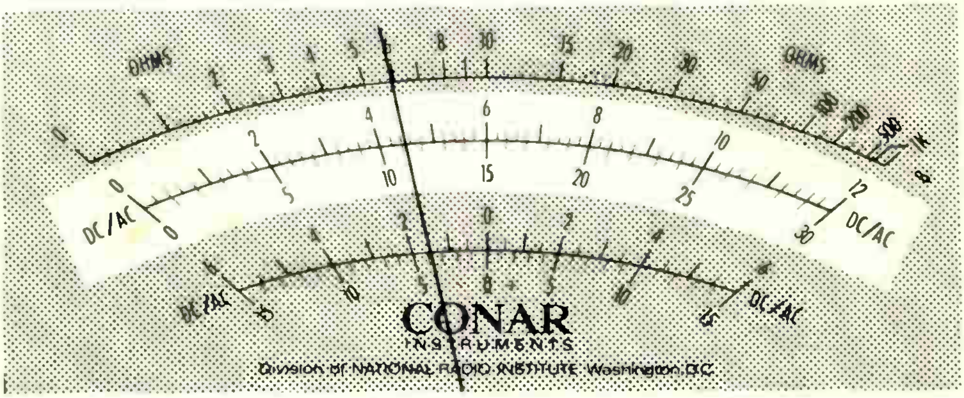

Fig. 41. Here is another meter reading for you to practice on.

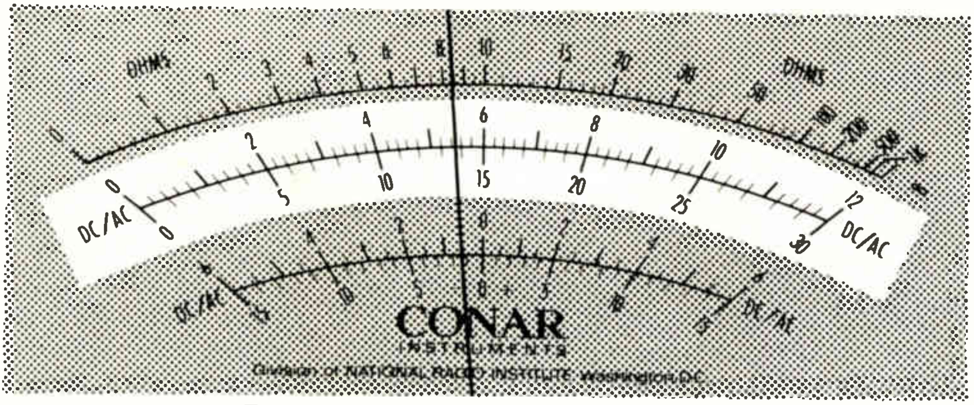

Fig. 42. What is the indication on this meter?

scale. This would be a reading of 4.5 volts. On the 0 to 30 volt scale it is just as easy. The pointer falls one fourth of the way between the first and second mark after 10, so the reading is 11.25 volts.

As a final example, try your hand at reading the two values indicated in Fig. 42. Again, the pointer does not fall on any of the scale marks of either scale. Let us see how close we can come to reading the meter by applying what we have already learned. On the 0 to 12 volt scale, the pointer is between 5 and 6. We can be more exact than that; it appears to be halfway between the second and third marks following the (unmarked) 5 volt mark. The first mark is 5.2 volts, the second mark is 5.4 volts and the third mark is 5.6 volts. Therefore the reading is between 5.4 and 5.6 volts. How much, is the question. The pointer falls about halfway between 5.4 and 5.6 volts so we would call it 5.5 volts. There is, of course, some uncertainty in this reading. For the purposes of your experiments, you would read it as 5.5 volts.

What reading does Fig. 42 represent on the 0 to 30 volt scale? Well, it is somewhere between 10 and 15 volts. Each short mark represents one volt, so the reading would be between 13 and 14 volts. Remember that the short mark on the *upper* scale (0 to 12 volts) is exactly halfway between the 13 and 14 volt marks, or in other words represents 13.5 volts. The pointer falls to the right of this mark so the reading must be between 13.5 and 14.0 volts. We would probably call this 13.75 volts; any value from 13.7 to 13.8 volts would be sufficient.

Building A Simple Series Circuit

You have already studied Ohm's Law and you know that there is a definite relationship between the voltage, current and resistance in a circuit. In Experiment 5, you will see just what happens to the current when you change either the resistance in the circuit or the voltage applied to the circuit. Before you begin Experiment 5 you will prepare the chassis by installing some parts on it. Then, when you begin Experiment 5 you will add some more parts and perform the Experiment.

In addition to your meter and chassis, you will need:

- 2 4.7K-ohm resistors (yellow-violet-red-silver)
- 1 6.8K-ohm resistor (blue-gray-red-silver)
- 1 1.5-volt flashlight cell
- Black hookup wire
- Red hookup wire
- Solder

Inspect the tip of your soldering iron. If necessary, file and retin the tip.

You will connect the three resistors to terminals 7, 8, 9 and 10 on your chassis. The chassis with the resistors in place is shown in Fig. 43. Begin by connecting one lead of a 4.7K-ohm resistor to terminal 10. (There should already be a red wire connected to terminal 10.) Temporarily solder the lead and the red wire to terminal 10. Bend the resistor leads near the body of the resistor and push the free lead through the slot in terminal 9. Connect one lead of another 4.7K-ohm resistor to terminal 9. Solder terminal 9. Connect the other lead of this resistor to terminal 8. Connect one lead of the 6.8K-ohm resistor from terminal 8 to terminal 7 as shown in Fig. 43. Solder terminal 8.

Remove 1/4" of insulation from each end of a 10" length of red hookup wire. Connect and solder one end to terminal 7. Leave the other end free.

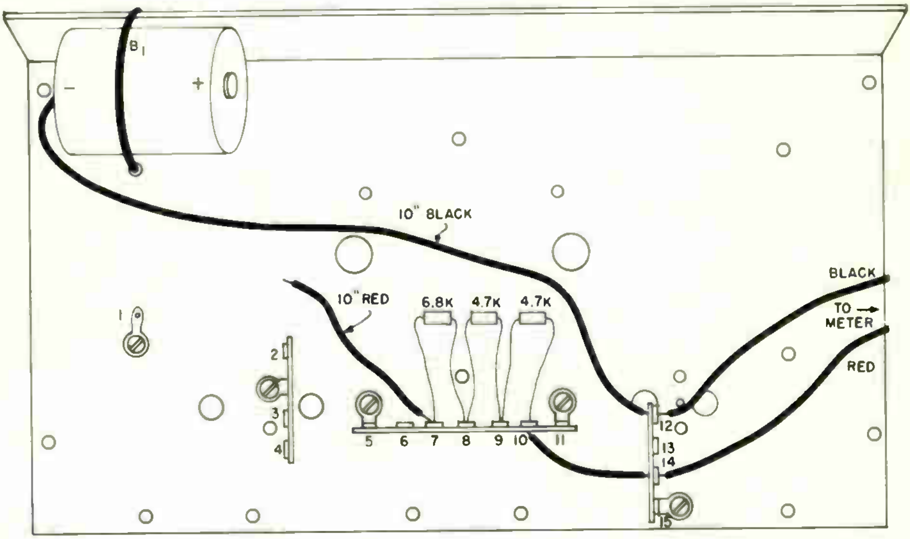

Fig. 43. Experimental chassis wired for Experiment 5.

Fig. 44. How to clean the center of the bottom of a flashlight cell with a piece of sandpaper.

You should now have three series-connected resistors going from the positive meter terminal (terminal 10) to terminal 7. The total resistance between terminal 7 and the positive meter terminal is the sum of the values of the three resistors; a total of about 16,000 ohms.

You now have a 0-200 microampere meter with approximately 16,000 ohms in series with it.

In order to measure current, your meter must be connected to a source of voltage with the proper polarity. The positive terminal of the voltage source must always be connected to the lead or circuit point that goes to the positive meter terminal.

At first, we will use a flashlight cell which produces 1.5 volts dc as a source of voltage. To do this, you are to connect a wire from the negative meter terminal, terminal 12, to the negative battery terminal. Notice that one end of your flashlight cell has a raised portion while the other end is flat. The negative battery terminal is the end with no raised section. Clean a spot in the middle of the bottom of the cell with a piece of fine sandpaper, as shown in Fig. 44.

Be sure that your soldering iron tip is clean and hot. Then, hold the end of your roll of solder on the negative terminal of the cell and touch your soldering iron to the solder. Rub the iron around so that the terminal becomes well-tinned.

Now cut a 10" length of black hookup wire and remove 1/4" of insulation from each end. Place one end of the 10" length black hookup wire on the tinned area of the negative terminal of the cell. Touch the tip of your soldering iron to the wire and the tinned portion of the cell. The solder should melt and run over the wire. Remove the heat and allow the joint to cool. If the solder does not flow smoothly over the wire, add a little more solder as you heat the connection.

If you like, you can use a piece of hookup wire to secure the cell in place along the bend in the chassis as shown in Fig. 43. Note that the negative terminal is toward the left side of the chassis.

Fig. 45. Schematic symbol for a battery.

The symbol we use on schematic diagrams to represent a battery is shown in Fig. 45. Each pair of lines represents one cell of the battery. The short wide line represents the negative terminal and the longer thin line represents the positive terminal. To represent one cell, we use only one pair of lines; but to represent several cells, we do not try to show the exact number, as two or more pairs are sufficient.

EXPERIMENT 5

Purpose: To show that current flowing in a series circuit will change when the

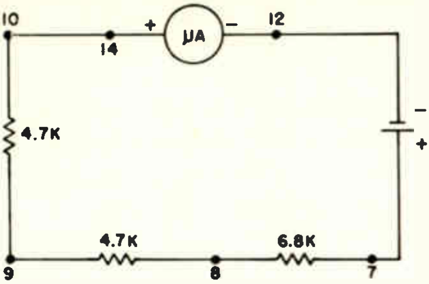

Fig. 5-1. The circuit you will use in Step 1 of Experiment 5.

resistance in the circuit or the voltage applied to the circuit is changed.

Introductory Discussion: Although the circuit you will use in this experiment is a simple circuit, it will act in the same way that a more complex circuit would act when either the resistance or voltage is changed.

This experiment will demonstrate Ohm's Law, which is one of the most important laws you will study. Do each step of the experiment carefully and make sure you understand exactly what you are doing and what the changes in current that you observe mean.

Experimental Procedure: In this experiment, in addition to the meter, chassis and the circuit you have just wired, you will need the following:

1 1.5-volt flashlight cell
Hookup wire

The first circuit you will use is shown in Fig. 5-1. When you read the meter, use the 30-volt scale which you practiced reading previously.

Step 1: To connect 1.5 volts across the meter and series resistor combination.

Touch the red wire from terminal 7 to the positive terminal of the flashlight cell. This closes the circuit and causes current to flow.

Observe the pointer on your meter. It should be slightly below one-half scale. If you get no reading, look for a bad connection or a short circuit. Check to be sure that your circuit is wired as shown in Fig. 5-1. Trace the wiring from terminals 12 and 10 back to the terminals on the meter. Also check for a short circuit between the meter terminals or leads.

The meter scale which you are using in this experiment (Fig. 5-2) is the 0 to 30 volt scale. However, in this experiment you are using this scale only as a relative indication of the amount of current in the circuit. The meter indicates a current of about 100 microamperes, since you know that a full scale reading (30) repre-

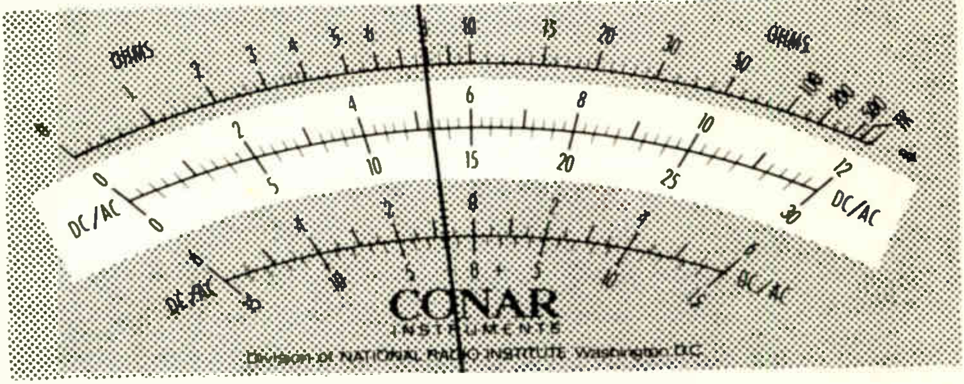

Fig. 5-2. The meter reading of Step 1 should be approximately 13 on the 0-30 scale.

STEP	READING
1	14.3
2	29.5
3	23.9

Fig. 5-3. Record your reading for Experiment 5 here.

sents a current of 200 microamperes.

In later experiments you will learn that the 0 to 30 volt scale will also be used to indicate 0 to 3 volts, and 0 to 300 volts. The 0 to 12 volt scale will also be used to indicate ranges of 0 to 1.2 volts, 0 to 120 volts and 0 to 1200 volts. For the time being, however, you need only be concerned with relative scale indications on the 0 to 30 volt scale. Read the meter carefully and write the reading of the meter in the space provided for Step 1 in Fig. 5-3. Remove the red wire from the positive terminal of the flashlight cell to open the circuit.

Step 2: To determine the effect of increasing the voltage in a series circuit.

To do this, you will connect another flashlight cell in series with the cell you used in Step 1. This is shown in the schematic diagram in Fig. 5-4.

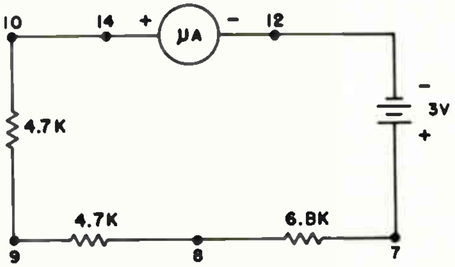

Fig. 5-4. Circuit to use for Step 2.

Clean the positive terminal of the second flashlight cell with a piece of fine sandpaper. Hold your soldering iron on the terminal and apply solder. Melt

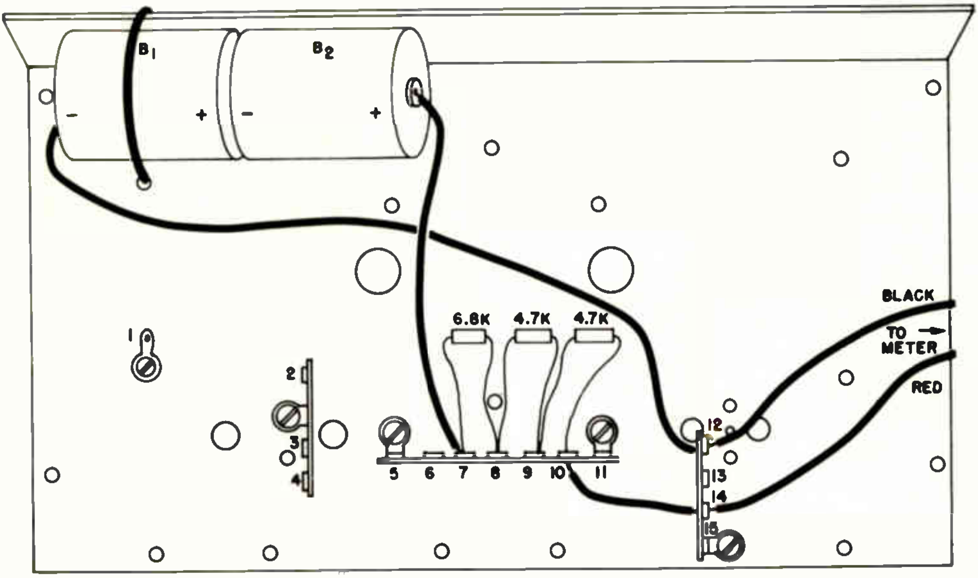

Fig. 5-5. Series resistor with 3-volt battery.

enough solder on the terminal to tin it. Rub the tip of the iron around so that the terminal is well-tinned.

Place the free end of the red wire connected to terminal 7 on the tinned area of the positive terminal of this flashlight cell and apply heat to solder the wire to the terminal. Use additional solder if necessary.

Now, to complete the circuit, hold the positive end of the first flashlight cell against the negative terminal of the second flashlight cell, as shown in Fig. 5-5. This places the two 1.5-volt cells in series, thus forming a 3-volt battery.

The meter pointer should swing to the right to just under 30 on the 30-volt scale. Look at the meter carefully, read the value as closely as you can, and write the reading in the space reserved in Fig. 5-3.

Step 3: To show that the amount of current will change when the resistance is changed.

The circuit you will use is shown in Fig. 5-6. Unsolder the red wire from the positive terminal of the second flashlight cell and from terminal 7 and set the cell to one side. Solder one end of the red wire you just removed to terminal 8.

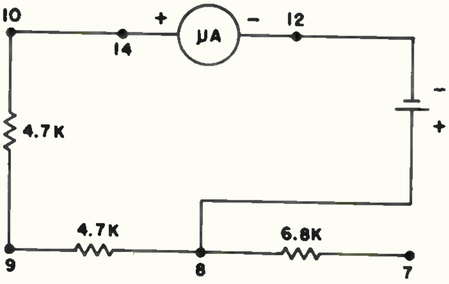

Fig. 5-6. Circuit you use for Step 3.

Touch the free end of the red wire to the positive terminal of the flashlight cell on the chassis. You now have a total of about 9,400 ohms in the circuit with a source voltage of 1.5 volts. Read the meter and record your readings in the space for Step 3 in Fig. 5-3.

Discussion: In this experiment, you have seen what happens in a series circuit when the voltage or resistance is changed. You should have a reading of something less than 15 for Step 1. When you doubled the voltage in the circuit by adding a second flashlight cell, you should have obtained a reading of about two times the original reading. In other words, when you double the voltage supplied to the circuit, the current in the circuit doubles. From this, you can see that there is a definite relationship between voltage and current in a series circuit.

In Step 3, when you reduced the resistance in the circuit, you should have found that the current was greater than in Step 1. This shows that if you reduce the resistance in a series circuit, the current will increase. We could have shown that increasing the resistance will cause the current to decrease, but this should have been obvious from the steps that you have already carried out in this experiment.

Instructions For Statement No. 5: In order to complete this statement you must obtain one additional reading. You will find the current through a resistance of approximately 7,500 ohms connected across a voltage of 1.5 volts. To get this reading, wire the circuit shown in the schematic in Fig. 5-7. Connect a short length of hookup wire from terminal 7 to terminal 9. Solder both connections. Fig.

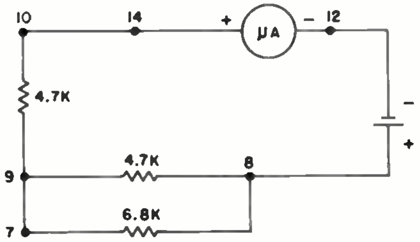

Fig. 5-7. Connect the free end of the resistors to the junction of the first and second resistors to get Statement answers.

5-8 shows the chassis wired according to Fig. 5-7. This places a 4,700-ohm resistor in parallel with the 6,800-ohm resistor. This combination is in series with the other 4,700-ohm resistor. Next, touch the red wire from terminal 8 to the positive terminal of the flashlight cell on the chassis.

Observe the meter reading on the 30-volt scale and answer the statement.

Remove the three resistors connected to terminals 7, 8, 9 and 10 and clean their leads so they will be ready for reuse. Also, disconnect and remove the short length of wire connecting terminals 7 and 9 and remove the 10″ length of red wire from terminal 8. Do not discard this wire as you can reuse it in later experiments. Do not remove any of the other wires.

Statement No. 5: When I touched the free end of the lead from terminal 8 to the 1.5-volt cell, I obtained a reading of approximately

(1) 15
[✓ *(2) 30*]
(3) 10

EXPERIMENT 6

Purpose: To show how to connect resistors in parallel; and to show that the net resistance of a group of parallel-connected resistors is less than that of the smallest resistor in the group.

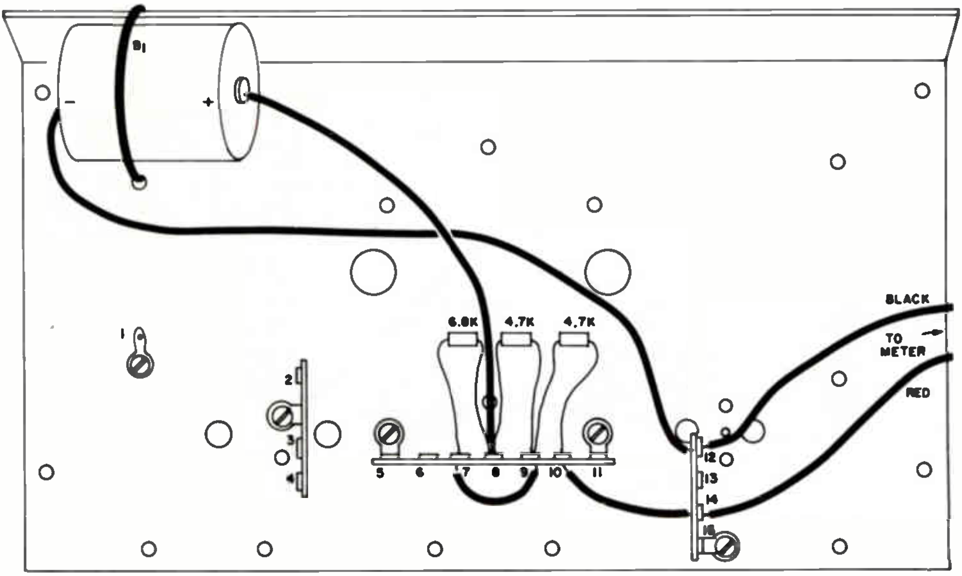

Fig. 5-8. Chassis arrangement for Statement 5.

Introductory Discussion: In the last experiment, you learned how to connect resistors in series with a source of voltage. When resistors or any other parts are connected across a voltage source, they are called a load. In a circuit of this type, each resistance, including that of the meter, can be considered as part of the total load resistance. Thus, the total load resistance is the sum of the individual resistances.

In this experiment we will show that loads can also be connected to the source voltage so that the entire source voltage is connected to each load. We will also show that when loads are connected in this manner, the net resistance of the combined load is less than the resistance of the smallest resistance in the group.

Experimental Procedure: In making these tests, you will use the following parts:

2 100,000-ohm resistors
1 82,000-ohm resistor
2 Flashlight cells
Red hookup wire

Since good connections will be required, we will solder leads to the batteries. To do this, clean the battery terminals (that you have not yet used) with a piece of sandpaper and tin them, as you learned to do in the last experiment.

Remove 1/2" of insulation from each end of an 8" length of red hookup wire. Place one end of one wire on the tinned area of the positive terminal of the cell connected to terminal 12. Touch the soldering iron to the junction. The solder on the tinned areas should melt and run over the wire. If necessary, add solder to get a good connection. Remove the heat, and let the joint cool. Solder the other end of the wire lead to the tinned area on

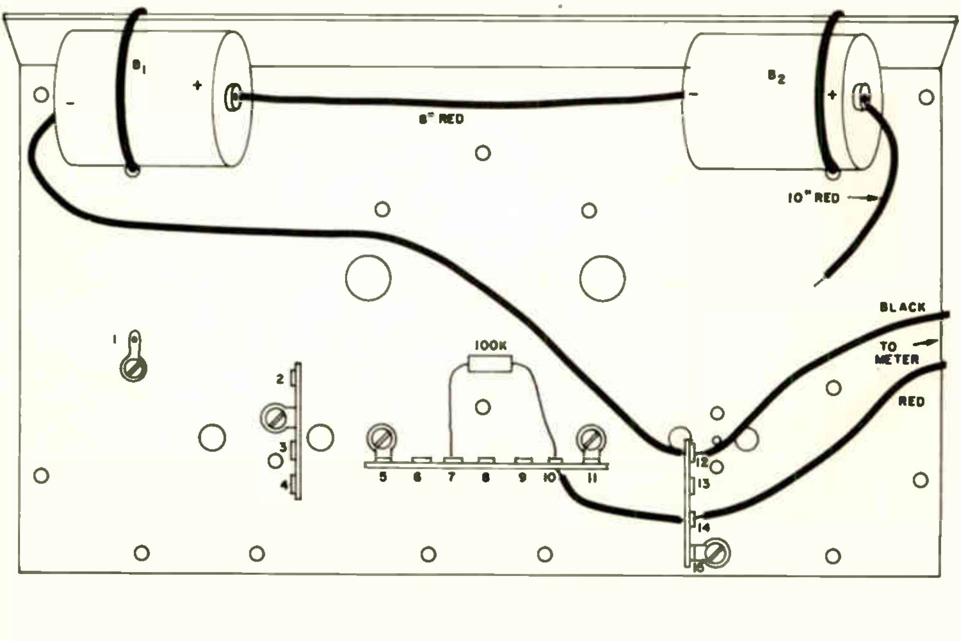

Fig. 6-1. Chassis wired for Step 1.

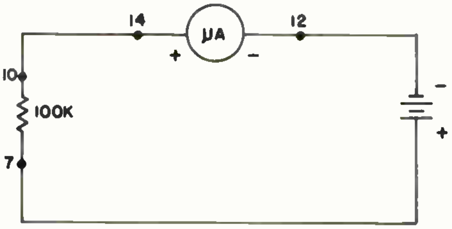

Fig. 6-2. Schematic diagram for Step 1.

the negative terminal of the second battery.

Secure the second battery to the right side of the chassis as shown in Fig. 6-1. You can pass a piece of string or hookup wire through the hole in the chassis and around the battery.

We will call the cell on the left side of the chassis B_1 and we will call the cell on the right B_2.

Locate the 10″ length of red hookup wire you used in the last experiment. Solder one end of this wire to the positive terminal of the flashlight cell, B_2. Leave the other end free.

You now have a 3-volt battery. The negative terminal of the 3-volt battery is the negative terminal of B_1 and is connected to terminal 12. The red wire connected to the positive terminal of B_2 is the "positive battery lead."

Complete the circuit shown in Figs. 6-1 and 6-2 by soldering a 100,000-ohm resistor between terminals 7 and 10.

Step 1: To get an indication of the current flowing with a 100,000-ohm resistor in the circuit.

Touch the free end of the positive battery lead, which is soldered to the positive terminal of B_2, to terminal 7. Read the meter indication on the 30-volt scale. The meter pointer should be in about the position shown in Fig. 6-3. Your reading may be somewhat higher or lower than the value shown in Fig. 6-3 because of normal tolerances in resistor values and the output voltages of different cells. Read the meter carefully and then remove the free end of the positive battery lead from terminal 7 to open the circuit. Record your reading in the space provided for Step 1 in Fig. 6-4.

Step 2: To connect a 100,000-ohm resistor in parallel with the resistor used in Step 1.

Clean the leads of the second 100,000-ohm resistor and connect it in parallel with the resistor used in the last

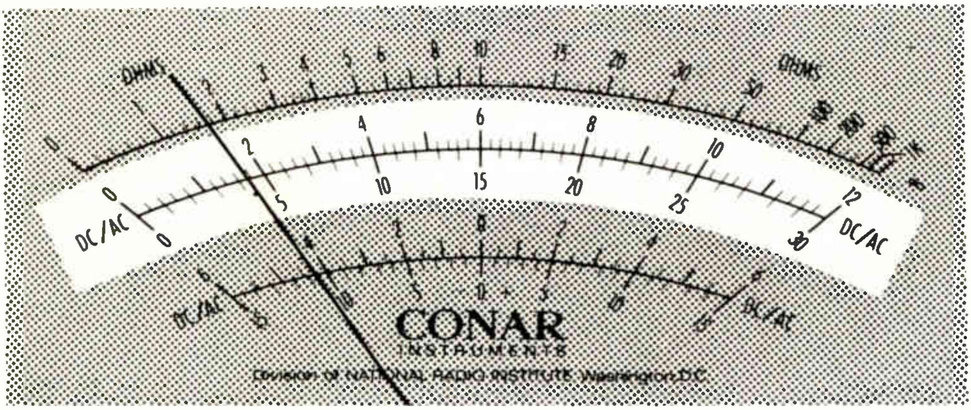

Fig. 6-3. Meter reading for Step 1.

STEP	READING
1	4.5
2	9.25
3	14.75

Fig. 6-4. Record your reading for Experiment 6 here.

step. You may solder the leads to terminal 7 and 10 or, if you prefer, you may solder the leads to the leads of the resistor already in the circuit. The circuit for this step is shown in Fig. 6-5.

Touch the positive battery lead to terminal 7 and read the meter on the 30-volt scale. Remove the positive battery lead after recording your reading in the chart in Fig. 6-4.

Step 3: To add an 82,000-ohm resistor to the parallel connected 100,000-ohm resistor.

Clean the leads of the 82,000-ohm resistor and solder it either to terminals 7 and 10 or to the leads of one of the resistors used in Step 2. The schematic diagram of the circuit for this step is shown in Fig. 6-6. Touch the positive battery lead to terminal 7 and note the reading on the meter. Open the connection after recording your reading in Fig. 6-4.

Discussion: In this experiment you have demonstrated what happens to the current in a circuit when resistors are connected in parallel. You should have discovered that as you added the second 100,000-ohm resistor to the circuit, your reading on the meter was about twice what it was with only one resistor in the circuit. When you added the third resistor, you should have found that the current increased still more.

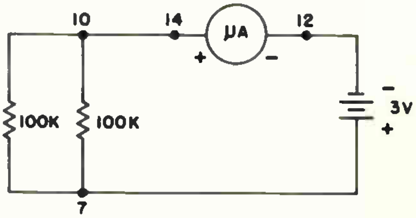

Fig. 6-5. Schematic diagram for Step 2.

You know from Ohm's Law that the amount of current that will flow in a circuit depends on the voltage applied to the circuit and the resistance in the circuit. In other words, I = E ÷ R. The value of E did not change; it was 3 volts throughout the entire experiment. Therefore, the change in current must have been entirely due to the change in resistance. In fact, the total resistance in the circuit decreased as you added more

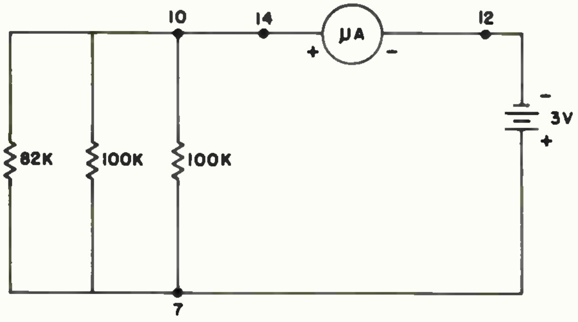

Fig. 6-6. Schematic diagram for Step 3.

resistors in parallel to produce the increase in the circuit current.

Of the three resistors used in this experiment, the 82,000-ohm resistor has the lowest resistance, and we will use this resistor by itself in the statement for this experiment.

Instructions for Statement No. 6: Remove all three resistors from terminals 7 and 10. Separate the resistors and reconnect the 82,000-ohm resistor to terminals 7 and 10.

Touch the positive battery lead to terminal 7 and note the reading on the
5,75 meter. Open the circuit, and write the reading in the margin of this page. Answer the statement, and then disconnect the 82,000-ohm resistor. Clean and straighten its leads so that it will be ready for re-use. Leave all other connections alone as they will be used in the next experiment. Leave the two flashlight cells connected together and the lead from the negative terminal of the battery connected to terminal 12.

Statement No. 6: When I connected an 82,000-ohm resistor in place of the parallel group, the reading was:

~~*(1) higher*~~
[✓ *(2) lower*]

than the reading obtained in Step 3.

This indicates that the resistance of the parallel group was:

[✓ *(1) more than*]
(2) less than

that of the 82,000-ohm resistor by itself.

EXPERIMENT 7

Purpose: To show that the current is the same at every point in a series circuit.

Introductory Discussion: You already know that current in a circuit is the flow of electrons through the circuit. Electrons flow from the negative terminal of the voltage source, which is the battery in this experiment, through the load, and back to the positive terminal of the battery. Inside the battery, electrons flow from the positive terminal to the negative terminal.

In any series circuit, the current is the same throughout the entire circuit. In other words, if you connect a current-measuring instrument into the circuit to measure the current, it will not make any difference where you connect the instrument -- you will always get the same current reading. In this experiment you will demonstrate this. You will even show that the current flowing in the battery itself is the same as the current flowing in the external circuit.

Experimental Procedure: In this experiment, in addition to the meter, chassis and flashlight cells you will need the following parts:

1 100,000-ohm resistor
1 82,000-ohm resistor
1 22,000-ohm resistor
Hookup wire

Fig. 7-1 shows the circuit you will use for Step 1. This is the same setup used in

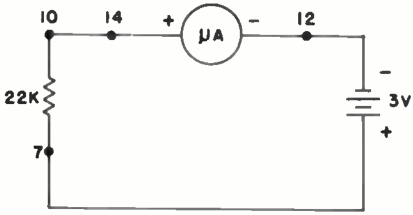

Fig. 7-1. Schematic of circuit for Step 1.

STEP	READING
1	20.5
2	20.5
3	20.25

Fig. 7-2. Record your reading for Experiment 7 here.

the last experiment. To construct the circuit, solder the leads of the 22,000-ohm resistor to terminals 7 and 10. When you have made these connections you should have:

(1) a wire from the negative battery terminal (negative terminal of B_1) to terminal 12,
(2) a wire connecting terminal 14 and terminal 10,
(3) a 22,000-ohm resistor connected from terminal 10 to terminal 7,
(4) a wire from the positive terminal of B_1 to the negative terminal of B_2, and
(5) a wire soldered to the positive battery terminal with the other end free. There should be no wire soldered to terminal 7.

If your circuit is properly wired, you may proceed with the first step.

Step 1: To measure the current leaving the battery.

Touch the free end of the positive battery lead to terminal 7. Read the meter on the 30-volt scale and record the reading in the space provided for Step 1 in Fig. 7-2. On the schematic in Fig. 7-1, you can see that the battery current flows from the negative battery terminal, through the meter to the resistor. It then flows through the resistor and back to the positive battery terminal.

Step 2: To measure the current returning to the battery.

Rewire the circuit as shown in Fig. 7-3. To do this, first unsolder and remove the red wire from terminal 10 to terminal 14. Unsolder the black negative battery lead from terminal 12. Solder the free end of the black wire to terminal 10. Connect and solder a length of hookup wire from terminal 7 to terminal 12.

Notice on the schematic in Fig. 7-3 that the meter is now between the resistor and the positive battery terminal.

Touch the free end of the positive battery lead to terminal 14 to complete the circuit. Read the meter on the 30-volt scale. Open the circuit after recording the reading for Step 2 in Fig. 7-2.

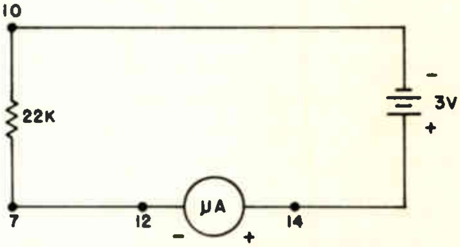

Fig. 7-3. Circuit for Step 2.

Step 3: To show that the current flowing inside the battery itself is the same as the current flowing in the external circuit.

The battery you are using in this experiment consists of two flashlight cells. Large batteries of the type used in earlier tube-type portable radios have voltages of 45 and 90 volts and are made up of groups of 1.5-volt cells, similar to flashlight cells. These are connected in series to get the required voltage. The more cells that are connected in series, the higher the voltage.

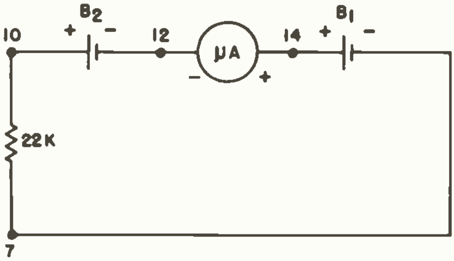

Fig. 7-4. Circuit for Step 3.

With an external circuit connected to the battery, you can measure the internal current in the battery by inserting a meter between any two adjacent cells.

To illustrate this in the experiment, wire the circuit shown in the schematic in Fig. 7-4. Fig. 7-5 shows a pictorial diagram of the wiring. Unsolder and remove the short length of hookup wire connected from terminal 7 to terminal 12.

Locate the wire connecting the two flashlight cells. Unsolder this wire from the positive terminal of B_1. Solder the free end of the wire to terminal 12.

Solder the negative battery lead to terminal 7.

Connect and solder a length of hookup wire from terminal 14 to the positive terminal of B_1. Check to see that your circuit is wired correctly.

Touch the positive battery lead (from B_2) to terminal 10 to complete the circuit. Read the meter carefully and open the circuit after recording your reading in the space provided for Step 3 in Fig. 7-2.

Discussion: In Step 3 of this experiment, the circuit is connected as shown in Fig. 7-4. Here the meter is actually placed between the two flashlight cells, and is measuring the current flowing from one cell into the second cell. Compare your readings for this step with your readings in Steps 1 and 2.

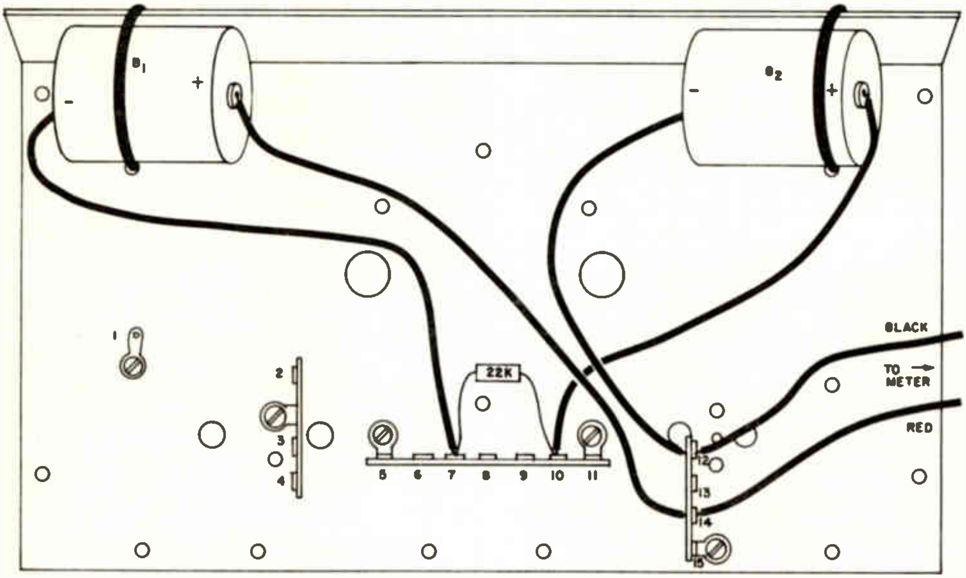

Fig. 7-5. Chassis wired for Step 3.

Notice that the readings are the same in all three steps. This demonstrates an extremely important fact. The value of the current is the same throughout the entire circuit. This means you can connect a meter at any point in a simple series circuit to measure the current; the reading will be the same regardless of where the meter is connected.

It is easy to see why the current in a series circuit is the same throughout the entire circuit. When you close the circuit by touching the battery wire to the circuit, electrons begin to leave the negative terminal of the battery. They strike other electrons and cause them to move. These electrons, in turn, strike additional electrons, and so on throughout the entire circuit. This, of course, occurs instantaneously; as soon as the circuit is completed, electrons start moving through the entire circuit.

At the same instant that electrons begin to leave the negative terminal of the battery, pushing other electrons before them, other electrons begin entering the positive terminal of the battery, because the electrons are attracted by the positive potential. The number of electrons moving in one part of the series circuit is exactly equal to the number of electrons moving in any other part of the series circuit.

Instructions for Statement No. 7: In the preceding experiment, you demonstrated that when resistors are connected in parallel, the total resistance of the combination is lowered. If the applied voltage does not change, this results in an increase in current. For this Report Statement, you will connect a low resistance in series with a high resistance. Then you will shunt each resistance with an 82,000-ohm resistor and note the effect on the total circuit current.

To carry out the experiment for this statement, you will need one 100,000-ohm resistor and one 82,000-ohm resistor. Wire the circuit as shown in Fig. 7-6. Connect a 100,000-ohm resistor from terminal 10 to terminal 13. Solder both connections. Check your circuit to see that it is wired according to Fig. 7-6. Solder the positive battery wire to terminal 13.

Note the reading on the meter on the 30-volt scale. Bend the leads of the 1.8 82,000-ohm resistor so that you can conveniently bridge the resistor across either the 100,000-ohm or the 22,000-ohm resistor. Bridge the 82,000-ohm resistor 2 first across the 100,000-ohm resistor and note the meter reading on the 4 margin. Next move the 82,000-ohm resistor over and bridge the 22,000-ohm resistor. Again, read the meter and note the reading in the margin.

Compare the two meter readings and answer the Report Statement.

Unsolder the positive battery lead from terminal 13. Unsolder and remove the 100,000-ohm resistor connected between terminals 10 and 13 and the 22,000-ohm resistor connected between terminals 7 and 10. Unsolder and remove the short red wire between the positive terminal of B_1 and terminal 14. Unsolder the red wire from terminal 12. (The other end of

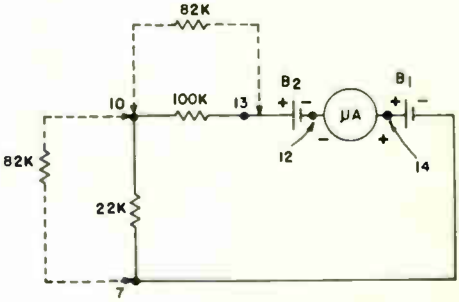

Fig. 7-6. Circuit for Statement 7.

this wire is soldered to the negative terminal of B_2.) Solder the free end of this wire to the positive terminal of B_1 to connect the two cells in series again. Clean and straighten the leads of the resistors you removed and clean all unused terminals.

Statement No. 7: When I shunted the 100K-ohm resistor with an 82K-ohm resistor, and then shunted the 22K-ohm resistor with the 82K-ohm resistor, I found that the effect on the current was:

(1) greater when the 22K-ohm resistor was shunted.
(2) greater when the 100K-ohm resistor was shunted.
(3) the same in both cases.

EXPERIMENT 8

Purpose: To show that the total current flowing in a parallel circuit is the sum of the currents flowing in the branches.

Introductory Discussion: In any piece of electronic equipment, there are usually several tubes or transistors connected across a single power supply. Each circuit, or stage, as they are usually called, generally draws a different current. The total current that the power supply must provide is equal to the sum of the currents drawn by the individual stages. Each stage acts as a separate load connected across the power supply. If a defect develops in one stage so that the stage draws more current than it should, not only will that stage be overloaded, but also the total current that the power supply must furnish will increase. As a result, the power supply may be overloaded. It is important for you to remember this when you start doing repair work. If a power transformer overheats, it does not necessarily indicate that the transformer is defective; it often indicates

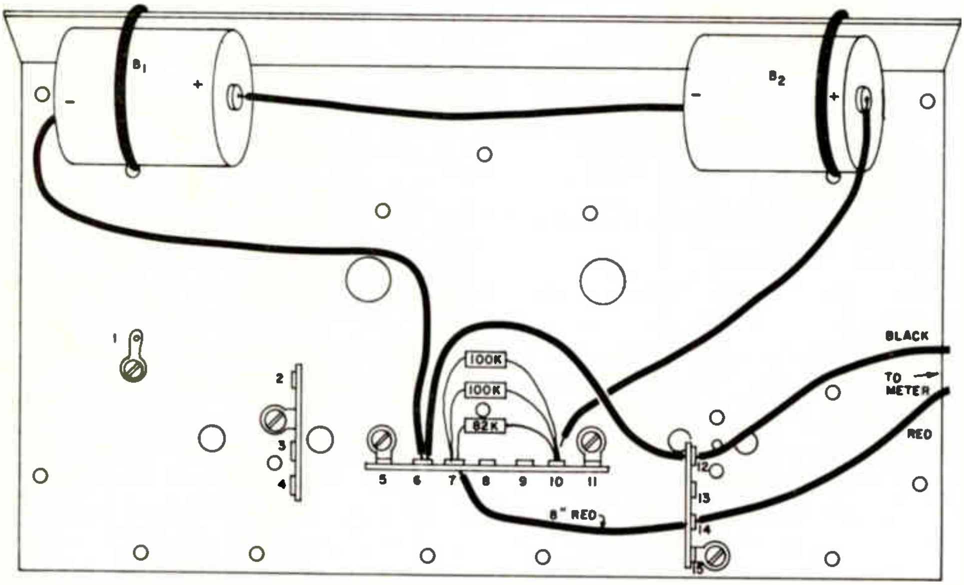

Fig. 8-1. Chassis for Step 1.

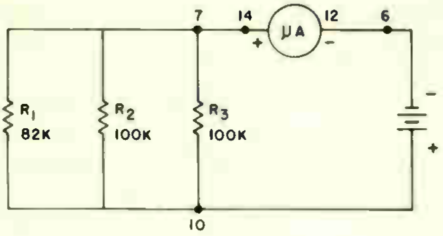

Fig. 8-2. Schematic of circuit for Step 1.

that a defect in some stage other than the power supply is causing the transformer to overheat.

In this experiment you will prove that the sum of the individual branch currents in a parallel circuit is equal to the total circuit current.

Experimental Procedure: In addition to the parts already on the experimental chassis you will need the following parts:

2 100K-ohm resistors
1 82K-ohm resistor
Hookup wire

You should have the two flashlight cells connected to form a 3-volt battery on your chassis. For this experiment, you must wire your circuit as shown in Figs. 8-1 and 8-2.

Solder the two 100,000-ohm resistors and the 82,000-ohm resistor to terminals 10 and 7. You should then have two 100,000-ohm resistors and the 82,000-ohm resistor connected in parallel. Connect the black wire from the negative terminal of B_1 to terminal 6. Next strip 1/4" of insulation from each end of a 5" length of black hookup wire and solder this wire to terminals 6 and 12 as indicated in Fig. 8-1.

Remove about 1/4" of insulation from each end of an 8" length of red hookup wire. Solder one end to terminal 14 and solder the other end to terminal 7. Do not connect the positive battery lead at this time.

Before you go to Step 1, carefully check your work with the schematic of Fig. 8-2 and the pictorial drawing of Fig. 8-1. Make sure you have made all of the connections correctly.

Step 1: To measure the total current flow in a parallel circuit.

Touch the positive battery lead (connected to the positive terminal of B_2) to terminal 10. Observe the readings on the 30-volt scale on your meter. Remove the positive battery lead from terminal 10 after recording your reading in the space provided for Step 1 in Fig. 8-3.

STEP	READING
1	14.6
2	4.60
3	5.00
4	5.75

15.35

Fig. 8-3. Record your reading for Experiment 8 here.

With the arrangement shown in Fig. 8-2, the three resistors are in parallel and the current which you measured is the total current flowing in the circuit.

Step 2: To measure the current through a 100,000-ohm resistor.

You will use the circuit shown in the schematic diagram in Fig. 8-4. To change your wiring to make this circuit, unsolder the lead of the 82,000-ohm resistor and the lead of one 100,000-ohm resistor from terminal 7. Solder these two leads to terminal 6.

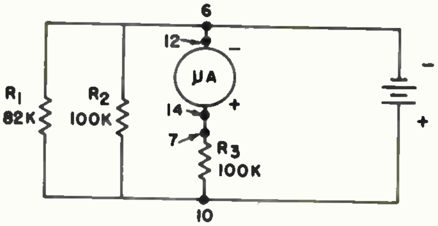

Fig. 8-4. Circuit for Step 2.

As you can see in the schematic, when the circuit is completed, current will flow through all three resistors. However, only the current through R_3 the 100,000-ohm resistor connected to terminal 7 will flow through the meter.

Touch the positive battery lead to terminal 10. Read the meter on the 30-volt scale and record your reading for Step 2 in Fig. 8-3.

Step 3: To measure the current through the second 100,000-ohm resistor, R_2.

Fig. 8-5 shows the circuit. To make the necessary changes, unsolder the 100,000-ohm resistor lead from terminal 7 and resolder it to terminal 6. Then unsolder the lead of the other 100,000-ohm resistor from terminal 6 and resolder it to terminal 7.

Touch the positive battery lead to terminal 10 and observe the meter indication on the 30-volt scale. Remove the battery lead from terminal 10 after recording your reading in the space for Step 3 in Fig. 8-3.

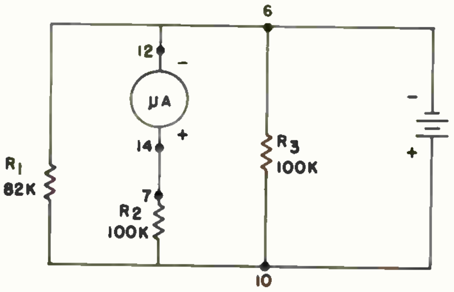

Fig. 8-5. Circuit for Step 3.

Step 4: To measure the current through the 82,000-ohm resistor.

Modify the circuit as shown in the schematic in Fig. 8-6. Unsolder the 100,000-ohm resistor lead from terminal 7 and resolder it to terminal 6. Unsolder the lead of the 82,000-ohm resistor from terminal 6 and resolder it to terminal 7. This places the meter in the 82,000-ohm resistor circuit only.

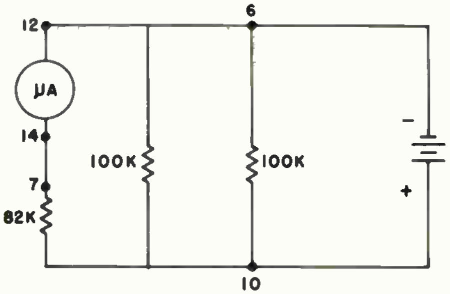

Fig. 8-6. Circuit for measuring the current through the 82K-ohm resistor.

Touch the positive battery lead to terminal 10. Read the meter on the 30-volt scale. Remove the positive battery lead from terminal 10 after recording your reading in the space provided for Step 4 in Fig. 8-3.

Discussion: In this experiment, you have measured the total current flowing in a circuit, and also the current flowing in the individual branch circuits. Since you used two 100,000-ohm resistors, you should have found that the current flowing through these resistors was the same.

In other words, the readings you obtained in Steps 2 and 3 should have been equal.

In actually taking this measurement, you may have found a slight variation because the resistors have a tolerance of 10%. Even though we call the resistor a 100K-ohm resistor, its actual resistance may be as much as 10,000 ohms more or less than 100,000 ohms. The resistance in series with the meter, therefore, may be any value between 90,000 and 110,000 ohms, which would account for the variation in your measurements. The 82,000-ohm resistor can have any value between 73,800 ohms and 90,200 ohms. Therefore, it is actually possible to have little or no difference in reading between the 82,000-ohm resistor and one or both of the 100,000-ohm resistors. In most electronics work, resistor values are not critical, and it is much more economical to use a resistor having a 10% tolerance, than it is to use a resistor having a 1% tolerance.

To show that the total current flowing in the circuit is equal to that in the individual branch circuits, add your readings for Steps 2, 3, and 4, and compare the result with the readings for Step 1. The sum of the readings recorded in Steps 2, 3, and 4 should be approximately equal to the reading you have recorded in Step 1.

Instructions for Statement No. 8: For this Statement, you do not need to take any additional measurements. You can use the readings you took in the experiment to answer the statement.

Answer the statement and unsolder and remove the two 100,000-ohm resistors and the 82,000-ohm resistor from terminals 6, 7, and 10. Remove the red wire from terminals 7 and 14 and remove the black wire from terminals 6 and 12.

Statement No. 8: When I measured the individual branch currents flowing in the circuit consisting of two 100K-ohm resistors and one 82K-ohm resistor, I found that the current was greatest

(1) through one of the 100K-ohm resistors.
[✓ (2)] through the 82K-ohm resistor.

This shows that maximum current will flow through the branch in the parallel circuit having

[✓ (1)] the lowest resistance.
(2) the highest resistance.

EXPERIMENT 9

Purpose: To show that a microammeter can be used as a voltmeter if a suitable resistor is placed in series with the meter.

Introductory Discussion: You have seen how a microammeter can be used to indicate the presence of current and to show if the current increases, decreases, or remains constant when circuit conditions are changed. We have not been able to measure the current in microamperes or milliamperes because the meter is not calibrated to read in microamperes. It would be possible to calculate the current from your scale readings, but since we are not interested in exact values, it is not necessary.

Your meter is a 0-200 microammeter. This means that a current of 200 microamperes must flow through the meter to give a full-scale deflection. In other words, when the pointer is at 30 on the 30-volt scale, the current flowing through the meter is 200 microamperes. (Microamperes is abbreviated μa.)

If your meter had a 200 microampere (200 μa) scale printed on it, and we inserted a resistance in series with the meter, and then connected the combination across a voltage source, you could read the current through the meter. The current would depend upon two things: the voltage of the source, and the resistance we placed in series with the meter. If we knew what the resistance was, we could read the current from the meter, and then calculate the voltage by using Ohm's Law. Ohm's Law states that $E = I \times R$. So we would multiply the current in amperes by the resistance in ohms to get the voltage of the source.

This arrangement has one drawback, however. It takes quite a bit of time to make the mathematical calculations. Actually, it is not necessary to do this, because as long as the resistance remains unchanged, the current will depend only on the voltage. Therefore, we can calibrate the meter to read directly in voltage. Now let us see how we can find out what resistor we need in order to use the 3-volt range on the meter.

To do this, we again turn to Ohm's Law. One form of Ohm's Law states that the resistance is equal to the amount of voltage divided by the amount of current. In other words, $R = E \div I$. We want the meter to read full scale when the voltage applied is 3 volts; therefore E will be equal to 3. We know that the meter is a 200 microampere meter; it takes 200 microamperes (200 μa) of current to make the meter read full scale. Converting this value to amperes, we get .0002 ampere. Now, to get the value of resistance needed, we divide 3 by .0002. This will give us 15,000. Therefore, the resistance value that should be added to the circuit is 15,000 ohms.

If we want to build an accurate meter, we will have to subtract the resistance of the meter itself from the resistance to be placed in series with the meter. However, the resistance of your microammeter is small compared to 15,000 ohms, so we will simply connect the 15,000-ohm resistor in series with the meter to give us a voltmeter that will read 3 volts on full scale. The error introduced by disregarding the meter resistance will be unimportant in this experiment.

As mentioned earlier, the scales on the meter are labeled 0 to 12 and 0 to 30. For the 3-volt scale, read the 0 to 30 volt scale but mentally divide the reading by 10, or place a decimal point before the last digit. For example, for a full scale reading, the pointer will point to 30. Dividing this by 10 gives us 3.0. Similarly, a reading of 20 is actually 2.0 on the 3-volt scale, just as 15 is 1.5 volts, 5 is 0.5 volts and so on.

Experimental Procedure: In this experiment, in addition to your meter and chassis with parts mounted, you will need the following parts:

1 15,000-ohm resistor
Hookup wire

Prepare 1′ lengths of red and black hookup wire. Remove about 1/2″ of insulation from each end of the wires.

Step 1: To convert your microammeter to a voltmeter.

Unsolder the red meter lead from terminal 14 and reconnect to terminal 13. Connect the 15,000-ohm resistor from terminal 13 to terminal 14. Solder terminal 13. Solder one end of the 1′ length of red wire to terminal 14. Leave the other end free.

Solder one end of the 1′ length of black hookup wire to terminal 12. The meter can now be used as a 0 to 3 volt voltmeter. The black wire connected to terminal 12 is your *negative voltmeter lead* and the red wire connected to terminal 14 is your *positive voltmeter lead.*

Step 2: To measure the voltage of the two flashlight cells connected in series.

The cells should still be connected in series as they were in the last experiment. Touch the negative meter lead (the black wire connected to terminal 12) to the negative terminal of the 3-volt battery, and touch the positive meter lead to the positive terminal of the 3-volt battery. Fig. 9-1 shows the circuit used in this step. Note the reading on the 3-volt scale on your meter. The reading should be approximately full scale, indicating a voltage of about 3 volts. The reading might be a little higher or lower than full scale, depending upon the tolerance of the 15,000-ohm resistor and the actual voltage of your battery. In general, new flashlight cells have a terminal voltage of 1.55 volts which drops to about 1.5 volts when the cells are heavily loaded (are supplying large current). In this circuit there is hardly any load so the battery voltage should be 2 times 1.55 volts or about 3.1 volts which would make your meter read slightly above full scale.

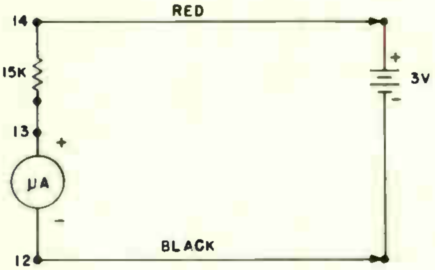

Fig. 9-1. Circuit to measure battery voltage.

Step 3: To measure the voltage of a single flashlight cell.

Touch the positive voltmeter lead to the positive terminal of one cell, and touch the negative meter lead to the negative terminal of the same flashlight cell. Note the reading on the meter. The reading should be about center scale, indicating a voltage of approximately 1.5 volts. Check the voltage of the other flashlight cell in the same way.

Discussion: The meter that you constructed in this experiment is often referred to as a 5,000-ohms per volt voltmeter. We usually write this as 5,000 ohms/volt. Notice that to convert the meter to a 3-volt voltmeter, we use a 15,000-ohm resistor. If we wanted to convert the meter to a 12-volt meter, we would have used a 60,000-ohm resistor. If we wanted to convert the meter to a 30-volt meter, we would have used a 150,000-ohm resistor. In all cases, to find the resistance needed, we multiply the required full scale voltage by 5,000.

In the early days of electronics, meters with sensitivities of 1,000 ohms/volt and 5000 ohms/volt were the only types available. Today most meters have sensitivities of 20,000 ohms/volt to 150,000 ohms/volt.

The sensitivity of the meter used in service work is important. If the meter has a sensitivity of only 5,000 ohms per volt, it is quite possible that you will not get an accurate indication of the voltage in a circuit. In the next experiment we will show you exactly how this can happen and why the sensitivity of the meter is important to the serviceman.

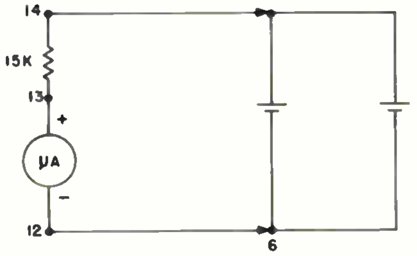

Fig. 9-2. Circuit for Statement 9.

Another type of meter, the vacuum tube voltmeter or the transistor voltmeter, has an even higher sensitivity than the meters previously discussed. For this reason most electronics technicians prefer this type to the simple voltmeter of the type you have just constructed. You will build a sensitive transistor voltmeter in the next Training Kit.

Instructions for Statement No. 9: In this statement, you are to measure the voltage of the two flashlight cells when they are connected in parallel. To do this, unsolder the red wire from the positive terminal of cell B_1 which is on the left side of your chassis. This wire should still be attached to the negative terminal of cell B_2. Solder the free end of this wire to terminal 6. Solder the free end of the positive battery lead (the wire soldered to the positive terminal of B_2) to the positive terminal of B_1. Check your work against Figs. 9-2 and 9-3.

Touch the positive voltmeter lead to the positive terminal of battery B_1 or B_2 and the negative meter lead to terminal 6. Note the reading on your meter, and answer the statement.

Unsolder the red wire from the positive terminal of battery B_1 and push the free end out of the way. Unsolder the red wire from terminal 6 and solder the free end to the positive terminal of flashlight cell B_1. Leave the 15,000-ohm resistor connected to terminals 13 and 14, and the

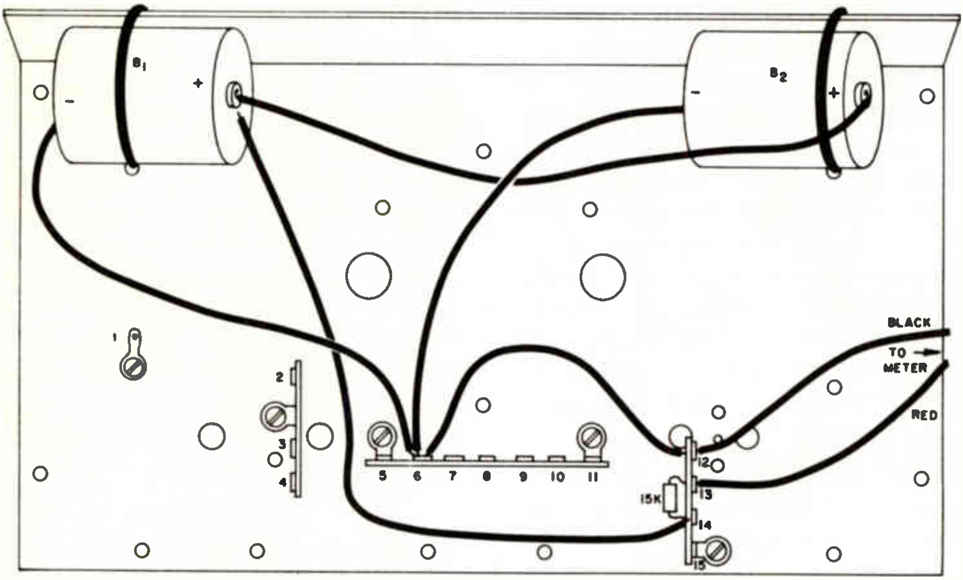

Fig. 9-3. Chassis used for Statement 9.

red and black voltmeter leads connected to terminals 12 and 13.

Statement No. 9: When I measured the voltage of the two parallel-connected flashlight cells, I found that it was approximately

(1) 3 volts.
[✓ *(2) 1.5 volts.*]
(3) 0.

EXPERIMENT 10

Purpose: To show that in a series circuit, there is a voltage across each part, that the sum of the voltages is equal to the source voltage, and that a voltmeter can upset the voltage division.

Introductory Discussion: You already know that if you connect your voltmeter across the battery, you get an indication of the voltage produced by the battery.

When the battery is connected to a series circuit, the battery voltage drives electrons through the circuit. The electrons, in moving through each part of the circuit, set up a voltage across each part. If you accurately measure the voltage across each part and add these voltages, you will find that the sum of these voltages is equal to the source voltage.

In this experiment, you will construct a simple circuit and measure the voltage across each of the individual parts in the circuit to prove that the sum of the voltages is equal to the battery voltage.

Experimental Procedure: In this experiment, in addition to the meter and chassis, you will need:

1 470-ohm resistor
1 680-ohm resistor
1 1,000-ohm resistor
2 100,000-ohm resistors
1 82,000-ohm resistor
2 Flashlight cells

Your flashlight cells should still be connected in series to form a 3-volt battery.

Construct the circuit shown in Fig. 10-1. Solder one lead of a 1,000-ohm resistor to terminal 6. Push the free lead through the slot in terminal 4. Connect the 680-ohm resistor between terminals 3 and 4 and solder terminal 4. Connect the 470-ohm resistor between terminals 2 and 3. Solder terminal 3. Solder the resistor lead and the free end of the positive battery lead to terminal 2.

Step 1: To measure voltages in a low-resistance series circuit.

You will use your 3-volt meter to measure the voltages in the circuit shown in Fig. 10-1.

To measure the source voltage, hold the negative voltmeter lead on terminal 6, and touch the positive meter lead to terminal 2. Observe the meter on the 3-volt scale and place your reading in the space for the source voltage in Fig. 10-2.

Next, while holding the negative voltmeter lead on terminal 6, touch the positive lead to terminal 4 and measure

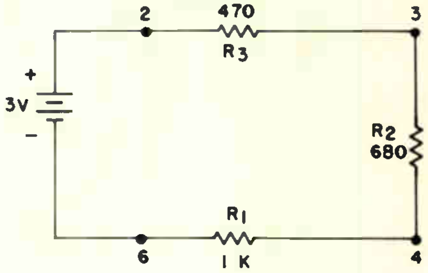

Fig. 10-1. Circuit for Experiment 10.

	READINGS
R_1	1.32V
R_2	.925V
R_3	.650V
$R_1+R_2+R_3$	2.895
SOURCE	3.1V

Fig. 10-2. Record your reading for Step 1 here.

the voltage across resistor R_1. Record this voltage in the space provided for R_1 in Fig. 10-2.

Move the positive meter lead to terminal 3 and the negative meter lead to terminal 4 and measure the voltage across resistor R_2. Record your reading in the space provided for R_2 in Fig. 10-2.

To measure the voltage across resistor R_3, touch the positive meter lead to terminal 2 and the negative meter lead to terminal 3. Read the voltage on the 3-volt scale on your meter and record your reading in the space provided for resistor R_3, in Fig. 10-2. Now add together the three voltages you recorded for R_1, R_2, and R_3 and put this value in place labeled $R_1 + R_2 + R_3$ in Fig. 10-2.

Unsolder the positive battery lead from terminal 2, to open the circuit. Unsolder and remove the 470-ohm, the 680-ohm and the 1,000-ohm resistors.

Step 2: To measure voltage in a higher resistance series circuit.

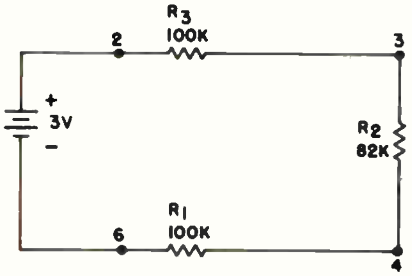

Fig. 10-3. Circuit used in Step 2.

Construct the circuit shown in Fig. 10-3. Solder one lead of a 100,000-ohm resistor, R_1, to terminal 6. Connect the other lead to terminal 4. Connect one lead of the 82,000-ohm resistor to terminal 4 and solder. Connect the other lead of this resistor to terminal 3. Connect and solder the other 100,000-ohm resistor, R_3, from terminal 3 to terminal 2. To complete the circuit, solder the positive battery lead to terminal 2.

Measure the voltage applied to the circuit by holding the positive voltmeter lead on terminal 2 and touching the negative voltmeter lead to terminal 6. Read your meter on the 3-volt scale and record your reading in the space reserved for the source voltage in Fig. 10-4.

	READINGS
R_1	.2 V
R_2	.2 V
R_3	.2 V
$R_1+R_2+R_3$	.6V
SOURCE	3.1V

Fig. 10-4. Record your readings for Step 2 here.

Using the same technique you used in Step 1, measure the voltages across each of the three resistors. Record these voltages in the spaces provided for it in Fig. 10-4. Now add together the three voltages you recorded for R_1, R_2, and R_3 and put this value in the place labeled $R_1 + R_2 + R_3$ in Fig. 10-4.

When you have made your readings, disconnect the positive battery lead from terminal 2.

Discussion: In Step 1, you measured the source voltage applied to the circuit and you measured the voltage across each resistor. You found that the source voltage was about 3 volts. This is the voltage across the three series-connected resistors.

The voltage drop across R_1 was about 1.4 volts, across R_2 it was about .95 volts and across R_3 about .7 volts. When you added the voltage drops across resistors R_1, R_2 and R_3, you should have found the sum to be approximately equal to the source voltage.

The voltage across a resistor is determined by the current in the resistor and the value or resistance of the resistor. As you would expect from Ohm's Law, the largest resistor has the largest voltage across it while the smallest resistor has the smallest voltage.

Another important point that you should learn from the experiment is how to connect the voltmeter to measure voltage. A voltmeter is always placed in parallel with or across the voltage you are interested in measuring.

To measure the battery voltage in the circuit in Fig. 10-1, you measure between terminals 2 and 6, which are directly across the battery. To measure the voltage across resistor R_1, you measure the voltage between terminals 4 and 6. In every case, the positive meter lead is connected to a more positive point than is the negative meter lead. The negative battery terminal is the most negative point in the circuit. In Fig. 10-1, the voltage at terminal 4 is more positive than the voltage at terminal 6. Similarly, the voltage at terminal 3 is more positive than the voltage at terminal 4 and the voltage at terminal 2 is more positive than the voltage at terminal 3.

You must always connect your voltmeter so the positive lead is connected to the more positive terminal. Otherwise, your meter will read backwards and may be damaged.

In Step 2, you also found that the supply voltage is about 3 volts. However, when you add the three readings taken for Step 2, you will find that the three voltage drops do not add up to 3 volts. At first glance, you might think that something is wrong.

Actually, the error is due to your meter resistance. The circuit you have when you connect the meter across R_1 is shown in Fig. 10-5.

Since the resistance of the voltmeter, which consists of the 15,000-ohm resistor and the resistance of the 0 to 200 microammeter, is only slightly more than

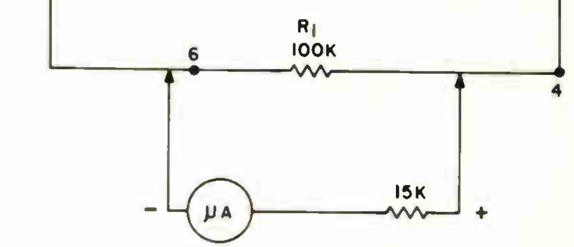

Fig. 10-5. Circuit for Experiment 10 with meter connected across R_1.

15,000 ohms, the total resistance of R_1 and the meter in parallel with it is much less than the 100,000-ohm value of R_1 alone. The resistance of the combination is very close to 15,000 ohms. Therefore, most of the voltage will be dropped across resistor R_2 and R_3, and very little will appear across the combination of R_1 and the meter circuit in parallel with it.

The same thing is true when you connect your meter across R_2 and R_3. Each time you connect the meter across a high resistance, the parallel combination of the meter and the resistor across which you are measuring voltage forms a resistance that is much lower than the original resistor value. The entire circuit, therefore, is upset and the voltage you measure is not the true voltage that is across the resistor when the meter is not connected to it.

To prevent such erroneous readings, you need a meter with a very high resistance. If your meter had a sensitivity of 100,000 ohms per volt on the 3-volt scale, you would have a total resistance of 300,000 ohms in the voltmeter circuit. Then, when you make your measurements, you would be placing 300,000 ohms in parallel with 100,000 ohms. Although the meter resistance is still low enough to upset the circuit you used in this experiment, it would not upset the circuit nearly as much as the 15,000-ohm resistance did.

The resistor values used in the first step were much less than the combined value of the meter and its series resistor. For this reason, the meter resistance has very little effect on the readings you made in the circuit in Step 1.

In your next set of experiments, you will build a transistorized voltmeter. This meter has a resistance of several megohms. Thus, when you use this meter to measure the voltage in high resistance circuits, you will get a more accurate voltage indication than you would using a simple voltmeter such as that which you used in this experiment.

Instructions for Statement 10: For this statement, you are to measure the voltage drop across two resistors. R_1 and R_2 in Fig. 10-3. Solder the positive battery lead to terminal 2. Touch your negative meter lead to terminal 6 and the positive meter lead to terminal 3. Observe your meter indication on the 3-volt scale and write the reading in the margin on this page.

Statement No. 10: When I measured the voltage across resistors R_1 and R_2, I found that the voltage was .44

[✓ *(1)*] *less than 1 volt.*
(2) approximately 1.5 volts.
(3) approximately 3 volts.

After you have answered the statement, unsolder the positive battery lead from terminal 2 and push it out of the way. Unsolder and remove the red and black meter leads and all other parts and wires connected to terminals 12, 13, and 14. Straighten and clean the leads of the 15,000-ohm resistor and set it aside.

You should still have the two flashlight cells connected in series and attached to the chassis. You should also have the two 100K-ohm and one 82K-ohm resistors soldered to terminals 2, 3, 4 and 6. These resistors and the 3 volt battery will be used in the first experiment of the next training kit.

Looking Ahead

This completes the experiments in Kit 1T. One of the most important things you should have learned is how to solder correctly. As we pointed out, you will make soldered connections in all your electronics work, and one poorly soldered connection can cause you hours of unnecessary work.

In later kits you will have further experience in reading the meter. Of course, you will use the meter throughout your Practical Demonstration Course. You should have learned how to read the 0 to 30 volt and 0 to 12 volt scales in this group of experiments; in the next kit, you will learn how to read the ohmmeter scale. You also demonstrated a number of important basic circuit actions. It is much easier to study and understand the more advanced circuits that you will encounter later if you understand how the simple circuits work, and what changes in the circuit will do to voltage distribution and current flowing in the circuit.

In the next kit, you will build a transistorized voltmeter (tvom). You will find this work extremely interesting, and at the same time you will be building an instrument that will be useful to you in the rest of your experiments, and later when you start work in any branch of the electronics field. In addition to building the tvom you will continue with your studies of basic circuits.

Check to see that your training Kit Report sheet is completed and send it to NRI for grading.

While waiting for the return of this Report and for your next kit, prepare the parts you have left over for use in later kits. The parts left over are shown in Table I. *Remove the meter from its box and unsolder and remove the diodes and wires from the meter terminals.* Also, remove the solder lugs. Clean the meter terminals, and place the meter back in its box. Since the meter is a delicate instrument, be sure to put it in a safe place.

TABLE I

1	Pot mtg. bracket
1	Chassis plate
1	Etched circuit board with tube socket
1	Marking crayon
1	Meter
1	6-32 hex nut
2	4-40 hex nuts
1	1000-ohm potentiometer
1	470-ohm resistor
1	680-phm resistor
3	1000-ohm resistors
2	4700-ohm resistors
1	6800-ohm resistor
1	15,000-ohm resistor
1	22,000-ohm resistor
1	1/4" X 6-32 machine screw
2	1/4" X 4-40 machine screws
2	Large solder lugs
2	Silicon diodes
	Hookup wire
	Solder

IMPORTANT: Be sure to save ALL PARTS from this Kit, including screws and nuts, because you will need them later. Keep small parts in individual envelopes or boxes.

The following parts are attached to the chassis plate:

2 Flashlight cells
1 3-lug terminal strip
1 4-lug terminal strip
1 7-lug terminal strip
1 Small solder lug
5 1/4" X 6-32 machine screws
5 6-32 hex nuts
2 100,000-ohm resistors
1 82,000-ohm resistor

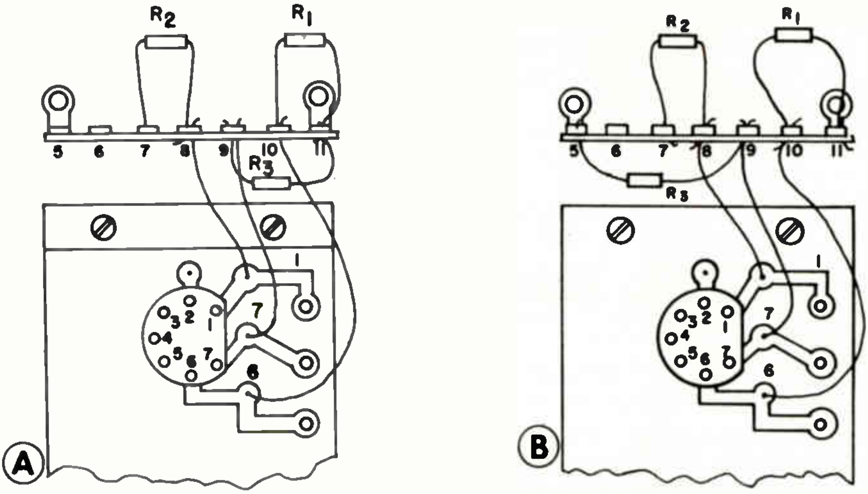

Fig. 4-6. Examples of how you could have wired the circuit used in Experiment 4.

Important Notice

As you use your soldering iron, a scale will accumulate on it. Eventually this scale will keep the iron from heating properly, and you will have to remove it. To do so, remove the tip from the barrel. Remove the scale from the tip and tap the end of the barrel against the workbench to loosen and remove the scale in the barrel. Refile the tip, if necessary, and put it back in the barrel.

If you have a soldering gun, poor contact may develop between the tip and the metal terminals of the gun. This can be eliminated by loosening and then tightening the nuts holding the tip in place. Make sure the nuts are tightened securely. Clean and re-tin the tip when it gets dirty, and replace it when it gets pitted.

Warning

You are expected to make a grade of A, B, C, or D for each group of ten experiments in this Practical Demonstration Course. If any of your reports come back to you marked "Low," you are to repeat the experiments and report statements marked "X" and then send in a complete new set of answers, using the new report blank we will send you. Since this procedure may mean that you will have to dismantle equipment that is to be used as a unit in succeeding experiments, do not begin work on the next Kit until you have received a grade of A, B, C, or D.

Each Day Counts . . .

Each day of our life offers its own reward for work well done, its own chance for happiness. These rewards may seem small, and these chances may seem petty in comparison with the big things we see ahead.

As a result, many of us pass by these daily rewards and daily opportunities, never recognizing that the final goal, the shining prize in the distance, is just a sum of all these little rewards we must win as we go along.

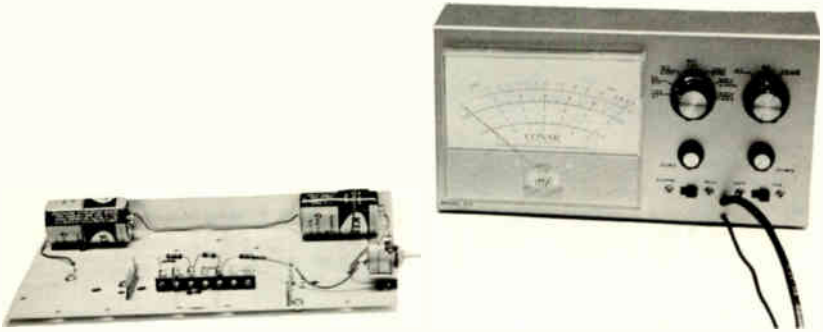
TRAINING KIT MANUAL 2T

PRACTICAL DEMONSTRATIONS IN BASIC ELECTRONICS



INDEX OF SECTIONS

JP2M772 1975 EDITION Litho in U.S.A.

INSTRUCTIONS FOR ASSEMBLING YOUR TVOM AND PERFORMING EXPERIMENTS 11-20

In the first part of this training kit you will build a modern, battery-operated, transistorized volt-ohmmeter (abbreviated tvom), which you will use in working the experiments in the second part of this training kit as well as in later training kits. This instrument is a professional quality meter and you should do the very best work that you can in assembling it. If you follow the instructions carefully and exactly, and use the soldering practices you learned in your first training kit, you should have no trouble at all in doing an excellent construction job.

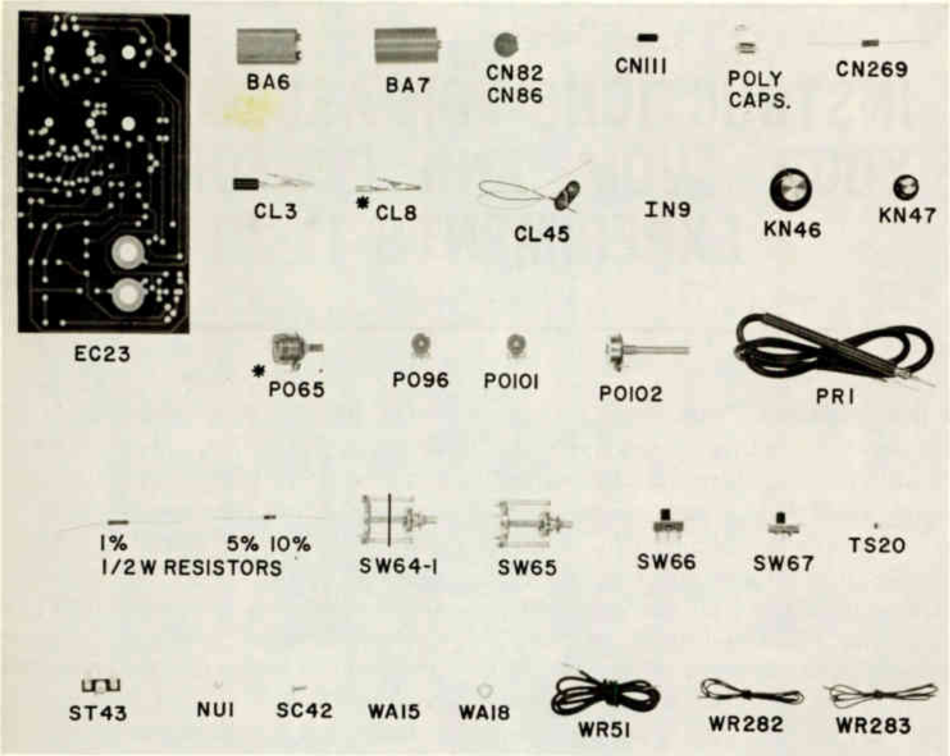
Most of the parts for the tvom are assembled on the large etched circuit board. Be very careful when soldering to the circuit board to follow the procedures given in the first training kit. If you have forgotten these procedures, or are in doubt in any way about how much heat or solder to use, go back and review the section in Training Kit 1T on soldering. The finished etched circuit board represents a fairly large amount of money, and any damage which you do to it may require replacing the entire circuit board, at your expense. We do not say this to frighten you, but merely to try to impress you with the importance of doing good work and of following the instructions *exactly*!

The parts supplied with this kit are shown in Fig. 1 and are listed below. Examine the parts you received to make certain they are all there and that no parts are obviously damaged. If any part is missing or damaged, be sure to let us know right away; we will supply the replacement part as quickly as possible so that you can begin construction of your tvom.

Before you start the actual assembly of your tvom, we want to bring to your attention certain facts about the resistors, capacitors and other parts supplied with this kit and others. This information will help you identify the various parts and ensure that you use the correct part for each step of the assembly.

CAPACITORS

There are four types of capacitors used in the assembly of your tvom: ceramic disc, polystyrene, tubular, and electrolytic. The disc capacitors are round and thin with lead wires coming from one edge. The ***value*** of the capacitor, ***type***, and ***working voltage*** are stamped on the body of the capacitor. The value will be either in picofarads (pf) or microfarads (mfd). If the number is a whole number,



* Experimental Parts

Fig. 1. Parts supplied with this kit are shown above and listed below.

Quan.	Part No.	Description	Price Each
1	BA6	9V battery	.68
1	BA7	1.5V "C" cell battery	.23
1	CL3	Alligator clip	.14
1	CL45	Battery clip	.26
1	CN82	.01 mfd, 2 KV disc cap	.22
3	CN86	.01 mfd, 1KV disc cap	.18
3	CN111	5-mfd elect. cap	.35
1	CN151	56 pf disc cap	.08
1	CN263	22 pf poly cap	.12
1	CN264	27 pf poly cap	.12
1	CN265	200 pf poly cap	.12
1	CN266	390 pf poly cap	.12
1	CN267	2000 pf poly cap	.15
1	CN268	3900 pf poly cap	.18
1	CN269	.012-mfd tubr. cap	.25
1	EC23A	Etched circuit board	4.17
1	IN9	2" spaghetti tubing	.15
2	KN46	Large knobs w/pointer	.40

Quan.	Part No.	Description	Price Each
2	KN47	Small knobs	.32
1	LU1	No. 6 solder lug	12/.15
5	NU1	6-32 hex nuts	12/.15
1	PA31	Panel	3.00
1	PO96	10K-ohm trimmer pot	.45
1	PO101	100K-ohm trimmer pot	.23
2	PO102	10K-ohm pot	.42
1	PR1	Probe	1.05
1	RE1	10-ohm, 5% res.	.24
1	RE3	100-ohm, 5% res.	.24
1	RE9	51K-ohm, 5% res.	.24
1	RE10	100K-ohm, 5% res.	.24
1	RE25	10-megohm, 5% res.	.24
1	RE33	22K-ohm res.	.15
1	RE34	27K-ohm res.	.15
1	RE39	1-megohm res.	.15
1	RE44	2.2-megohm, 10% res.	.15
2	RE50	6.8K-ohm res.	.15

Quan.	Part No.	Description	Price Each
1	RE73	1-megohm, 5% res.	.24
1	RE74	10K-ohm, 5% res.	.24
1	RE94	10K-ohm, 1% res.	.78
1	RE95	30K-ohm, 1% res.	.78
1	RE96	60K-ohm, 1% res.	.78
1	RE97	300K-ohm, 1% res.	.78
1	RE98	600K-ohm, 1% res.	.78
1	RE99	3-megohm, 1% res.	.78
1	RE162	6-megohm, 1% res.	.78
1	RE163	2.2-megohm, 1% res.	.78
1	RE164	1K-ohm, 5% res.	.24
5	SC42	6-32 X 3/8" Phillips head screws	12/.25

Quan.	Part No.	Description	Price Each
1	ST43	2-lug terminal strip	.06
1	SW64-1	Function switch with nut and flat washer	1.75
1	SW65	Range switch	1.76
1	SW66	DPDT slide switch	.16
1	SW67	SPST slide switch	.21
2	TS20	N channel FETs	1.00
5	WA15	No. 6 lockwashers	12/.15
4	WA18	No. 10 flat washers	12/.15
1	WR51	Ground wire	.30
1	WR282	Stranded black wire, 2'	.15
1	WR283	Stranded red wire, 2'	.15

All resistors are 1/2-watt, 10% tolerance unless otherwise specified.

2T EXPERIMENTAL PARTS

Quan.	Part No.	Description	Price Each
1	CL8	Alligator clip	.07
1	PO65	500K-ohm pot w/switch	.95
1	RE31	10K-ohm res.	.15
1	RE32	18K-ohm res.	.15
1	RE33	22K-ohm res.	.15
1	RE36	100K-ohm res.	.15
1	RE37	220K-ohm res.	.15
1	RE38	470K-ohm res.	.15
1	RE39	1-megohm res.	.15
2	RE42	10-megohm res.	.15
1	RE45	3.3K-ohm res.	.15

All resistors are 1/2-watt, 10% tolerance unless otherwise specified.

such as 120, the value is in pf. If the number has a decimal, such as .01 or .1, the value is in microfarads. The type may be any of several numbers or letters and for our purposes will be unimportant. Likewise, the voltage rating is also relatively unimportant in this kit. You should be certain, however, that the voltage rating is at least as great as that indicated for the part in the parts list.

The polystyrene capacitors are tubular in shape and have a thin lead wire coming from each end. These capacitors have a clear plastic outer covering through which you can see the aluminum foil of the capacitor plates. As with the disc capacitors, the value of the capacitor is stamped on the outside of the capacitor in pf or mfd. The largest polystyrene capacitor, CN268, may be stamped "3900" or ".0039"; either indicates a value of .0039 mfd.

There is only one tubular capacitor, CN269, a .012-mfd capacitor. This capacitor will have its value stamped on the outside of the case.

Electrolytic capacitors have polarity. They must be put into the circuit exactly as indicated, otherwise they may be damaged. The positive lead of the electrolytic, CN111, can be identified by a "+" mark printed at one end, or by the fact that one end will be colored red. The value and voltage rating are printed on the side of the capacitor.

RESISTORS

Many of the resistors used in this kit are similar to the ones you used in the first training kit. They are 1/2-watt resistors and are identified by their color code. Although you do not need to memorize this color code, it will be to your advantage to do so, as it will speed up your work to be able to identify resistors at a glance.

The fixed, color-coded resistors supplied in this kit are of 10% and 5% tolerance. It is very important that you use the correct resistor in the correct circuit. While we might possibly substitute a 5% (gold) tolerance resistor for a 10% (silver) tolerance resistor, you should *not* use a 10% tolerance resistor where a 5% tolerance resistor is called for.

There are other fixed resistors in this kit that may or may not be color-coded. These are the 1% precision resistors used in the input divider chain of the tvom. It is very important that these resistors be used *only* where called for in the instructions. If these resistors are *not* color coded, then the value will be printed right on the body of the resistor. On these resistors, the letter "K" stands for 1000, and "M" stands for one million; thus, "10K" means a 10,000-ohm resistor, and "2.2M" means a 2,200,000-ohm or 2.2-megohm resistor. If these resistors are color coded the fourth or tolerance band will be brown.

OTHER PARTS

The other parts you receive in this kit should be fairly easy to identify. For example, the two rotary switches, SW64-1 and SW65, are similar in appearance but the SW64-1 switch has two switch wafers while the SW65 switch has only one switch wafer. You can also note that the SW64-1 has 11 clips coming from the rear of the switch, while the SW65 has only 8 clips.

The two slide switches, SW67 and

SW66, do not have the part number stamped on them. They may be identified by counting the number of lugs they have; SW67 has two and SW66 has six.

The potentiometers all have their part number and value stamped on them. Be particularly careful not to confuse the two small trimmer potentiometers, PO96 and PO101. They both look alike; however, the PO96 has a value of 10K ohms and the PO101 has a value of 100K ohms.

You should have no difficulty identifying the remaining parts in this kit, using Fig. 1 and the various descriptions of the parts in the parts list under Fig. 1.

Figs. 2, 3 and 4 and a schematic diagram of the complete tvom are on the two pages in the center of this manual. You can loosen the staples and remove these pages when you assemble the tvom. When you have finished assembling the tvom, replace the pages in the center of the manual so you will have the schematic handy if you should ever need it.

Assembling Your TVOM

The assembly of your tvom is divided into several stages. In each stage you will perform only a few simple steps. In this way you can stop at frequent intervals and check to make certain that you have done what was expected for each stage. Or, if you are interrupted for any reason, there are very convenient stopping points. Just note where you stopped so that you can pick up your work conveniently.

Before you begin the assembly of any stage, read over the entire list of instructions and make sure you know exactly which parts you will need. Then select the required parts and perform the assembly steps indicated.

When you install parts on the etched circuit board, the assembly steps are given as numbered blocks around a picture of the board with arrows going from the block to the location on the board where the part is to be placed. Use the skills you learned in the first kit to install, solder and cut off leads for each step.

Some parts are installed from the foil side of the board. Be careful not to let solder bridge from one place to another when you work on the foil side of the board, and remember to clip off leftover lead lengths on the phenolic side of the board.

After you have assembled the etched circuit board you will install the meter and other parts on the panel. Then you will wire the battery, probe and switches. Finally you will fasten the circuit board to the panel and meter and perform the calibration procedure.

ETCHED CIRCUIT BOARD ASSEMBLY
STAGE I

Before you begin the first assembly stage, check to make certain that your soldering iron is clean and well tinned. If it is not in good condition, plug it in and clean and retin it as described in the first training kit.

Clear a space on your worktable and put a clean, soft cloth down on which to place the circuit board as you work on it. This will protect both the circuit board and the table. Identify and gather the following parts:

1 Etched circuit board (EC23A)
1 Battery clip connector (CL45)
1 56 pf disc capacitor (CN151)
1 .01 mfd, 1KV disc capacitor (CN86)
2 10K-ohm pots (PO102)
1 10K-ohm trimmer pot (PO96)
1 100K-ohm trimmer pot (PO101)
2 6.8K-ohm, 10%, 1/2-watt resistors (RE50, blue-gray-red-silver)
1 22K-ohm, 10%, 1/2-watt resistor (RE33, red-red-orange-silver)
1 27K-ohm, 10%, 1/2-watt resistor (RE34, red-violet-orange-silver)
1 51K-ohm, 5%, 1/2-watt resistor (RE9, green-brown-orange-gold)
1 1-megohm, 10%, 1/2-watt resistor (RE39, brown-black-green-silver)
2 N channel FETs (TS20)
Red stranded wire
Black stranded wire
Hookup wire (from Kit 1T)
Solder

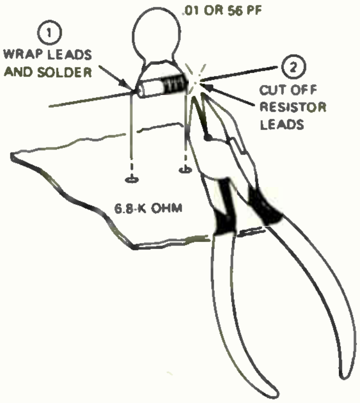


Fig. 2. Detail A.

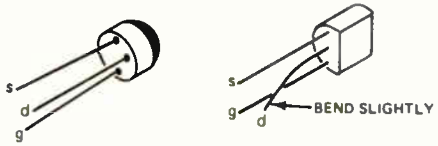

Fig. 2. Detail B.

The assembly instructions are given in Fig. 2 (centerfold).

Prepare a 7-1/2" length of red stranded wire and a 7-1/2" length of black stranded wire for use in Steps 5 and 6. Remove 1/4" of the insulation from each end of both wires, and twist the strands at the end of each wire tightly together. Tin all four ends with solder to hold the strands together. When you install these wires in Steps 5 and 6, the other end of each wire will remain free.

The red lead of the 9V battery connector installed in Step 11 goes to the "+9V" location while the white lead goes to the "-9V" location.

In Step 8 of Fig. 2 you will install a parallel combination of a 6.8K-ohm resistor and a .01 mfd disc capacitor. Detail A of Fig. 2 shows how to make this combination. Wrap each capacitor lead one time around each resistor lead close to the body of the resistor. Solder both of these connections, then clip off the resistor leads as shown. Insert the capacitor leads into the 6.8K-ohm location on the circuit board and solder as you would any other component. The 56 pf disc capacitor and the second 6.8K-ohm resistor used in Step 12 are installed in the same manner.

The two potentiometers installed in Steps 1 and 2 may have a large nut on the bushing. Remove and set aside these nuts, if present, as they will not be needed to hold the potentiometers in place. The potentiometers are installed by passing the shaft through the hole from the phenolic side of the board. Rotate the body of the control so that the three solder pins of the potentiometer line up with the corresponding holes in the circuit board as shown. With the holes lined up, push the control fully forward so the pins go through the board and the front of the control is tight up against the board. Turn the board over, making sure that the control stays tight up to the board, and solder the three pins to the foil. Do *not* try to cut off the ends of the pins.

Detail B for Fig. 2 shows two possible types of TS20 you may have received with this kit. The bottom side (lead side) of the transistors is shown. The transistor on the left in Detail B has a round case and the three leads come from the bottom of the case in a triangular configuration. The gate (g), source (s), and drain (d) leads are identified in Detail B. These symbols (g, s, d) correspond to the holes marked g, s, d on the circuit board at locations Q_1 and Q_2 (Steps 9 and 10) of Fig. 2.

The transistor on the right in Detail B has a black plastic body which is "D" shape in cross section. The three leads, g, s, d, are "in-line" on this transistor and the middle lead will have to be bent outward slightly in order to have the leads fit the holes in the circuit board.

When you are sure you have identified the leads correctly and are ready for Steps 9 and 10, push the three leads into the corresponding holes of the circuit board so that they protrude about 1/8" from the foil side of the board. Turn the board over, and while holding the transistor in place, quickly solder each of the three leads to the foil.

As mentioned earlier, be certain you use the correct trimmer potentiometers in Steps 13 and 15.

When you are certain you understand all of the steps, proceed to install the parts for Stage I, shown in Fig. 2. As you complete each step, place a check mark in the space ( ) provided.

ETCHED CIRCUIT BOARD ASSEMBLY STAGE II

In this stage of the assembly you will install the 1% resistors and the capacitors on the circuit board. Gather the following parts:

1 2.2 meg, 1/2W, 1% resistor (RE163)
1 6 meg, 1/2W, 1% resistor (RE162)
1 3 meg, 1/2W, 1% resistor (RE99)
1 600K, 1/2W, 1% resistor (RE98)
1 300K, 1/2W, 1% resistor (RE97)
1 60K, 1/2W, 1% resistor (RE96)
1 30K, 1/2W, 1% resistor (RE95)
1 10K, 1/2W, 1% resistor (RE94)
1 .01-mfd, 2KV disc capacitor (CN82)
1 22-pf polystyrene capacitor (CN263)
1 27-pf polystyrene capacitor (CN264)
1 200-pf polystyrene capacitor (CN265)
1 390-pf polystyrene capacitor (CN266)
1 2000-pf polystyrene capacitor (CN267)
1 3900-pf polystyrene capacitor (CN268)
1 .012-mfd tubular capacitor (CN269)
3 5-mfd electrolytic capacitors (CN111)

There are no special precautions to observe in this stage of the assembly, other than the polarity of the three electrolytic capacitors installed in Steps 5, 6, and 11. The one used in Step 5 has its "+" end to the *left*, the one used in Step 6 has its "+" to the *right*, and the one used in Step 11 has its "+" end *down*.

You will notice that the hole spacing for some of the capacitors is much greater than the length of the capacitors. Simply center the body of the capacitor between the holes and bend the leads to fit.

Now proceed to install the parts in accordance with Fig. 3, which is in the centerfold of this manual.

ETCHED CIRCUIT BOARD ASSEMBLY STAGE III

In this stage of the assembly of your circuit board you will install components on the foil side of the board as shown in Fig. 4 (centerfold). You will need:

1 Range switch (SW65)
1 Function switch (SW64-1)
1 .01 mfd, 1KV disc capacitor (CN86)
1 10-ohm, 1/2-watt, 5% resistor (RE1, brown-black-black-gold)
1 100-ohm, 1/2-watt, 5% resistor (RE3, brown-black-brown-gold)
1 1K-ohm, 1/2-watt, 5% resistor (RE164, brown-black-red-gold)
1 10K-ohm, 1/2-watt, 5% resistor (RE74, brown-black-orange-gold)
1 100K-ohm, 1/2-watt, 5% resistor (RE10, brown-black-yellow-gold)

1 1 megohm, 1/2-watt, 5% resistor (RE73, brown-black-green-gold)
1 10 megohm, 1/2-watt, 5% resistor (RE25, brown-black-blue-gold)
Hookup wire from last training kit

The two rotary switches, SW64-1 and SW65, can only fit into the holes in the circuit board one way – the right way. Examine SW65 carefully. Notice that it has eight solder lugs pointing back (away from the rear of the switch wafer) and eight solder terminals on the front side of the switch wafer. When the switch is correctly positioned, the eight lugs on the rear of the wafer will fit into the corresponding holes of the circuit board; the flat locating lug on the front of the switch will be to your left (see Fig. 4); and the two nuts which hold the switch together will fall into two larger holes of the circuit board.

If any of the lugs on the rear of the switch wafer are out of line, they must be straightened or it will be impossible to install the switch correctly. With the lugs correctly lined up, you should be able to push the switch firmly up against the board so that the shoulder of every lug is in firm contact with the foil and protrudes the same distance from the phenolic side of the board. The switch shaft will then be perpendicular to the surface of the circuit board.

Be very certain that each switch is properly installed before you solder it to the foil. If even one lug misses its hole, or if the switch is at a slight angle, your meter will not operate properly and you probably will not be able to install the board into the cabinet.

When you are absolutely certain that you have the range switch, SW65, properly positioned, solder each of the eight lugs to the foil. To do this, make sure your soldering iron is clean and hot. Melt a small amount of solder on the tip of the iron to "wet" it (this promotes good heat transfer) and touch the tip to the solder lug and the foil at the same time, just as you did when you soldered the tube socket to the circuit board in the first kit. Add enough solder so that it flows smoothly around the solder lug and also adheres to the foil. Remove the iron and allow the joint to cool. When you are satisfied that you have a good connection, proceed to solder the remaining lugs to the foil.

SW64-1 is installed in exactly the same manner. This switch has eleven lugs to be soldered to the foil and only one solder terminal on the front of the rear switch wafer. (This terminal is *not* shown in Fig. 4 as it is not used.) There are also two terminals on the front switch wafer. Position the SW64-1 as indicated in Fig. 4 and solder all eleven lugs to the foil as you did for the range switch.

In Step 1, install the .01 mfd capacitor by cutting both leads to 1/2" and soldering them to the circuit board foil, as shown in Fig. 4 and Detail A. First tin the circuit board foil in the areas shown and press the capacitor leads as close as possible against the circuit as you melt the solder on the board. Avoid shorting the leads to any of the adjacent foils; the blue solder mask material is a good insulator but is easily cut, so be careful.

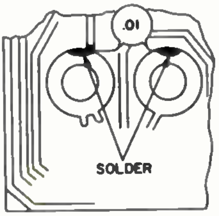

Fig. 4, Detail A.

The only remaining parts to install are the seven 5% resistors and three lengths of hookup wire. The first piece of hookup wire goes from hole number 8 of the circuit board to solder terminal 8 of SW65 as indicated in Step 9 of Fig. 4.

In Step 10, connect a 5-1/4" length of hookup wire from lug 2 of the front wafer of the Function switch to the hole marked "J" on the foil. Solder both connections. Similarly, in Step 11 connect a 7-1/2" length of hookup wire from lug 1 of the Function switch to hole "H". Solder both connections, then dress both leads close to the board, as shown in Fig. 4.

The 5% resistors go from the numbered holes to the solder terminals of SW65. Position each resistor as shown and bend one lead at right angles so it will go through the numbered hole in the board. The body of the resistor should be parallel to the circuit board and at a distance from the circuit board as determined by the location of the solder lug on SW65. As each resistor is soldered in place, cut off the excess lead length from both ends.

When you are sure you understand how to install the resistors and the hookup wire, proceed to do the steps indicated in Fig. 4.

This completes the preliminary assembly of the tvom. You will notice that there are several places on the circuit board where parts are indicated, but you have not installed the parts. These parts are installed in the next training kit to enable you to measure ac voltages. The instrument you construct in this training kit will enable you to measure dc volts in seven ranges, 1.2 volts to 1200 volts, and to measure ohms in seven ranges, R X 1 to R X 1 megohm.

MOUNTING PARTS ON THE PANEL

At this point in the assembly of your tvom you have almost completed your wiring. All that remains to be done is to mount the meter, two slide switches, assemble the probe and ground lead, install the batteries and connect the etched circuit board to the panel wiring.

You will now install the meter, prewire and mount the two switches, and assemble and install the probe and ground leads. You will need the following parts:

1	Panel (PA31)
1	Meter (ME21) and hardware (from Kit 1T)
1	.01 mfd, 1KV disc capacitor (CN86)
1	2.2 megohm, 10% resistor (RE44)
1	Probe (PR1)
1	Ground wire (WR51)
1	Alligator clip (CL3)
1	SPST slide switch (SW67)
1	DPDT slide switch (SW66)
5	6-32 X 3/8" Phillips head screws (SC42)
5	No. 6 lockwashers (WA15)
5	6-32 hex nuts (NU1)
1	2-lug terminal strip (ST43)
2	Large knobs with pointer (KN46)
2	Small round knobs (KN47)
1	2" length of insulating tubing (spaghetti, IN9)
1	No. 6 soldering lug (LU1)
	Red stranded wire
	Black stranded wire
	Hookup wire (from Kit 1T)
	Solder

Locate the panel and put it on your work area, face up in the position shown in Fig. 5. You will use the panel as a temporary support to hold the two slide

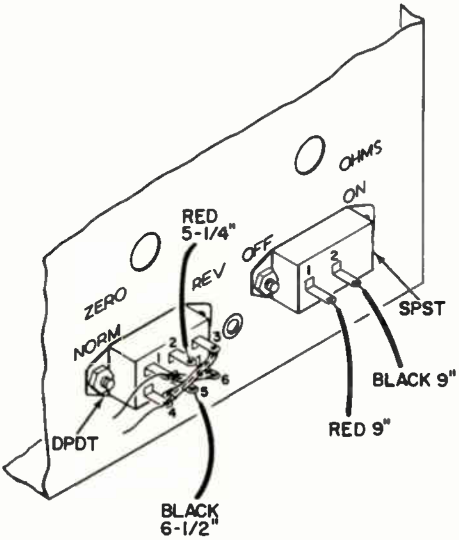

Fig. 5. Prewiring the slide switches.

switches as you wire them. As you work on the front of the panel, be very careful not to scratch or mar it with your screwdriver. Be very careful not to drip any solder onto the panel or touch the panel with your soldering iron.

Temporarily fasten the SPST slide switch as shown in Fig. 5. Position the switch so the two lugs are to the left. One screw and nut are all you need to hold the switch temporarily in place.

Prepare a 9″ length of red stranded wire by removing 3/8″ of the insulation from one end of the wire. Twist the strands tightly together and tin them with your soldering iron and solder to hold the wires together . . . . (✓)

Do the same thing for the other end of the red wire . . . . (✓)

Bend a hook in one end of the wire and pass it through terminal 1 of the SPST switch. Bend the hook closed and solder terminal 1 . . . . (✓)

In a similar manner prepare both ends of a 9″ black stranded wire. Solder one end of the wire to terminal 2 of the SPST switch . . . . (✓)

Remove the SPST switch and set it aside . . . . (✓)

Mount the 6-terminal DPDT slide switch as shown. Use one 6-32 screw and nut. NOTE: The switch can be mounted in either of two positions, both are correct . . . . (✓)

Prepare a 6-1/2″ length of black stranded wire as you did above and solder one end to terminal 5 . . . . (✓)

In a similar manner prepare a 5-1/4″ length of red stranded wire and solder one end to terminal 2 . . . . (✓)

Strip 2-1/4″ of insulation from a piece of solid hookup wire (left over from the last kit). Cut off the bare wire and permanently solder one end to terminal 3 of the DPDT switch . . . . (✓)

Cut off a 1/2″ length of the insulating tubing (spaghetti) and slip it over the bare wire soldered to terminal 3 . . . . (✓)

Feed the free end of the bare wire coming from terminal 3 through terminal 4, leaving all the extra wire on the other side of terminal 4. The spaghetti should be between terminal 3 and terminal 4. Solder terminal 4 . . . . (✓)

In a similar manner prepare a 2-1/4″ length of bare wire and a 1/2″ length of

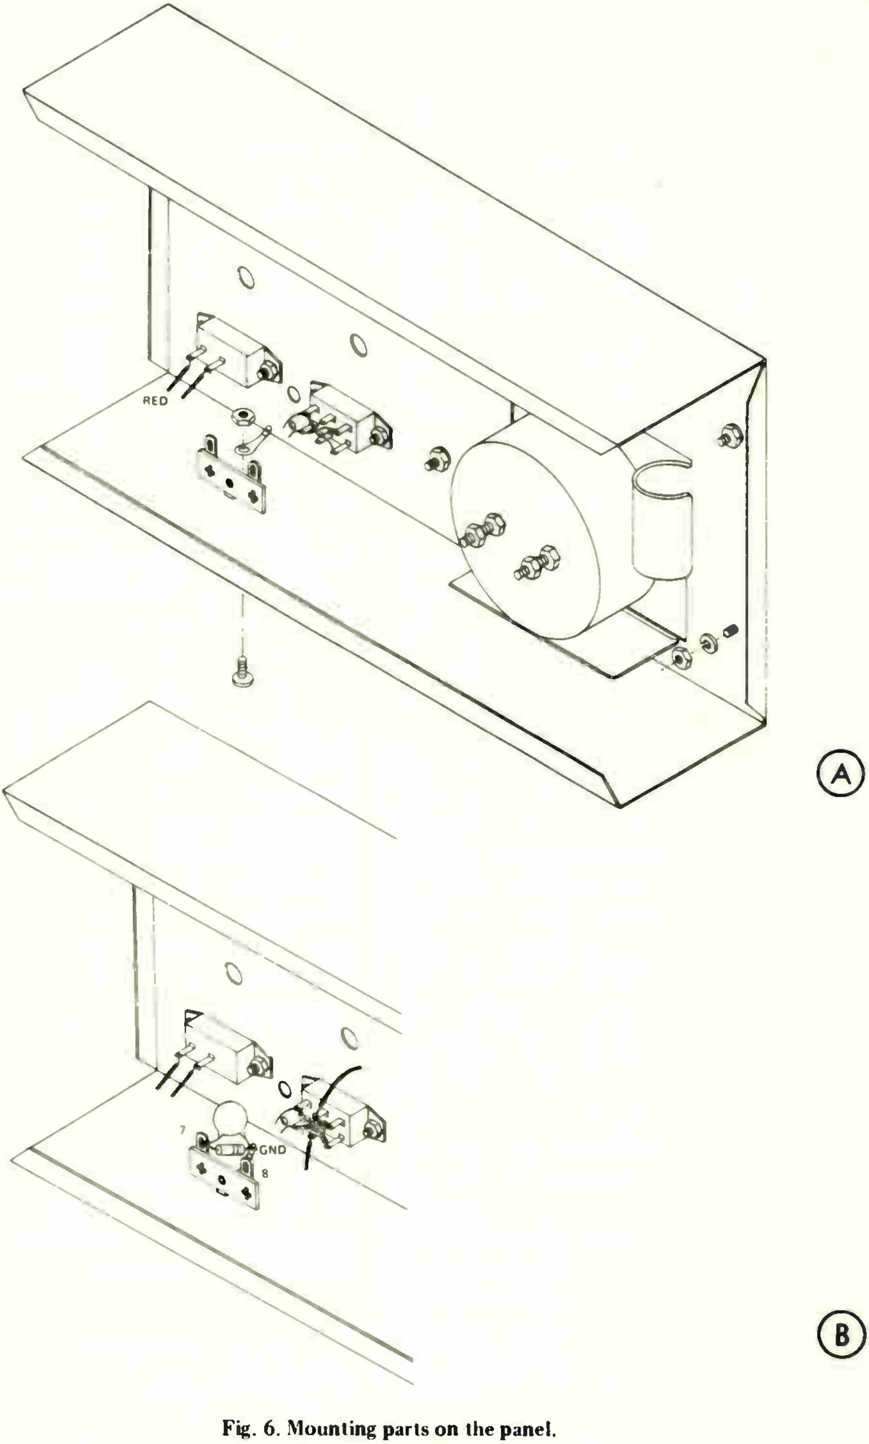

Fig. 6. Mounting parts on the panel.

spaghetti, and connect terminals 1 and 6, leaving the extra wire to the left of terminal 1 as shown in Fig. 5 . . . . . .(✓)

After you have the wires in place on the DPDT switch, remove the switch and set it aside . . . .(✓)

Refer to Fig. 6 for the following steps.

Position the ME21 meter over the large cutout in the panel. The four mounting screws should line up with four of the holes in the panel, as shown, with the barrel of the meter passing through the large cutout in the panel. With the meter firmly up against the panel, install a lockwasher and nut (meter hardware) on each of the four mounting screws. Save the four large nuts (meter hardware) as they will be used later . . . .(✓)

CAUTION: With the meter now installed on the panel, be especially careful not to scratch or otherwise damage the meter face. Always place a clean, soft cloth on your work area to protect the meter as you work behind the panel.

Position the SPST slide switch as shown in Fig. 6 with the red wire to your left. Line up the two mounting holes with those in the panel and secure the switch with two 6-32 X 3/8" Phillips head screws, two No. 6 lockwashers and two 6-32 hex nuts . . . .(✓)

Position the DPDT switch as shown in Fig. 6 with the bare wires from terminals 1 and 4 to your left. Line up the two mounting holes with those in the panel and secure the switch with two 6-32 X 3/8" Phillips head screws, two No. 6 lockwashers and two 6-32 hex nuts (✓)

Before you mount the terminal strip, use a knife or screwdriver to scrape away the paint from around the mounting hole. Scrape off the paint on the *inside* only (✓)

Install the 2-lug terminal strip and solder lug as shown in Fig. 6A with the 6-32 X 3/8" Phillips head screw, a No. 6 lockwasher and a 6-32 hex nut. Place the No. 6 solder lug between the terminal strip and the lockwasher . . . .(✓)

Referring to Fig. 6B, connect the 2.2 megohm resistor from terminal 7 to the ground lug. Keep the resistor leads short and do not solder either connection (✓)

Connect the .01 mfd disc capacitor from terminal 7 to the ground lug. Keep the leads short and solder *only* the ground lug . . . . (✓)

Examine the red test probe with the coaxial cable attached (PR1). You will notice that the end of the probe lead looks like Fig. 7 with a bare wire surrounded by a length of insulation, a braided shield wire and an outer covering. To install the probe lead, pass the end of the lead through the bushing in hole T from the front of the panel . . . . . (✓)

Rotate the lead wire so that the bare wire can be connected to terminal 8 of the 2-lug terminal strip and the braid lead

Fig. 7. End of probe lead.

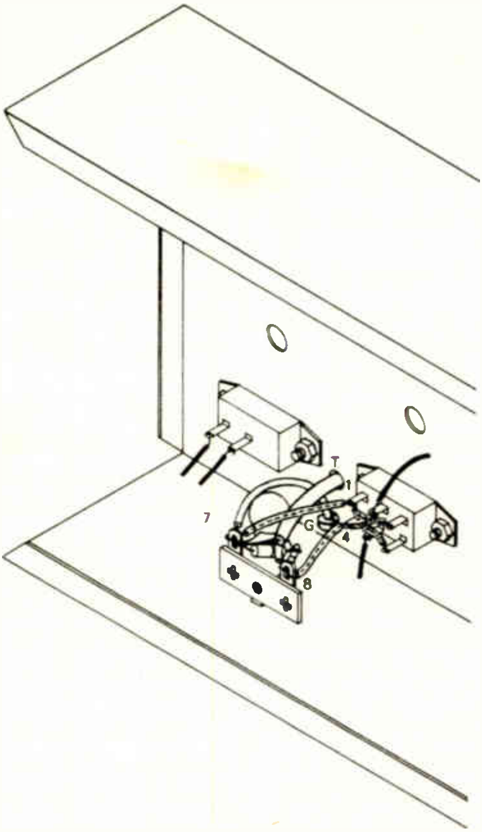

Fig. 8. Connections to terminals 7 and 8 of the 2-lug terminal strip.

can be connected to terminal 7 as shown in Fig. 8. Make these connections but do not solder . . . . (✓)

Remove 1/2" of the rubber insulation from each end of the 3′ ground wire (WR51), twist the strands and tin the wire . . . . (✓)

Pass one end of this wire through the small bushing at hole G, and tie a knot in the wire approximately 2" from the end. Bring the end of the wire over to terminal 7 and connect but do not solder . . . . (✓)

Cover the bare wire coming from terminal 1 of the switch with a length of spaghetti. Connect and solder this wire to terminal 7 of the 2-lug strip. Be sure to solder all the leads at this terminal. You will probably have to heat this connection for quite a long time before the solder will flow smoothly over all five leads . . . . (✓)

In a similar manner, cover the bare wire coming from terminal 4 of the switch with a length of spaghetti and solder the wire to terminal 8 of the 2-lug strip . . . . (✓)

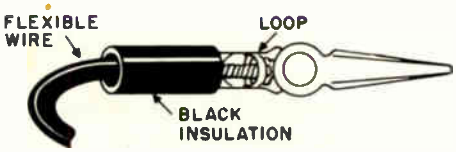

Fig. 9. How to attach the flexible wire to the alligator clip.

Now take the alligator clip with the plastic handle (CL3) and pass the free end of the 3′ ground wire through the plastic handle and the solder loop as shown in Fig. 9. Solder the ground wire to the solder loop . . . . (✓)

This completes the panel assembly. You will next fasten the etched circuit board into position, complete the wiring and then calibrate your tvom.

COMPLETING AND CALIBRATING THE TVOM

You will need the following parts:

1	1.5-volt "C" size flashlight cell (BA7)
1	9-volt battery (BA6)
2	Control nuts
2	Large flat washers
4	No. 10 washers (WA18)
4	10-32 nuts (meter hardware)
	Solder

With the panel and etched circuit board in the positions shown in Fig. 10, take the red and black wires which are fastened to terminals 1 and 2 of the SPST switch, and twist them together loosely. Insert the black lead into the upper hole of the etched circuit board labeled "SW"

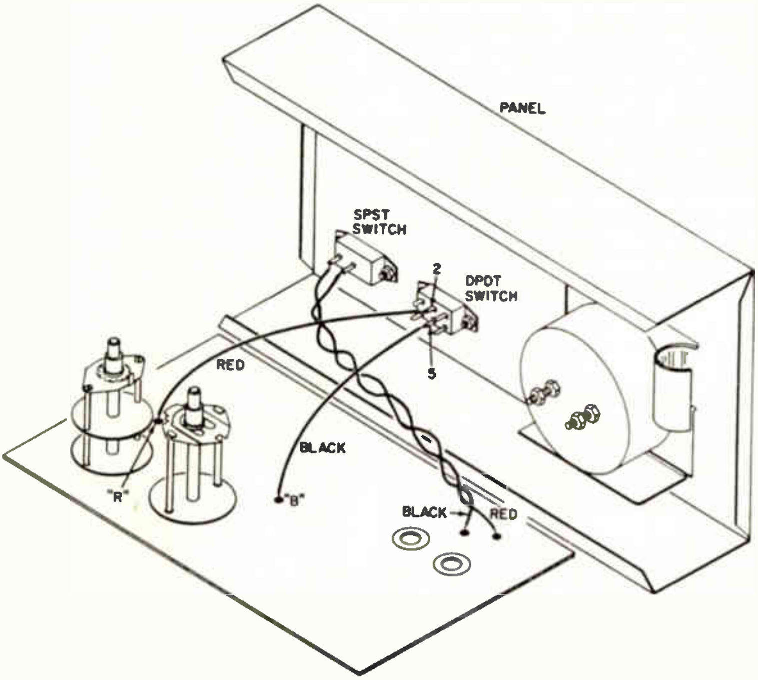

Fig. 10. Connecting the wires from the panel to the circuit board.

and the red lead into the lower hole labeled "SW" as shown. Solder both leads and clip off any excess lead length . . (✓)

Place the free end of the red lead from terminal 2 of the DPDT switch into the hole labeled "R" near the function switch. Solder this lead and clip off any excess lead length from the phenolic side of the board . . . . (✓)

In a similar manner, solder the black wire from terminal 5 of the DPDT switch to the hole labeled "B" on the foil side of the board . . . . (✓)

Take two of the 10-32 nuts supplied with the meter and run one down on each meter terminal stud so the top of the nut is 5/16" from the end of the stud as shown in Fig. 11 . . . . (✓)

Place one No. 10 flat washer on each meter stud . . . . (✓)

Now carefully rotate the etched circuit board into position so that the two switch shafts will come through the upper holes in the panel and the two potentiometer shafts will come through the lower holes in the panel. The two meter studs should pass through the two large holes of the etched circuit board. Make certain that the wires from the two slide switches on the panel are free and not pinched between the switch bushings and the panel. The locating lugs of the two switches should pass through the small slots in the panels.

When you are sure the switches are correctly seated, place a large flat washer over each of the switch bushings and lightly fasten the switches with the two large control nuts. Tighten these nuts only "finger tight" for now . . . . . . (✓)

Now sight along the etched circuit board from the end near the meter. The board should be straight and resting on the two washers on the meter studs. If the board is "bowed" out or must be pushed in to rest on the washers, adjust the position of the 10-32 nuts on the meter studs so the board rests on the washers without bowing . . . . (✓)

Place the remaining No. 10 flat washers over the meter studs and fasten lightly (finger tight) with the remaining 10-32 nuts. Be careful not to strike Q_1 or Q_2 as you tighten the nuts . . . . (✓)

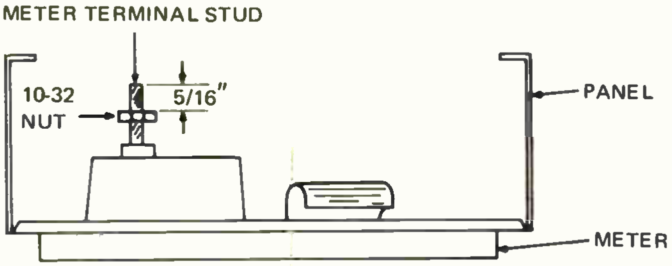

Fig. 11. Put 10-32 nuts on meter terminal studs 5/16" from end.

Now look at the two potentiometer shafts coming from the front of the panel. They should be fairly well centered in the panel holes. If they are not, slightly loosen the two control nuts, which secure the two rotary switches and the two meter stud nuts. With these four nuts loosened, you can move the etched circuit board around enough to center the potentiometer shafts. With the shafts centered, hold the circuit board in place and tighten securely the two control nuts of the rotary switches . . . .(✓)

Now tighten securely the two nuts that fasten the circuit board to the meter studs, being careful not to damage Q_1 or Q_2 . . . .(✓)

Now take the 1.5-volt "C" flashlight cell and tin a spot in the center of the bottom of the cell. Also tin the positive terminal of the cell . . . .(✓)

Slip the "C" cell into the curved clamp beside the meter barrel, so that the positive terminal is toward the top of the panel . . . .(✓)

Now locate the red and black wires which go to the + and − 1.5V locations on the circuit board. Bring the black wire over to the battery and solder to the negative battery terminal . . . .(✓)

In a similar manner solder the red wire to the positive battery terminal . . . .(✓)

Make sure that the SPST slide switch is in the "off" position, then take the battery clip (connected to the "9V" location on the circuit board) and snap the connector onto the terminals of the 9-volt battery . . . .(✓)

If you look into the end of your tvom where the "C" cell is mounted, you will see that there is a small shelf of metal directly below the barrel of the meter. This shelf forms a spring clamp which will hold the 9-volt battery securely. To install the 9-volt battery, bend the shelf up very slightly with your finger and slide the 9-volt battery under the shelf so that it rests on one side of the battery, holding it between the shelf and the inside wall of the panel . . . .(✓)

Take one of the large knobs, with pointer, and check to see that the set screw does not protrude into the shaft opening. Place this knob on the shaft of the range switch so that the set screw will bear on the flat part of the shaft. Tighten the set screw . . . .( )

In a similar manner install the other pointer knob on the function switch (✓)

There are no flats on the ZERO adjust and OHMS adjust potentiometer shafts so install the two small round knobs on these shafts in any position you like .(✓)

This completes the assembly of the DC and OHMS portion of your tvom. Before you can use it, you must balance the circuit and calibrate it. These procedures are covered in the next section.

Balancing and Calibrating the TVOM

To balance and calibrate the tvom, clip the ground lead to the probe tip and set the controls as indicated:

FRONT PANEL	
Range Switch	3V - X10
Function Switch	DC
Polarity Switch	NORM
ON-OFF Switch	OFF
Zero Control	Fully Clockwise
Ohms Control	Fully Counter-clockwise

CIRCUIT BOARD	
Balance Pot	Mid-position
DC Cal Pot	Mid-position

Fig. 12 shows the settings of the front panel controls. The two potentiometers on the circuit board can be adjusted either by using your fingers on the edge of the adjusting disc or by using a screwdriver with a small blade through the access holes in the edge of the panel. These holes are identified by "DC" and "BAL" stamped in the metal over the holes. For ease of adjustment, it is suggested that you use the small-blade screwdriver to make these adjustments. You can practice finding the potentiometer slot with your screwdriver before you start the actual adjustments.

MECHANICAL ZERO ADJUST

Place the tvom on your work area so that the meter and controls are facing up. Look carefully at the pointer of the meter. It should be resting squarely over the "zero" marks at the left side of the scales. If the pointer is not over the zero marks, turn the plastic screw in the lower center of the meter with a screwdriver, until the pointer is over the zero marks as shown in Fig. 13. Use a screwdriver which fits the plastic screw slot or you may damage the screw. You will seldom have to make this adjustment, as the mechanical zero will not usually change. However, if you do need to do it at some later time,

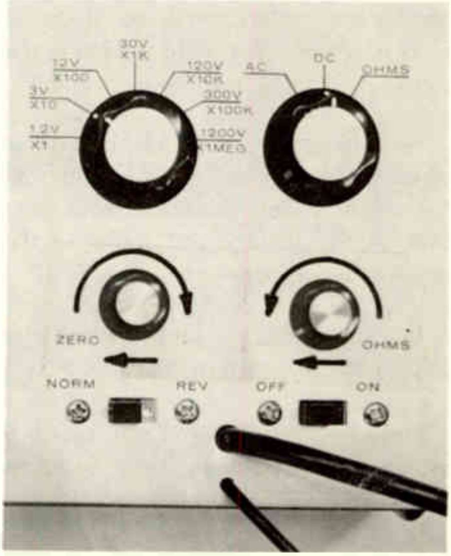

Fig. 12. Setting of the front panel controls.

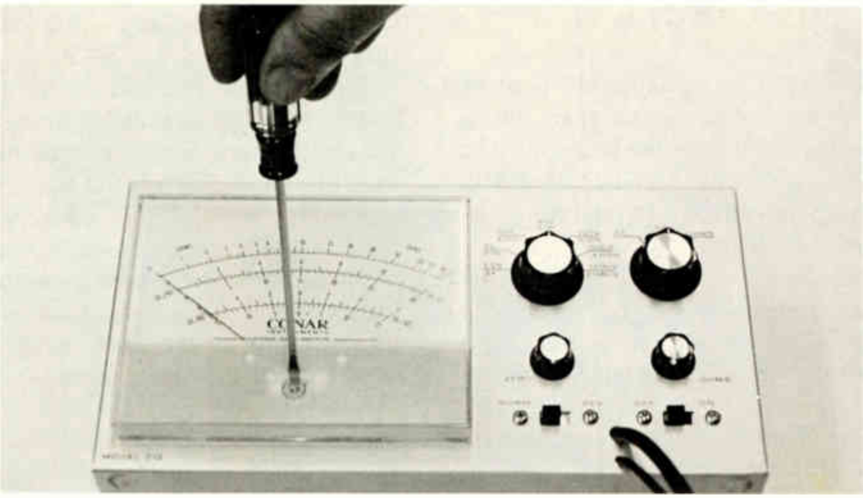

Fig. 13. Adjusting the meter pointer to zero.

remember that the tvom must be OFF when you make the adjustment.

BALANCING THE TVOM

The two field-effect transistors used in your tvom in all likelihood have slightly different characteristics even though they are both the same type of transistor. Since the basic principle of the tvom is one of a balanced bridge circuit, we must adjust the operating voltages of the two transistors so that the bridge circuit is truly balanced. There are two controls which affect the balance of the circuit. The first control is the zero adjust control on the front panel. This control is used on a day-to-day basis to insure correct balance. It could be considered a "fine tuning" adjustment. The other control is the balance potentiometer on the circuit board. This control is used to compensate for the difference in transistor characteristics, as mentioned earlier.

With all the controls adjusted and set as previously indicated, you are now ready to balance the circuit. Read the following instructions through first and then, when you are sure you know what to do, carry them out to balance the circuit.

With the tvom facing up in front of you, insert your screwdriver through the hole marked BAL and into the slot of the balance potentiometer. When you turn the power on with the panel switch, the meter pointer will, in all probability, go upscale past the highest marking on the right or, it may possibly move violently to the left, past zero. In either case, quickly adjust the balance potentiometer with your screwdriver to bring the pointer approximately to midscale (15). Now turn the zero adjust knob to the left (counterclockwise) to see if you can bring the pointer back to zero with the zero adjust. Readjust the balance potentiometer slightly, if necessary, so that you can zero the meter with the zero adjust control. This provides the preliminary balance of the tvom, and after you carry out the calibration procedure you may have to readjust the balance control.

CALIBRATING THE TVOM

With the tvom on and in the position used in the balancing procedure, unclip the ground lead from the probe tip. The range switch should be set to 3V - X10, the function switch to DC and the polarity switch to NORM.

Touch the tip of the probe to the positive terminal of the "C" cell and the meter pointer should swing upscale, to the right. Now, while holding the probe on the positive terminal of the "C" cell, insert your small-blade screwdriver through the hole labeled "DC" and engage the slot of the DC CAL potentiometer. Slowly adjust this control until the pointer indicates exactly 1.55 volts on the 3-volt scale. The pointer will then be just 1/2 division to the right of the center mark on the 3-volt scale. This is halfway between the 1.5-volt marking and the next (1.6-volt) marking and can be precisely located by using the short mark on the other (12-volt) scale as you learned in the last training kit . . . . (✓)

When you have made this adjustment, remove the probe from the "C" cell and touch it to the ground clip. Readjust the zero adjust control for zero and repeat the procedure . . . . (✓)

Now turn the zero adjust knob fully clockwise and note the scale reading. If it is not indicating at least 2 volts on the 3-volt scale, readjust the balance control with your screwdriver to bring it to about 2 volts. If you had to adjust the balance control, you will have to check the calibration procedure you just went through, following each step exactly. When you have completed the calibration and balancing, record the scale reading you obtain with the zero adjust control fully clockwise here: 2.75

This reading will serve as a check of the battery condition later on. As the battery voltage decreases, the reading you obtain with the zero adjust control fully clockwise will change. It may go higher or lower, depending upon the characteristics of the particular transistors in your tvom. In any case, if this reading changes more than 0.5 volt on the 3-volt range, you should replace the 9-volt battery.

If you should ever have occasion to replace one or both of the transistors, you will have to go through the entire balance/calibration procedure again. However, if you use your tvom intelligently and observe the operating procedures which follow in your second experimental manual, you should not need to replace a transistor.

IN CASE OF DIFFICULTY

If you are not able to calibrate your tvom according to the preceding instructions, one or more of the parts may be defective, there may be an error in the wiring of the instrument, or you may have a poor solder connection. If you have trouble calibrating the tvom, read the following before writing to us.

If you get no meter reading whatever, check to be sure that the two meter terminal nuts are tight and that the 9-volt battery is good. Check to be certain you have installed the two transistors correctly as well as the leads from the two slide switches. Check all soldered connections and if you are in doubt about any of them, reheat with your soldering iron and resolder. Beware of letting solder run over from one terminal to another, particularly in the area around the 1% resistors.

After checking your soldered connections, attempt to balance and calibrate the tvom again. If you still have no success, go back to the beginning of the manual and check your work in each assembly stage with the various figures. Be certain always that the correct part was installed in the correct position on the circuit board.

If you still cannot get your tvom to operate satisfactorily, write to us on a Consultation Sheet, giving full details of how the tvom behaves, and the results you obtained when you attempted to calibrate the instrument, and the results of any tests you may have made (such as the battery voltage). Be sure to give us enough information so that we will have a clear picture of your difficulty and can help you get your tvom in proper operating condition.

When you have your tvom operating properly, you are ready to go ahead with your second set of experiments.

Instructions for Performing the Experiments

The experiments in this manual and in the following ones will familiarize you with the mechanical operation of your tvom -- how to set the knobs, read the scales, and connect the test leads. At the same time, you will learn the causes of incorrect voltage and resistance measurements in electronic circuits.

You are now ready to begin learning how to troubleshoot with a tvom. Remember, taking measurements is only the beginning; it is what you can do with the results of your measurements that counts.

You cannot get a better tvom of the service type than your CONAR Model 212 TVOM. It was designed by service engineers for the service expert. Learn to use it understandingly, and it will be your most powerful tool. It will give you information quickly and accurately; your regular lessons and these experiments teach you what to do with this information.

The parts to be used in the experiments are listed in the parts list on page 3. You should have checked them when you checked your other parts.

In doing the experiments in this manual, you will also use some of the parts left over from Kit 1. All of the parts you will need for each experiment will be listed at the start of the Experimental Procedure for each experiment.

In carrying out your experiments, be sure to follow these steps:

1. Read the entire experiment, paying particular attention to the discussion of the experiment.

2. Carry out the experimental procedure, and perform each step of the experiment exactly as directed. Record

your results in the charts or tables provided for that purpose.

3. Study the discussion of the experiment and analyze your results. If they do not seem to be right, repeat the measurements to make sure you did not make a mistake. Do not go ahead with the next experiment until you get the desired results.

4. Follow the instructions for carrying out the Statement that accompanies each experiment. Fill in the correct answer in the blank space provided at the end of each experiment, and again on the Report Sheet you received with this manual.

You will notice instructions to turn off the tvom at the end of many of the experiments. However, it is not necessary to turn off the instrument if you are going to perform more than one experiment without stopping. These instructions were given as a reminder, and they should be used as such. When you have performed all of the experiments that you are going to do at one time, then turn off the tvom.

WARNING

Failure to follow the instructions given in the experiments may result in serious damage to your meter. Be sure that you carefully read and fully understand the instructions before proceeding with the experiments.

EXPERIMENT 11

Purpose: To show that the tvom will give more accurate readings than the 1000 ohms-per-volt meter in high-resistance circuits.

Introductory Discussion: The sensitivity of a voltmeter consisting of a current meter with a series multiplier resistor is given in ohms-per-volt. This is necessary because the meter usually has several different ranges, and the technician needs to know the total meter resistance he is connecting across the voltage source being measured. To determine the resistance, multiply the ohms-per-volt rating by the full-scale value for the particular range being used.

In the 3-volt meter you constructed in Kit 1, the sensitivity was 5000 ohms-per-volt; the total meter resistance was 3 X 5000, or 15,000 ohms. If the meter range had been extended to 30 volts, a 150,000-ohm multiplier resistor would have been used, and the total meter resistance would have been 150,000 ohms. These figures are true regardless of the amount of voltage being measured on a particular range.

A tvom uses a voltage divider; a switch mechanism is used to connect the input of the bridge circuit to the proper point on the divider for the scale in use. The bridge circuit must be adjusted, or balanced, so that when no voltage is applied to the input, the meter reads zero, regardless of the setting of the voltage divider.

In your tvom, approximately 1 volt is used to give maximum meter deflection. If you are using the 1200-volt range, the selector switch connects the input of the bridge to the lowest tap on the divider; and although 1200 volts is applied to the probes, only 1 volt is applied to the bridge. The same thing happens with the lower ranges. The selector switch connects the bridge to the proper tap on the divider for the range in use, and when maximum voltage for that range is measured, 1 volt is fed to the bridge.

Because of this arrangement, the resistance across the source being measured is always constant, and for this reason transistor voltmeters are not rated in ohms-per-volt. Instead, they are rated according to the voltage-divider network resistance, which is called the input resistance. In your tvom, the input resistance is approximately 12.2 megohms. When you make a measurement, you are connecting 12.2 megohms across the source being measured. Since this is such a very high resistance, the original circuit values in a low-resistance circuit change only slightly, and you measure the true operating voltages. Only in extremely high resistance circuits will there be an appreciable change, and then the measured values will be somewhat different from the true values that exist when the voltmeter is not connected.

Experimental Procedure: In this experiment, in addition to your experimental chassis and tvom, you will need:

- **1 500K potentiometer with switch**
- **1 Potentiometer mounting bracket**
- **1 6-32 hex nut**
- **2 10-megohm resistors**
- **1 1/4" X 6-32 screw**

Turn the tvom "on" and set the function switch to dc, the polarity switch to normal.

In the first part of this experiment you will repeat the measurements made in Experiment 10 of Kit 1, using your completed tvom instead of the 5,000 ohms-per-volt meter of Kit 1. The experimental chassis used in Kit 1 should still have the two 1.5-volt flashlight cells, the three terminal strips and the three series connected resistors in place, as shown in Fig. 11-1.

Install the potentiometer mounting bracket at hole W, using a 1/4" X 6-32 screw and a 6-32 nut. Then install the 500K-ohm potentiometer with on-off switch (PO65) in the potentiometer mounting bracket. Position as shown, attach a control nut and tighten.

Terminals 19 and 20, on the back of the potentiometer, are the on-off switch terminals. Terminals 16, 17 and 18 are the potentiometer terminals.

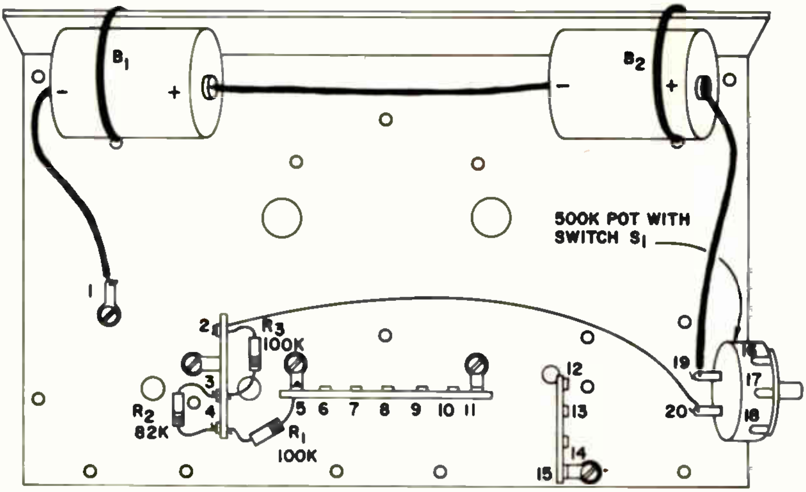

Fig. 11-1. Circuit for Experiment 11.

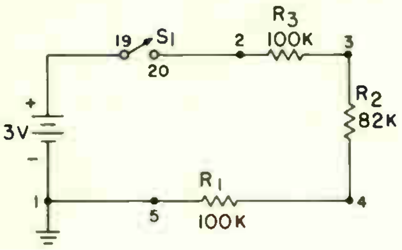

Fig. 11-2. Schematic diagram of circuit for Experiment 11.

Turn the shaft of the potentiometer fully counterclockwise to insure that the switch is off. Then, proceed to wire the circuit shown in Figs. 11-1 and 11-2. Solder the lead from the + terminal of the 3-volt battery to terminal 19 of the on-off switch. Disconnect the negative battery lead from terminal 6 and solder it to the solder lug, terminal 1. Disconnect the lead of the 100K-ohm resistor from terminal 6 and solder it to terminal 5. Finally, connect a length of hookup wire from terminal 2 to terminal 20 of the on-off switch.

The circuit becomes a complete series circuit when you turn the switch on, the return path from the 100K-ohm resistor, R_1, to the negative battery terminal being made through the chassis (ground) from terminal 5 to terminal 1. This arrangement of using the chassis as part of the circuit is quite common and will be used frequently from now on in your experiments.

Step 1: To measure the source voltage.

Clip the "ground" test lead of the tvom to the chassis. Touch the probe of the tvom to the positive battery terminal, and read the meter on the 3.0-volt dc scale. This is the scale you used in the experiments in your first kit. Record the reading in the space provided opposite Step 1 in Fig. 11-3. This may be slightly over 3 volts. If so, mark the value 3+.

Step 2: To measure the voltage across R_1.

Turn on switch S_1 by rotating the potentiometer shaft clockwise. With the ground lead of the tvom still connected to the chassis, touch the probe to the junction of the 100K-ohm and 82K-ohm resistor leads, terminal 4. Observe your reading on the 3-volt dc scale, and record it in the space provided for Step 2 in Fig. 11-3.

Step 3: To measure the voltage across R_2.

Move the ground lead of the tvom to terminal 4 and touch the probe to terminal 3. Record the voltage measured across resistor R_2 beside Step 3 in Fig. 11-3.

Step 4: To measure the voltage across R_3.

Move the ground lead of the tvom to terminal 3 and touch the probe to termi-

STEP	READING
1	2.99
2	1.08
3	.85
4	1.25

Fig. 11-3. Record your readings for Experiment 11 here.

nal 2. Again read the voltage on the 3-volt dc scale, and record your reading in the space provided in Fig. 11-3. Turn off switch S_1.

Discussion: Since the circuit in Fig. 11-2 is exactly the same as the circuit you constructed in Experiment 10, the voltage distribution across the resistors is the same. You should have noticed, however, that the measured values in Experiment 11 are considerably different from those you measured in Step 2 of Experiment 10. When you connected the tvom across a resistor, the resistance value in that part of the circuit did not change appreciably, because the parallel resistance of the tvom was extremely high compared to the value of the resistor.

With the 15,000-ohm meter resistance connected across a resistor, the resistance value was lowered, which changed the entire voltage distribution throughout the circuit while the meter was connected.

The readings you recorded in Fig. 11-3 are for all practical purposes the same as the voltage drops across the resistors with the meter disconnected. If you add them, they will be quite close to the source voltage you measured in Step 1.

This means that in measuring voltages in fairly high resistance circuits, the meter will not affect the voltage appreciably, and you will get an accurate idea of the true operating conditions.

In service work, the fact that the measured value may be slightly lower than the actual value is relatively unimportant. Many manufacturers of electronic equipment list the voltages that should be measured with a tvom. These may be taken as the actual operating values, and variations above and below normal indicate trouble that should be located and corrected.

You have used the tvom just as you did the 5,000 ohms-per-volt meter; you connected the positive meter probe to the end of the resistor nearest the positive battery terminal and the ground lead to the end of the resistor nearest the negative battery terminal.

Because you have a reversing switch on the meter, you could have put the selector switch in the reverse position and connected the ground terminal of the tvom to the positive terminal of the battery and the hot probe to the junction of resistors R_2 and R_3, moving around the circuit in the opposite way. The results would have been almost identical with those taken with the switch in the positive voltage position.

In later experiments, you will see just how the positive and negative dc voltage settings of the polarity switch are used.

Instructions for Statement No. 11: Although, as we have shown, the sensitivity of the tvom is far superior to that of the 5,000 ohms-per-volt meter, you should remember that the tvom does have a definite amount of resistance, and under some conditions can upset the operating voltages.

To obtain data for your statement, solder one lead of a 10-megohm resistor to terminal 2 of Fig. 11-1. Solder one lead of the other 10-megohm resistor to terminal 1 (ground) of Fig. 11-1. Now tack-solder the free ends of the two resistors together to form a 20-megohm voltage divider.

Clip the ground lead of your tvom to the chassis and measure the battery voltage at terminal 19. Enter this value in Fig.

SOURCE VOLTAGE	2.99
VOLTAGE ACROSS FIRST 10 MEG RESISTOR	1.06
VOLTAGE ACROSS SECOND 10 MEG RESISTOR	1.05
SUM OF VOLTAGES ACROSS THE TWO 10 MEG RESISTORS	2.11

Fig. 11-4. Record your readings for the Statement for Experiment 11 here.

11-4 on the top line. Turn S_1 on and measure the voltage at the junction of the two 10-megohm resistors. Enter this value on the second line of Fig. 11-4. Finally, reconnect your tvom to read the voltage across the other 10-megohm resistor and enter your reading on the third line of Fig. 11-4. Now add the voltages across the two resistors and compare this sum with the battery voltage.

Turn off S_1 and your tvom and unsolder and remove all 5 resistors.

Answer the Report Statement here and on the Report Sheet.

Statement No. 11: I found that the sum of the voltages across the two 10-megohm resistors was:

(1) greater than
[✓ *(2)*] *less than*
(3) approximately equal to

the voltage measured across the battery terminals.

EXPERIMENT 12

Purpose: To show that a certain point in a circuit may be positive with respect to one point, and negative with respect to another point.

Introductory Discussion: Many of the expressions used in radio and TV servicing do not seem to have any sensible meaning to the beginner until he uses them himself in practical work.

One expression that causes confusion is "positive or negative with respect to". This means that a point in a circuit is at a positive or negative potential if the voltmeter probes are touched to it and to some other point in the circuit.

For example, we may say that the plate of a tube is 250 volts positive. This statement has no real meaning since a point by itself cannot have a voltage. Voltage means a potential difference between two points. Thus, when we say there is 250 volts on the plate of a tube, we mean there is a potential difference of 250 volts between the plate and the cathode. Another way of saying this is that the plate is positive with respect to, or with regard to, the cathode.

It follows that if the plate is positive with respect to the cathode, the cathode is negative with respect to the plate. At the same time, the grid may be negative with respect to the cathode or, what is the same thing, the cathode may be positive with respect to the grid.

Thus, the cathode can be both positive and negative at the same time, depending on the reference points we have in mind.

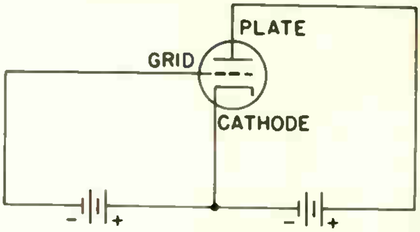

Fig. 12-1. A typical triode tube with batteries for the plate-to-cathode and grid-to-cathode supplies.

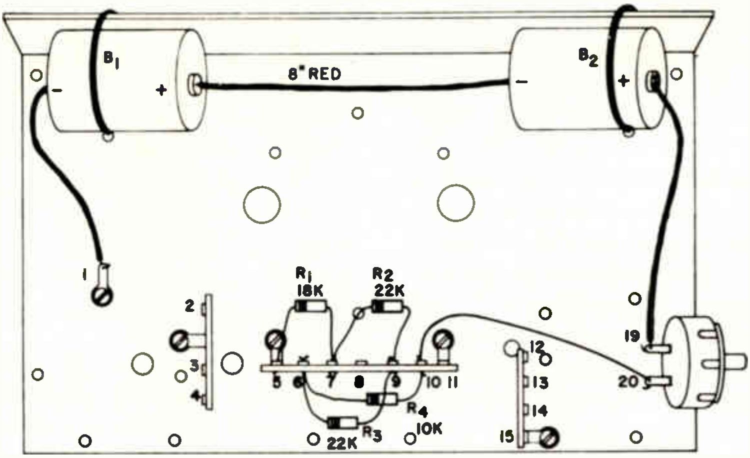

Fig. 12-2. Circuit for Experiment 12.

Fig. 12-1 shows a typical triode tube with batteries for the grid-to-cathode and plate-to-cathode supplies. When the voltage between the grid and the cathode is measured, the positive meter probe should be connected to the cathode, and the negative probe should be connected to the grid. When the plate-to-cathode voltage is measured, the negative meter probe should be connected to the cathode, and the positive probe to the plate. From this you can see that the cathode can be either positive or negative, depending on whether we are referring to the cathode and the grid or to the cathode and the plate. In later kits we will measure grid-to-cathode and plate-to-cathode voltages many times in actual tube circuits.

In this experiment, however, we will use resistors and our 3-volt battery supply. Just remember that a plate or any other point cannot correctly be called positive or negative by itself.

Experimental Procedure: To perform the experiment, in addition to your tvom, you will need the experimental chassis with parts previously installed and:

1 18K-ohm resistor
2 22K-ohm resistors
1 10K-ohm resistor

For this experiment, you will construct the circuit shown in Fig. 12-2. The schematic of this circuit is shown in Fig. 12-3. Connect an 18K-ohm resistor from terminal 5 to terminal 7, connect a 22K-ohm resistor from terminal 7 to terminal 9, connect a 22K-ohm resistor between terminals 6 and 9 and connect a 10K-ohm resistor from terminal 6 to

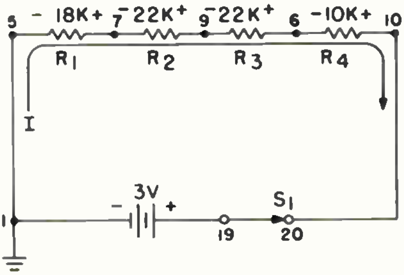

Fig. 12-3. Schematic diagram of the circuit used in Experiment 12.

terminal 10. Disconnect the length of hookup wire from terminal 2 and connect it to terminal 10. Solder all connections.

Fig. 12-3 is a schematic of the circuit you have just constructed. With S_1 closed, a current I will flow as indicated in Fig. 12-3. You know that current goes from minus to plus through a resistor, therefore we have indicated the polarity of the voltage appearing across each resistor in the divider. The left end of each resistor is negative with respect to the right end. It is this fact that you will establish in this experiment.

With your tvom in the dc position and the polarity switch in the normal position, the ground lead is the negative meter lead, while the probe is the positive lead. When the ground lead is connected to one point and the probe is connected to a second point that is positive with respect to the first point, the meter will read upscale in a normal manner. If the probe is connected to a point that is negative with respect to the point to which the ground lead is connected, the meter pointer will move downscale, to the left of zero.

To prove this, turn the tvom on and zero it, and then turn S_1 on. With the tvom set to dc, normal, clip the ground lead of the meter to the chassis and touch the probe to the positive terminal of the battery. The meter will read upscale. Now connect the meter ground lead to the positive terminal of the battery and momentarily touch the probe to the chassis. Note that the meter pointer deflects sharply downscale, to the left past zero, showing that the meter probe is negative with respect to the ground lead.

Step 1: To show that terminal 5 is negative with respect to terminal 7.

GROUND LEAD TO	PROBE TO	UP-SCALE	DOWN-SCALE
CHASSIS	7	✓	
7	CHASSIS		✓
7	9	✓	
9	7		✓
9	6	✓	
6	9		✓

Fig. 12-4. For each step, make a check in the proper box to indicate whether your meter pointer moves upscale or downscale.

Connect the ground lead of the tvom to the chassis, and the probe to terminal 7. Make a check mark in the proper box in Fig. 12-4 to indicate whether the meter pointer moves upscale or downscale. We will not record the exact readings since they are not important in this part of the experiment.

Now reverse the connections of the tvom by connecting the ground lead to terminal 7, and the probe to the chassis. Record the meter pointer movement in the space provided in Fig. 12-4.

An upscale reading on the meter indicates that the meter is connected with the proper polarity. A downscale reading means that the meter is connected with the wrong polarity. Since the meter reading was upscale when the negative lead was connected to the chassis and downscale when the negative lead was connected to terminal 7, the chassis must be negative with respect to terminal 7.

Step 2: To show whether terminal 7 is positive or negative with respect to terminal 9.

Connect the ground lead of the tvom

to terminal 7 and touch the probe to terminal 9. Record the direction of the meter pointer movement in Fig. 12-4.

Connect the ground lead of the tvom to terminal 9, and touch the probe to terminal 7. Again record the meter pointer indication.

Step 3: To show whether terminal 9 is positive or negative with respect to terminal 6.

Connect the ground clip to terminal 9 and touch the probe to terminal 6, and record the meter pointer indication.

Connect the ground clip to terminal 6 and touch the probe to terminal 9, and again record the indication. Open the circuit temporarily by turning S_1 off.

Discussion: If your experiment was conducted successfully, you should have had upscale readings on the first, third, and fifth measurements, and downscale readings on the others. This means that the chassis is negative with respect to terminal 7, terminal 7 is negative with respect to terminal 9, and terminal 9 is negative with respect to terminal 6.

You will notice that terminal 7 is positive with respect to the chassis. However, terminal 7 is negative with respect to terminal 9.

We can also say that terminal 9 is positive with respect to terminal 7 and negative with respect to terminal 6.

Thus, in a series circuit consisting of two or more parts, one point may be either positive or negative, depending upon what other point it is compared with.

In this experiment, we have left the function switch in the dc position and the polarity switch in the normal position, making the ground clip of the tvom the negative terminal and the probe the positive terminal. The probes had to be connected in a certain way in order to give an upscale reading.

In actual practice, this is not done. The function switch is placed in the dc position and the polarity switch is set to normal or reverse -- whichever one will give an upscale reading -- and by looking at the polarity switch you can tell whether the voltage at the probe is positive or negative with respect to the ground clip reference point. You will do this many times in later experiments.

For the present, remember that when we speak of a point as positive or negative, we mean with respect to another point. On a plate, we mean with respect to the cathode of the tube.

Instructions for Statement No. 12: To answer the Statement, we will make use of the polarity switch of the tvom to get an upscale reading and to show that terminal 9 in Fig. 12-3 can be positive with respect to the chassis and negative with respect to terminal 10.

Turn on S_1, and connect the ground clip of the tvom to terminal 9. Touch the probe to the chassis. If the meter reads downscale, slide the polarity switch to the reverse position, and record the actual voltage reading between terminal 9 and the chassis in volts on the margin of this page. Now touch the probe to terminal 10, reset the polarity switch for an upscale reading, and again record the actual voltage measured on the margin of this page. Turn off S_1 and answer Statement 12.

+1.36

Statement No. 12: I found that the polarity of the voltage at terminal 9 with respect to the chassis was:

[✓ *(1) positive*]
(2) negative

and the value was

[✓ *(1) greater than*]
(2) less than
(3) the same as

that measured from terminal 9 to terminal 10.

EXPERIMENT 13

Purpose: To show that a change in the resistance of one part of a series circuit will cause a change in the voltage drops across all of the series-connected parts.

Introductory Discussion: This experiment proves one of the basic facts that you as a technician will use time and again in your work.

The way a set is working may lead you to suspect that the voltage is too low at some point in a circuit or perhaps the voltage is too high at some point. You will use your tvom to see if the voltage is too high or too low. Then, you will look at the circuit diagram to see what could have happened to cause the abnormal readings. After deciding what the probable cause is, you will check the part you suspect of causing the trouble. Your regular lessons and your work on these kits will teach you to do this.

Let us take an example. Suppose you have a voltage divider with the correct source voltage applied to it. What will cause the voltage drop to be too high across some sections of the divider and too low across others?

Ohm's Law (E = I × R) gives the answer. If the voltage E is lower than expected, then I, the current through the part, or R, the resistance of the part, has decreased. You would look for a change in the resistance of the part or for some defect in another part that has decreased the circuit current.

If the voltage is higher than expected, you know that I or R has increased. In this case, you would check for an increase in the part resistance or for a decrease in resistance elsewhere in the circuit that would increase current flow through the entire circuit.

In this experiment you will demonstrate these facts so you will know what to look for when you find similar abnormal voltage readings in your maintenance work.

Remember, it is not enough to know how to take readings -- the important thing is to know what to do with the results of your readings.

Experimental Procedure: In this experiment you will use your tvom and the parts already in place on your experimental chassis.

To construct the circuit in Fig. 13-1, remove the 10K resistor, R_4, from terminals 6 and 10 and resolder the resistor

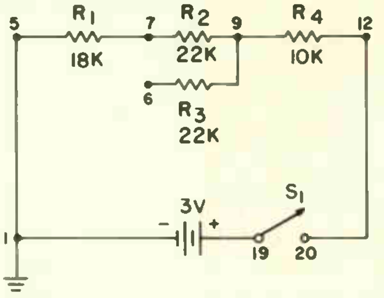

Fig. 13-1. This is the first circuit you will use in Experiment 13.

from terminal 9 to terminal 12. Terminal 12 is on the strip near the switch, S_1. Disconnect the switch lead from terminal 10 and connect it to terminal 12.

After you have constructed the divider circuit of Fig. 13-1, turn on S_1 and set your tvom to read dc normal.

Step 1: To measure the voltages in the circuit.

To measure the source voltage, connect the ground clip of your tvom to the chassis, and the probe to terminal 12. Read your meter on the 3-volt scale and record your reading in Fig. 13-2 in the column for normal resistance (the first blank column) beside "source."

VOLTAGE MEASURED ACROSS	RESISTANCE NORMAL	R_2 DECREASED	R_4 INCREASED
SOURCE	3+	3+	3+
R_1	1.05	1.34	.8
R_2	1.37	.93	1.05
R_4	.56	.72	1.15
	2.98	2.99	3.00

Fig. 13-2. Record your readings for Experiment 13 here.

To measure the voltage across R_1, move the probe to terminal 7. Record your reading beside R_1 in the first blank column of Fig. 13-2.

To measure the voltage across R_2, move the ground clip to terminal 7 and the probe to terminal 9. Record your reading beside R_2 in Fig. 13-2.

To measure the voltage across R_4, move the ground clip to terminal 9 and the probe to terminal 12. Again record your reading in Fig. 13-2.

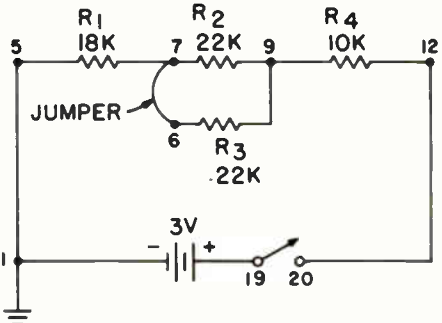

Fig. 13-3. Circuit for Step 2.

Step 2: To show that decreasing the resistance of one section of a voltage divider reduces the voltage drop across that section, and increases the voltage drop across the other sections.

You are to decrease the resistance of R_2 by adding another 22K-ohm resistor in parallel with it, as shown in Fig. 13-3.

To do this, simply solder a short jumper wire from terminal 6 to terminal 7 as indicated in Fig. 13-3.

As you have learned, the resistance of two equal resistors in parallel is equal to half the resistance of one alone. Therefore, we now have 11,000 ohms for R_2 and R_3 in parallel instead of 22,000.

Measure the voltages as you did in Step 1, and record your readings in Fig. 13-2 in the column for decreased resistance in R_2.

Step 3: To show that increasing the resistance of one section of a voltage divider increases the voltage drop across that section, and decreases the voltage drop across the other section.

Rewire the circuit as shown in Fig. 13-4. To do this, remove the jumper from between terminal 6 and terminal 7 and unsolder the switch lead from terminal

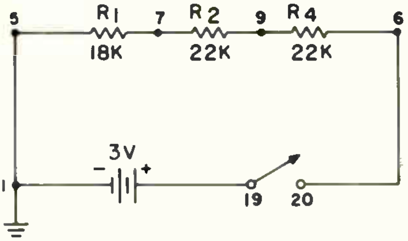

Fig. 13-4. Circuit for Step 3.

12. Resolder this lead to terminal 6 to complete the circuit of Fig. 13-4. The 22K-ohm resistor is now R_4.

Again measure the source voltage and the voltages across R_1, R_2, and R_4 as you did in Steps 1 and 2. Record your readings in Fig. 13-2 in the column for increased resistance of R_4. Turn off switch S_1.

Discussion: Look at the voltages you have recorded in Fig. 13-2. In Step 2, you decreased the resistance of R_2. What happened to the voltage across R_2? It should have decreased. However, the voltage drops across R_1 and R_4 should have increased, since the source voltage is the same, and the sum of the voltage drops is always equal to the source voltage.

Now let us look at the readings for Step 3. Here we increased the resistance of R_4. What happened to the voltage? The voltage across R_4 should have increased. Since the source voltage is still the same and the sum of the voltage drops must equal the source voltage, the other voltage drops should have been lower than they were in Step 1. Here you have seen a practical application of Kirchhoff's voltage law. The sum of the voltage drops in a closed circuit must equal the source voltage. From this we can see that, if the voltage drop across one part in a series circuit changes, the voltage drop across the other components must change in the opposite direction.

There is one thing to keep in mind. Although it is absolutely true that the sum of the voltage drops always equals the source voltage, the sum of the *measured* voltage drops may not exactly equal the source voltage for two reasons.

First, a good servicing type of tvom, such as your CONAR Model 212, has an accuracy of about 5% of the full scale reading. Although more accurate hand-calibrated meters can be made, they are not used in servicing equipment, because such accuracy is not necessary, they are costly, and they cannot stand up under rough treatment. Therefore, measured values can be .15V higher or lower than the true values, indicated on the 3V range (.15 = .05 X 3.0).

Second, you may not be able to read the actual values on the meter. For example, the actual voltage drops across a three-section voltage divider with a 3-volt source might be: .752 volt, 1.527 volts, and .721 volt. The closest you could read these values on your meter would be .75 volt, 1.5 volts, and .7 volt. When you add these, you get 2.95 volts instead of the 3 volts you would actually have. This is close enough. Even if the measured voltages added up to only 2.8 volts, it would be considered entirely normal. A variation of as much as 25% is usually considered normal in most circuits. Thus, if you read your meter scale to the nearest division, the reading will be accurate enough.

Instructions for Statement No. 13: For the Statement, you will use the same circuit used in Step 3. Connect the ground clip of your tvom to terminal 9 and the probe to terminal 6. Turn on S_1

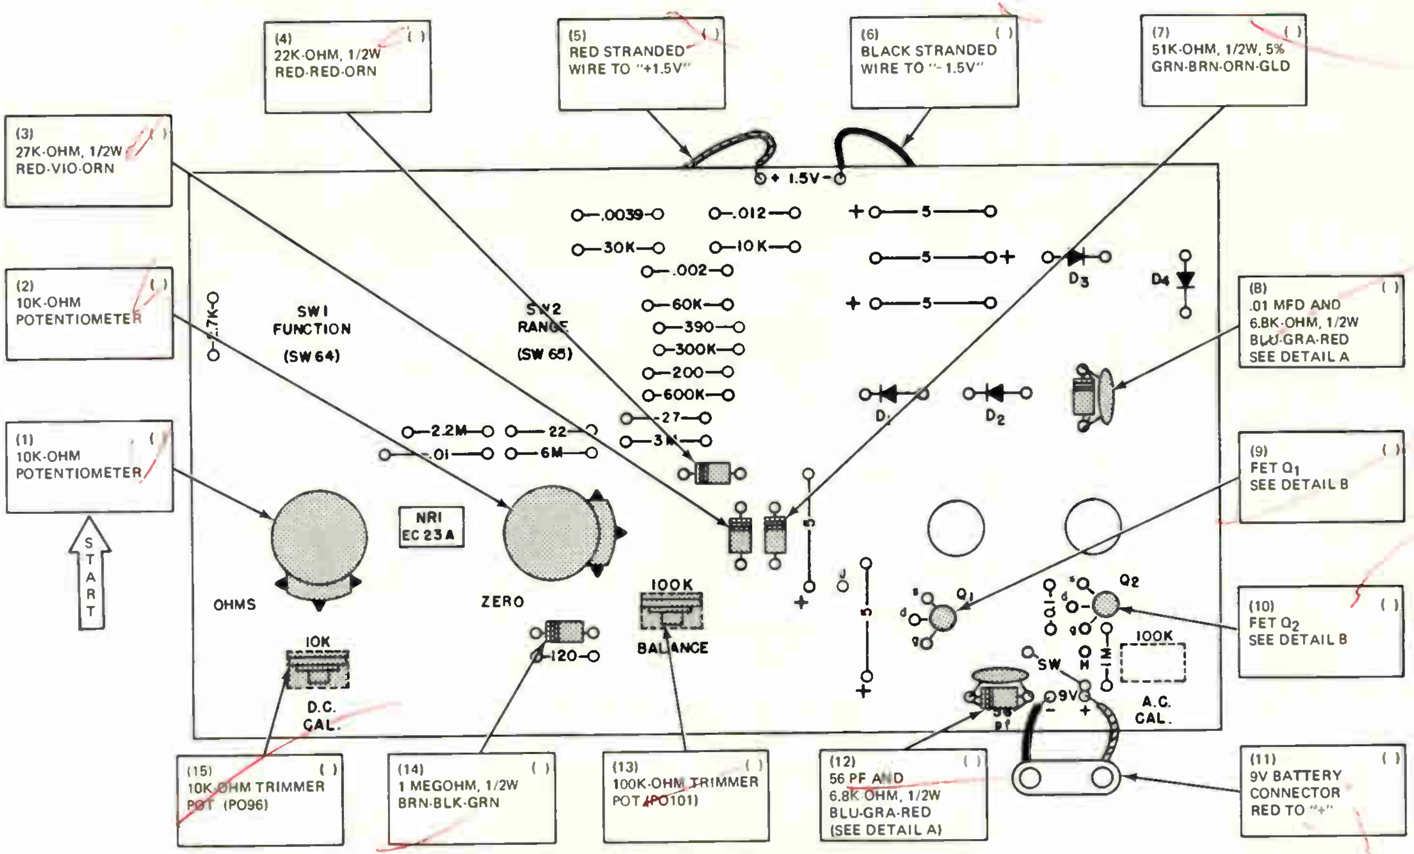

Fig. 2. Stage I Assembly.

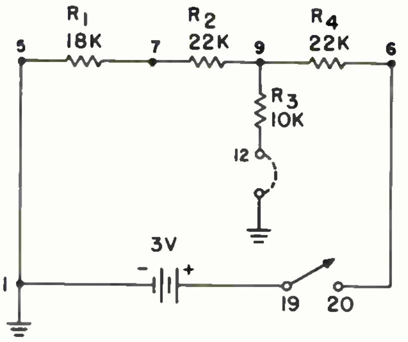

Fig. 13-5. Circuit for Statement 13.

and note the reading in the margin of this page. 1.14

For the statement you are to see what happens to the voltage across R_4 when you shunt R_1 and R_2 with a 10K-ohm resistor. To do this, simply short terminal 12 to the chassis with a screwdriver or a piece of wire as indicated in Fig. 13-5. Measure the drop across R_4 between terminal 9 and terminal 6 with terminal 12 shorted to the chassis. Compare your two voltage readings, and answer the 2.31 statement here and on the Report Sheet. Turn off your tvom and S_1.

Statement No. 13: When I shunted R_1 and R_2 with a 10K-ohm resistor I found the voltage across R_4:

[✓ *(1) increased.*]
(2) decreased.
(3) remained the same.

EXPERIMENT 14

Purpose: To show the effects of resistance variations in series-type voltage dividers; and to show how the resultant voltage variations can be kept to a minimum by using a resistor, called a bleeder.

Introductory Discussion: As you have seen in preceding experiments, if any resistance in a series circuit is changed in value, the voltage across each resistor changes. In some circuits we will want to have a changing resistance and yet have the voltage remain fairly steady as the resistance changes. The changing resistance is often referred to as a "load".

As you have previously learned, when a large resistor and a small resistor are in parallel, the combined resistance is essentially that of the smaller resistor. This means that even though the larger resistance may vary, it will still be enough higher than the smaller resistance so that the combined resistances will remain essentially the same. This very important fact is put to good use where we wish to stabilize the voltage across a load whose resistance varies. By properly designing the voltage divider, these voltage variations can be kept quite small.

In this experiment you will see how this is done. You will build a circuit in which the load resistance can be varied and in which the load requires considerably less than the source voltage of 3 volts. You will see how the voltage across the load changes when the load resistance is changed. Then, you will change the circuit so that the effects of the variations in a load resistance are reduced to a minimum.

As a technician you will not be particularly interested in being able to design voltage dividers, but you certainly will want to know how they work. If you find that a particular circuit is not operating satisfactorily, you must rely on your voltage measurements to tell you what could have happened in the circuit. A knowledge of how voltage dividers operate will go a long ways.

Experimental Procedure: In this experiment you will need your tvom, most of the parts on the experimental chassis and the following parts:

- **1 220K-ohm resistor**
- **1 470K-ohm resistor**
- **1 Slip-on alligator clip**
- **Hookup wire**

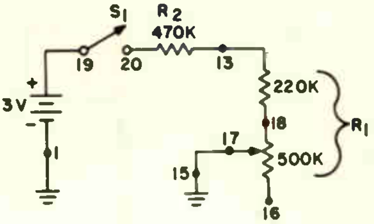

Fig. 14-2. Schematic of the circuit of Step 1.

If you have not done so recently, check the tip of your soldering iron. It may have become covered with the typical black insulating oxide that prevents heat from flowing from the iron to the parts, or the tip may have become pitted. If so, file and retin it as described in Kit 1. Check the tip frequently throughout all your experiments, and don't let it become dirty.

Begin by removing the 22K-ohm resistor connected between terminals 6 and 9 and the 10K-ohm resistor connected between terminals 9 and 12, leaving in place the 18K-ohm and 22K-ohm resistors shown in Fig. 14-1. You may leave the wire from terminal 20 to terminal 6 in place (although it is not shown in Fig. 14-1) as it will be used in later steps of this experiment.

Now construct the circuit shown in Fig. 14-2 and detailed in Fig. 14-1. Terminals 16, 17 and 18 are the three potentiometer terminals.

Slip the alligator clip over the tvom probe as shown in Fig. 14-3 so you can clip both leads of the meter to the circuit under test. It may be necessary to bend down the solder loop in the clip so that the clip will slip easily onto the probe. If the clip is too loose, squeeze the clip with

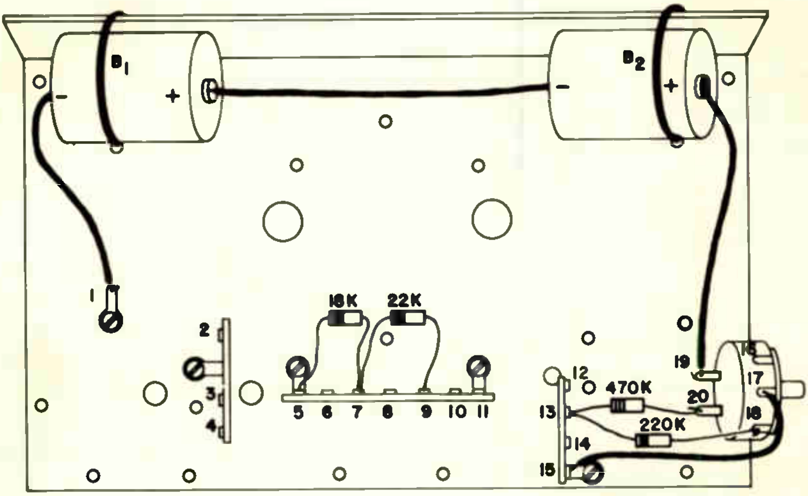

Fig. 14-1. Chassis connections for the circuit of Step 1.

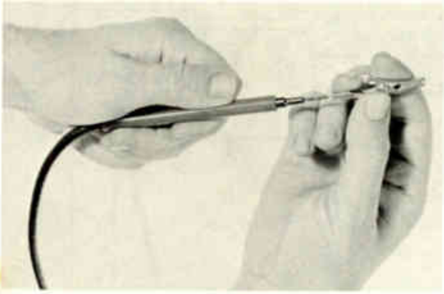

Fig. 14-3. How to slip the alligator clip onto the positive probe.

your combination pliers so it is tightly clamped on the probe tip.

You are now ready to see how the circuit works.

Step 1: To show how a variation in load resistance affects the load voltage.

Clip the ground lead of the tvom to the chassis. Now measure the load voltage by clipping the probe to terminal 13 in Fig. 14-2. In taking measurements, it is sometimes easier to clip it on and leave it there. In this step, it will be easier to clip the lead in place so that you will have both hands free. The meter is now connected across the 220K-ohm resistor and part of the 500K-ohm potentiometer. These two parts make up the load resistor R_1 in Fig. 14-2.

Turn the shaft of the potentiometer clockwise to turn on S_1. Adjust the potentiometer so that the meter reads 1.3 volts. This can be considered to be the normal resistance of R_1.

With the red probe still clipped to terminal 13, turn the potentiometer shaft all the way counterclockwise. This increases the resistance of the load and increases the voltage across the load. This increased load resistance is a smaller load because the circuit draws less current and dissipates less power. Record the voltage across the load at this time in the space provided for voltage with minimum load in Step 1 of Fig. 14-4.

Now rotate the potentiometer shaft fully clockwise, reducing its resistance practically to zero. The load resistance then consists of only the 220K-ohm resistor. This decreased load resistance is a larger or heavier load because the circuit draws more current and dissipates more power. Note the meter reading, and record it in the space for voltage with maximum load in Step 1 of Fig. 14-4.

	VOLTAGE WITH MINIMUM LOAD	VOLTAGE WITH MAXIMUM LOAD
STEP 1	1.52	8.6
STEP 2	1.26	1.22

Fig. 14-4. Record your readings for Experiment 14 here.

Step 2: To show how the load voltage can be kept fairly constant even though the load resistance varies.

Turn S_1 off and remove the 470K-ohm resistor from between terminals 13 and 20. Rewire the circuit to conform to Fig. 14-5. You will need to reconnect and solder the lead from terminal 20 to

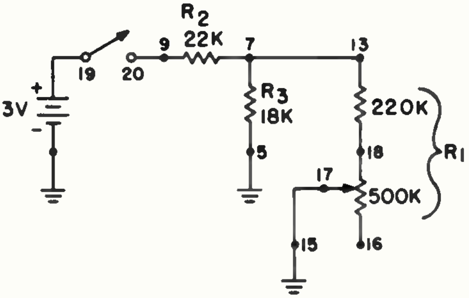

Fig. 14-5. Schematic diagram of circuit used in Step 2.

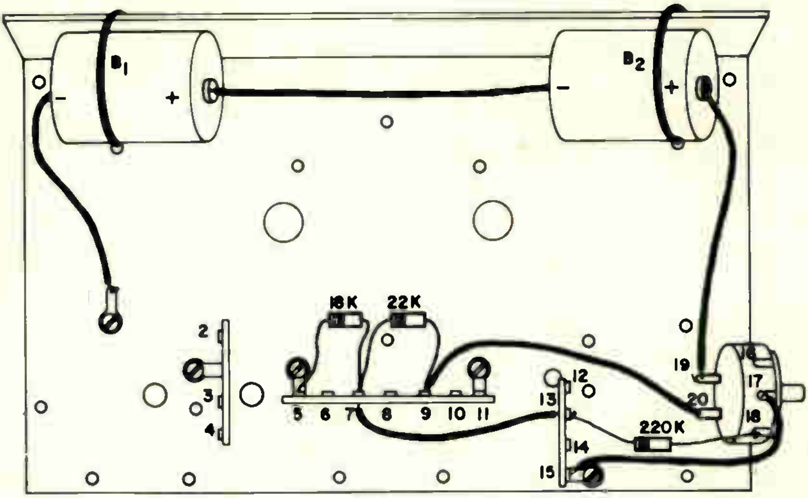

Fig. 14-6. Chassis arrangement for Step 2.

terminal 9, and add a length of wire between terminals 7 and 13 to make these changes as indicated in Fig. 14-6.

Turn S_1 on and adjust the potentiometer shaft fully counterclockwise, and measure the load voltage between the chassis and terminal 13. Record this as the voltage with minimum load for Step 2 in the space provided in Fig. 14-4.

Now turn the potentiometer shaft clockwise as far as it will go to reduce the value of R_1. Record the reading as the voltage with maximum load in Fig. 14-4. Turn off S_1.

Discussion: Look over the figures you have recorded in Fig. 14-4, and compare the two sets of readings. There should be a greater difference between the maximum and minimum voltages in Step 1 than in Step 2.

In any voltage divider, the source voltage divides between the circuit parts, the voltage across a part being proportional to its resistance. If there are two parts having equal resistances, the source voltage will divide equally between them. Both will have the same voltage drop. If one part is variable, some of the time it will have more than half the voltage across it, and some of the time less than half.

In Step 1, the difference between the voltages should have been large, because with the potentiometer set so that none of its resistance was in the circuit, the total load resistance was only 220K ohms -- less than half the 470K-ohm resistance of R_2 -- so there would be much less than half of the source voltage across the load. With the potentiometer set so that its total resistance was in the circuit, the load resistance was 720K ohms -- more than one and a half times the resistance of R_2 -- so there would be much more than half the source voltage across the load. The only time we would have the desired 1.3 volts across the load would be when the potentiometer was set so that the total load resistance of R_1 was slightly less than 470K-ohms.

In Step 2, the voltage difference should have been very small. Here you modified the circuit and put in a bleeder resistor. When two resistors are in parallel, the combined resistance will be less than that of the smaller resistor. Therefore, the combined resistance of R_1 and the 18K-ohm bleeder resistor R_3 in Fig. 14-5 will be less than 18K ohms, whether R_1 is at its maximum of 720K ohms or its minimum of 220K ohms. The combined resistance will vary from about 16.5K ohms to about 17.5K ohms. The voltage will divide almost equally between R_1 and R_2, and, therefore, will always be close to the desired 1.3 volts across R_1.

In your work, be on the lookout for bleeders. They can open or change in value just like any other part, and they must be taken into consideration when the parts with which they are in shunt are checked.

Instructions for Statement No. 14: For this Statement we will simulate a burned-out bleeder resistor R_3 in the circuit shown in Fig. 14-5. Unsolder the 18K-ohm resistor R_3 from terminal 5 and turn on S_1. Measure the voltage across load resistor R_1 by connecting the ground lead of your tvom to the chassis and the probe to terminal 7. Compare the reading you obtain with the voltage reading you have recorded for Step 2 in Fig. 14-4. Answer
2.35 the following Statement and mark your answer on your Report Sheet. Turn off
29.1 S_1 and your tvom, disassemble the circuit and clean the parts. Do not remove the leads from the positive and negative terminals of the 3-volt battery going to terminal 19 and terminal 1.

Statement No. 14: With the 18K-ohm bleeder resistor open, I found that the voltage applied to the load:

[✓ *(1)*] *increased.*
(2) decreased.
(3) remained the same.

EXPERIMENT 15

Purpose: To show that the current flowing in a circuit can be determined by measuring the voltage across a known resistance and applying Ohm's Law.

Introductory Discussion: Ohm's Law tells us that current in amperes is equal to voltage in volts divided by resistance in ohms. Therefore, if we measure the voltage drop across a known resistor, we can accurately determine the current through it by dividing the voltage by the resistance.

In this experiment, you will see that you can determine the current flowing in a circuit by measuring the voltage across any known resistor and applying Ohm's Law. You will also see that you can use the voltmeter scale to indicate current in milliamperes if there is a 1K-ohm resistor in the circuit.

Experimental Procedure: For this experiment, you will need your tvom, the experimental chassis and the following parts:

2	1K-ohm resistors
1	3.3K-ohm resistor

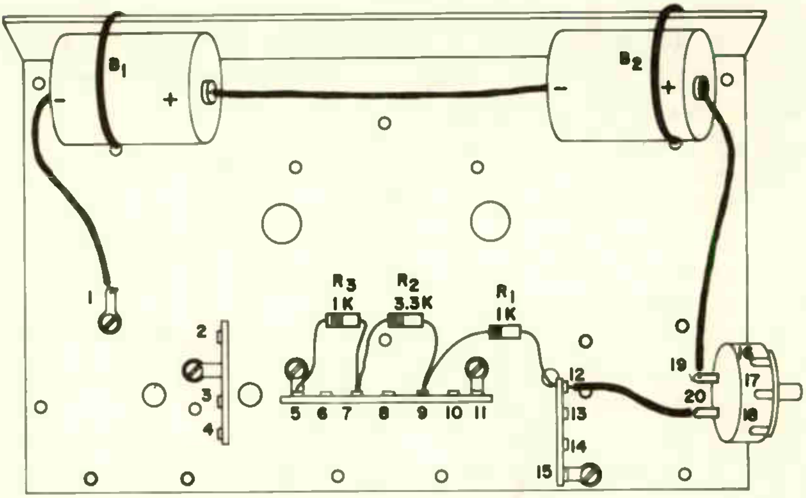

Fig. 15-1. Parts placement for Experiment 15.

First construct the series circuit shown in Fig. 15-1 and shown schematically in Fig. 15-2. Make sure S_1 is off.

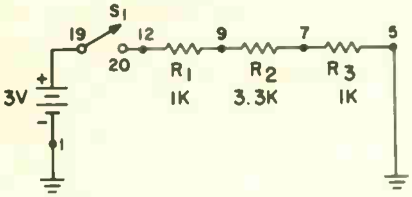

Fig. 15-2. Schematic diagram for the circuit used in Experiment 15.

Step 1: To find the current flowing through the 1K-ohm resistor R_1.

Turn on S_1. Measure the voltage across the 1K-ohm resistor by clipping the ground lead of your tvom to the junction of R_1 and R_2 and touching the probe to terminal 12. Record your reading in Fig. 15-3 in the space for the voltage reading across R_1.

Now, to find the current, we use Ohm's Law, which tells us that the current in amperes is equal to the voltage in volts divided by the resistance in ohms, I = E/R. By substituting the proper numbers for the letters in the formula (1000 for R, and the voltage you have just measured and recorded for E), you can find the current in amperes. To change the answer to milliamperes, we multiply by 1000, moving the decimal point three places to the right.

	VOLTAGE READING	CURRENT IN MA.
R_1 1K	.55v	.55ma.
R_2 3.3K	1.85V	.56ma.
R_3 1K	.57V	.55ma.

Fig. 15-3. Record your readings for Experiment 15 here.

Here is how to figure the current. When we measured the voltage across the 1K-ohm resistor, we obtained a voltage of about 0.6 volt. Using this figure we get:

$$I = E \div R$$

$$I = \frac{0.6}{1000} = .0006 \text{ amp}$$

To change this to milliamperes we multiply by 1000 which gives us:

$$.0006 \times 1000 = .6 \text{ milliamperes}$$

Notice that in performing the operation we simply had to move the decimal point three places to the right.

Now you determine the current through the 1K-ohm resistor from your experimental results. Remember that because of normal parts tolerances, you may not get exactly the same result that we got. Record your current in Fig. 15-3.

Step 2: To find the current through the 3.3K-ohm resistor R_2.

Measure the voltage across R_2 by connecting the tvom with the ground lead to the junction of R_2 and R_3 (terminal 7), and the probe to the junction of R_1 and R_2 (terminal 9). Record the reading in Fig. 15-3. Figure the current through R_2 just as you did for R_1 in Step 1. This time substitute 3300 for R in the formula, and the second voltage measurement for E. Record the current in Fig. 15-3, after multiplying the answer by 1000 to change amperes to milliamperes.

Step 3: To find the current through resistor R_3.

Measure the voltage across R_3 by connecting the ground lead to the chassis and the probe to the junction of R_2 and R_3 (terminal 7). Figure the current as before, again using the last voltage measured for E and 1000 for R. Record this in Fig. 15-3, after multiplying by 1000. Turn off S_1.

Discussion: Now let us compare your results for Steps 1, 2, and 3. The three current values should be approximately the same, because the same current flows through all components in a series circuit. Actually, the current is exactly the same anywhere in the circuit, but because of parts tolerances and the difficulty in reading the meter accurately, your figures may show slight differences.

Notice the voltage value you measured across the 1K-ohm resistor R_1 and the current you calculated for R_1. The number of volts across R_1 and the number of milliamperes flowing through it should be the same, because you divided the voltage by 1000 to find the current, and then multiplied by 1000 to change it to milliamperes. This means that when the resistance equals 1000, the voltage across it in volts is equal to the current through it in milliamperes. Because of this fact, you can read the current directly on the voltmeter scale if you are measuring across a 1K-ohm resistor. If the voltmeter indicates .2 volt, you have .2 milliampere of current. If it indicates 1.5 volts, you have 1.5 milliamperes of current, etc.

If you wanted to measure current with a voltmeter and there was no 1K-ohm resistor in the circuit, you could add a

1K-ohm resistor in series, and measure the voltage across it, provided the resistance already in the circuit is reasonably high so that the addition of the 1K-ohm resistor will not appreciably increase the total resistance in the circuit. However, technicians seldom go to the trouble of inserting a resistor in a circuit so they can read the current value from their voltmeter scale. It takes too long to unsolder leads to install a resistor and then remove the resistor and reconnect the circuit after the measurement has been completed. Also, the busy technician will not use Ohm's Law each time he wants to know something about the current in a circuit. In practical work, you seldom want to know the amount of current. All you want to know is whether the amount is correct, and it will be if the voltage is correct.

Circuit current values are not given for most electronic equipment. However, voltage values are generally given. If the correct voltage drop appears across a part, you can assume that the amount of current is correct for that circuit.

The technician is interested in three possibilities as far as current is concerned. These are:

1. Is the current normal?
2. Is the current too high?
3. Is the current too low?

Voltage measurements give all three answers without the use of Ohm's Law or the necessity of unsoldering and resoldering connections.

Instructions for Statement No. 15: For the statement, you will short out R_3 and determine the current in the series circuit composed of R_1 and R_2. To do this, connect your tvom to read the voltage across R_1, turn on S_1, and short terminal 7 to the chassis with a wire or a screwdriver. Since R_1 is a 1K-ohm resistor, the voltage across it will be equal to the circuit current in milliamperes. Write this value down in the margin of this page. Now turn off S_1 and answer the Report Statement. You will use the circuit already connected for the next experiment, so do not dismantle the experimental chassis.

6.9ma,

Statement No. 15: When I shorted R_3 I found that the circuit current was:

[✓ *(1) greater than*]
(2) less than
(3) the same as

the circuit current measured in Steps 1, 2, and 3.

EXPERIMENT 16

Purpose: To show that continuity can be checked by taking voltage measurements.

Introductory Discussion: The word "continuity" as used in electronics refers to the completeness of the path through which current is to flow. If there is no continuity, in other words, if the path is broken at some point, current cannot flow.

You know from studying your lessons and from the experiments you have already performed, that current flows only in a complete circuit, and that when current flows through a resistance, there is always a voltage drop across the resistance. These two facts are of utmost importance to a technician, because he uses them constantly in troubleshooting.

A complete circuit has a voltage source, connecting wires, and one or more parts through which current can flow. The parts in the circuit do not necessarily have to be resistors -- all parts through which current can flow have some resistance. Examples of these parts are coils, transformers, series tube filaments, and connecting wires. The fact that such parts have some resistance means that there is a voltage drop across each part.

You cannot measure a voltage drop across the connecting wires in a circuit because the resistance of the wire is so close to zero that the voltage drop across it is essentially zero. You can get a pretty good idea of what the voltage drop across each part in a circuit should be by looking at the schematic diagram. For example, if there are three resistors having approximately the same resistance in a series circuit, you should find that the voltage drop across each of the resistors is equal to about one-third of the source voltage. On the other hand, if one very high resistance is in series with one or more low resistances, the voltage drop across the high resistance will be very nearly equal to the source voltage, and the voltage drop across the low resistance will be almost zero.

If there is no voltage drop across one part in a circuit and there is a voltage drop across the other parts, there must be a complete short circuit across the part with no voltage drop. Then the current flows through the short rather than through the part. Since the resistance is essentially zero through the short, there is no voltage drop to measure.

If you measure the full source voltage across a part in a series circuit, you can assume the part is open (will not pass current). The full source voltage across a part indicates there is no voltage across the other parts in the circuit, and no current is flowing through them. The break, as you will prove, is in the part across which you measure the source voltage.

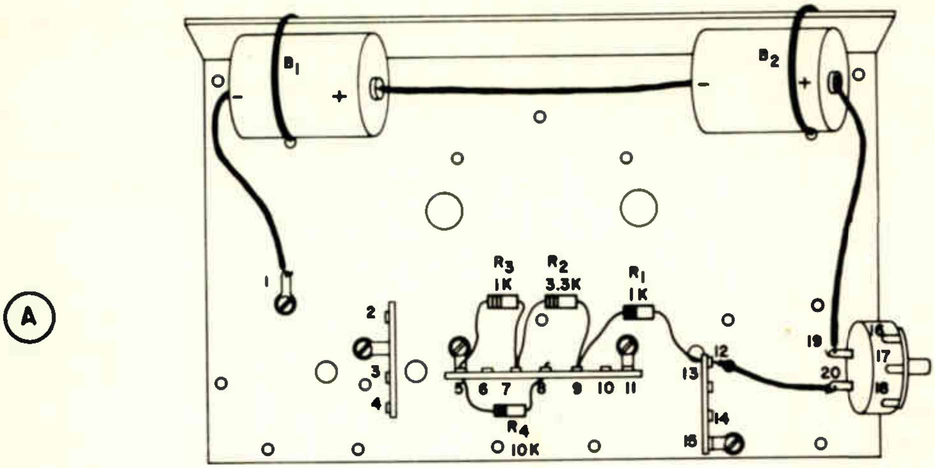
We will investigate these conditions in this experiment so that when you run across them in service work, you will know what to expect.

Here, of course, we are working with low voltages and simple circuits that show only the desired effects. In later kits you will apply the same tests to circuits using the voltage from your power line. You will work with circuits that amplify, that detect, that rectify, and that produce signals of their own. In short, you will learn all you need to know about the circuits.

Experimental Procedure: To perform this experiment you will need the tvom, the circuit you constructed in the last experiment, and the following parts:

1 10K-ohm resistor
1 10-megohm resistor
Hookup wire

For this experiment you will use the circuit shown in Fig. 16-1. As you can see, all you need to do is add the 10K-ohm resistor from terminal 5 to terminal 8 to make the circuit.



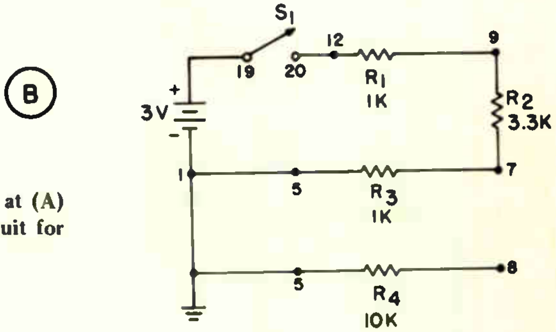


Fig. 16-1. The chassis layout is shown at (A) and the schematic diagram of the circuit for Experiment 16 is shown at (B).

Step 1: To show that there is a voltage drop across each part in a complete circuit.

Examine Fig. 16-1. You can see that there is a complete circuit consisting of R_1, R_2, and R_3 in series across the 3-volt source. Electrons will be pulled through the circuit into the positive terminal of the battery and pushed out into the circuit from the negative terminal of the battery. Electrons cannot be pushed into resistor R_4 because the electrons have no place to go. Unless electrons are removed from terminal 8, none can enter from ground. Since there is no current through this resistor, there will be no voltage drop across it.

Turn on S_1 and clip the negative terminal of your voltmeter to the chassis. Touch the probe to terminal 8. Although there may be a momentary quiver of the meter needle, there will be no steady reading. This shows that there is no voltage drop across R_4. Now touch the probe to terminal 7. Here there will be voltage, which will be less than the source voltage. Touch the probe to terminal 9. You will get a voltage reading greater than the one you measured at terminal 7. Move the probe to terminal 12 and you will measure the full source voltage. This indicates that there is continuity throughout the complete circuit. The fact that the voltage increased from terminal 7 to terminal 9 showed that there was a voltage drop across each part.

Previously, we have measured the voltage across individual resistors. We could have done so in this case, but in actual electronics work you usually make all your measurements with respect to one point in the equipment.

Step 2: To show that the lack of a voltage drop across only one part in a complete circuit shows that that part is shorted.

Cut a piece of hookup wire about two inches long and strip the insulation from it. Solder this lead from terminal 7 to terminal 5. R_3 is now shorted.

With the negative voltmeter lead clipped to the chassis, touch the probe to terminal 7. You should not get a reading because, although current flows through this part of the circuit, there is no appreciable resistance between these points. The current takes the easy path through the bare wire instead of the high resistance path through R_3. Touch the probe to terminal 9; this should give you a reading -- showing that current is flowing through R_2 and also through R_1. Move the probe to terminal 12. You will measure the full source voltage here. Remove the bare wire shorting R_3, and you are ready to go on to the next step.

Step 3: To show that an open part in an otherwise complete circuit has the full source voltage across it and that there are no voltage drops across the other parts.

Fig. 16-2. How to make a dummy open part with two pieces of wire.

Let us assume that R_3 has burned out. Rather than ruin a good resistor, we will make up a dummy part to simulate the effect of an open resistor. To do this, cut two pieces of hookup wire each about 1-1/2 inches long. Remove the insulation from only one end of each wire. Wrap the insulated ends of the wires over each other so you will have an "open part" with two leads. It should look something like Fig. 16-2.

Unsolder R_3 from terminal 7 and solder one lead of the dummy resistor to terminal 5 (leave R_3 and R_4 connected to this point). Solder the other lead of the dummy resistor to terminal 7 and imagine that this is R_3 after it has burned out and become open.

Clip the ground lead of the tvom to the chassis. Touch the probe to terminal 12. You should measure the full source voltage. Now touch the tvom probe to terminal 9. Again you should measure the full source voltage, showing that there is no voltage drop across R_1. Now move the probe to terminal 7. Again you should measure the full source voltage, showing that there is no drop across resistor R_2 and that all of the source voltage is across the dummy open resistor. To further prove that there is no voltage drop across the good parts, connect your ground clip to terminal 7 -- the junction of R_2 and dummy resistor R_3. Touch the probe to terminal 9. Except for a momentary flicker of the meter pointer, you will get no reading. Now move the ground clip to terminal 9 and touch the probe to terminal 12. Again you should get no reading, showing that there is no voltage drop across the parts.

This method of testing across each part individually is a more certain check than measuring from a fixed point such as ground.

Now remove the dummy resistor and resolder the free end of R_3 to terminal 7, completing the original circuit.

Step 4: To show that a check of the source voltage does not indicate the presence of continuity in the circuit connected to it.

Connect the ground clip of the tvom to the chassis. Touch the probe to terminal 19 of switch S_1 in Fig. 16-1. Note the exact reading. Now open the circuit by turning S_1 off. Repeat the measurement by touching the probe again to terminal 19. You will note that there is no difference in voltage at this point whether the circuit is open or closed. Because of this, a check of voltage across a part or across a series of parts directly at the source does not show if current can flow through the circuit or the part. Such a measurement only checks the condition of the voltage supply and not the parts connected to the source.

Step 5: To show that both ends of a part having no voltage drop are at the same potential, and that the continuity of the part can be checked by voltage measurements.

In Step 1 of this experiment, you found that there was no voltage drop across resistor R_4. Let us prove by measurements that terminals 5 and 8 are at the same ground potential. Turn on S_1 and clip the ground lead of your tvom to the chassis, and touch the probe to terminal 8. You will not get a reading. Now clip the ground lead to terminal 8 and touch the probe to the chassis. Again you will not get a reading. With the ground clip on terminal 8, touch the probe to terminal 7. This time there will be a reading. Note its value carefully, and jot it down on the side of the page. Now connect the ground clip to the chassis, and touch the probe to terminal 7. You should measure the same voltage between the chassis and terminal 7 as you did between terminals 8 and 7. Terminals 5 (chassis) and 8 are both negative with respect to terminal 7.

.59

Discussion: The facts that this experiment brings out are of such importance that they are listed here. Refer to this listing whenever you need refreshing on these points. Eventually, you will become so familiar with all of these facts that you will know at once what to look for when you run across similar conditions in your service work.

1. If current can flow through a circuit there will be a voltage drop across all unshorted parts in the circuit.

2. If one part in a complete circuit has no voltage drop across it, but there are voltage drops across all other parts, the one with no voltage drop is shorted. The short may be in the part itself or in some other part shunting it.

3. If in a circuit that should be complete, you find full source voltage across one part and no voltage across the other parts, the part with full source voltage across it is open.

4. If only one part is connected across a source, the presence of voltage across the part is meaningless, since full source voltage will be across it whether or not the part is open.

5. If there is no voltage drop across the part, but one lead of the part connects to an operating circuit, both ends of the part will be at the same potential with respect to all other points in the circuit.

Instructions for Statement No. 16: If the resistance of a part being checked is fairly large compared to the resistance of your tvom, you will not get the expected voltage measurements when you check the continuity of the part. We will prove this point in this statement experiment. We will substitute the 10-megohm resistor for R_4. To do this, solder one end of the 10-megohm resistor to terminal 15 (chassis). Leave the other end free. Clip the tvom ground clip to the free end of this resistor and touch the probe to terminal 7. A reading here indicates that
.34 continuity exists through the 10-megohm resistor. Now touch the probe to terminal
1.65 12. Jot down the approximate reading, and answer the Statement. Turn off S_1 and your tvom, unsolder the 10-megohm resistor but leave the batteries as well as R_1, R_2, and R_3 connected. Save the dummy resistor for later use.

Statement No. 16: When I measured the voltage between the free end of the 10-megohm resistor and terminal 12, I found that the meter pointer was closest to:

(1) zero
[✓ *(2) 1.5 volts*]
(3) 3 volts

on the 0-3 volt dc scale.

.17 μA

EXPERIMENT 17

Purpose: To show that the sum of the currents flowing away from a point is equal to the current flowing to that point.

Introductory Discussion: In this experiment we will construct the series-parallel circuit shown in Fig. 17-1. Current I_1 flows through the branch consisting of R_1 and R_4, and current I_2 flows through the branch consisting of R_2 and R_3. Both of these currents, which together make up the total current drawn from the battery, flow through resistor R.

Since R, R_1, and R_2 are 1K-ohm resistors, we can measure the three currents in terms of milliamperes. As you have learned, the voltage drop in volts across a 1K-ohm resistor is equal to the current in milliamperes flowing through it.

The accuracy of the measurements will depend on the tolerances of the three resistors. If each is exactly 1K ohm, then the current measured for I will exactly equal I_1 plus I_2. However, since the resistors have a tolerance of plus or minus 10 percent and therefore may not be exactly 1K ohm each, the readings may be off a little.

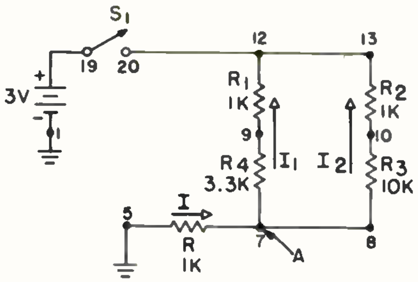

Fig. 17-1. Circuit for Experiment 17.

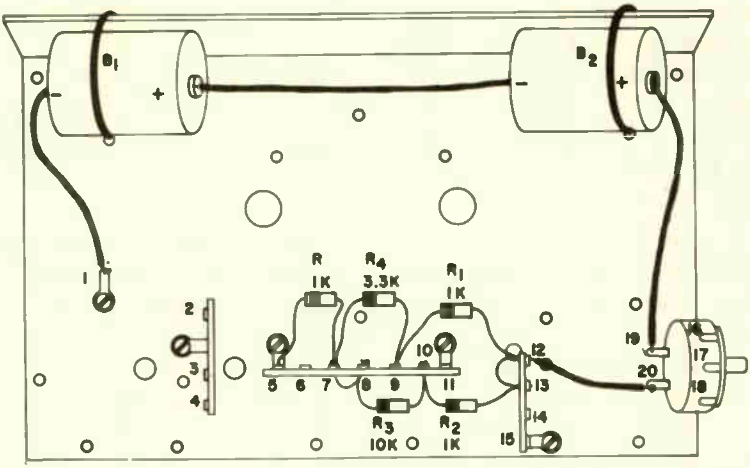

Fig. 17-2. Chassis arrangement for Experiment 17.

Experimental Procedure: For this experiment, you will need your tvom, the chassis with parts installed, and the following parts:

1 1K-ohm resistor
Hookup wire

Fig. 17-2 shows the parts arrangement needed to perform this experiment. To construct this circuit, unsolder the 10K-ohm resistor lead from terminal 5 and resolder it to terminal 10. Then install the 1K-ohm resistor from terminal 10 to terminal 13.

Finally, connect terminals 7 and 8 with a 2″ length of hookup wire, and connect terminals 12 and 13 with another 2″ length of hookup wire. These jumpers are purposely made longer than necessary so that the circuit can be changed easily later. Turn on S_1 and your tvom and proceed with Step 1.

Step 1: To measure current I through resistor R.

Clip the ground lead of your meter to the chassis and touch the probe to terminal 7. Record your reading on the 3-volt scale in Fig. 17-3 as the current I in milliamperes. As you can see from examining the schematic in Fig. 17-1, all the electrons making up the current drawn from the battery flow through resistor R.

Step 2: To measure current I_1.

Current I_1 flows through resistors R_1 and R_4. Since this is a series circuit, the

CURRENT MEASURED	YOUR READING
CURRENT I THROUGH R	.75 ma
CURRENT I_1 THROUGH R_1	.52 ma
CURRENT I_2 THROUGH R_2	.22 ma.
CURRENT $I_1 + I_2$	.74 ma

Fig. 17-3. Record your readings for Experiment 17 here.

same current flows through both resistors. By measuring the voltage drop across R_1 we can interpret this as current I_1 in milliamperes through both resistors. To make the measurement, clip the ground lead of the tvom to terminal 9, the junction of R_1 and R_4, and touch the probe to the end of R_1 going to terminal 12, the positive battery terminal. Record your reading in Fig. 17-3 as the current I_1 in milliamperes.

Step 3: To measure current I_2.

Since R_2 and R_3 are in series, the same current flows through each. Measuring the voltage drop across the 1K-ohm resistor R_2 gives us the current in milliamperes. To make the measurement, clip the ground lead of the tvom to terminal 10, the junction of R_2 and R_3, and touch the probe to terminal 12 or 13, the end of R_2 going to the positive battery terminal. Record in Fig. 17-3 the voltage across R_2 as the current I_2 in milliamperes. Turn off S_1.

Step 4: To find the sum of I_1 and I_2.

Add the values you obtained for I_1 and I_2 and record their sum in the space provided in Fig. 17-3.

Discussion: Compare the current you measured for I with the sum of the currents you measured for I_1 and I_2. They should be approximately equal. However, you must remember that because of parts tolerances, the measured values may not be exactly equal. If these values are equal, it means that the three 1K-ohm resistors that you have are exactly equal and that the measurements in each case happen to fall on a marked scale division so that you could read them exactly. This is extremely unlikely, although possible. If the difference between the sum of I_1 and I_2 and current I is not greater than ±20%, your results are good.

The current flowing to point A in Fig. 17-1 is the current I. The current flowing away from point A is the sum of I_1 and I_2. You should have found that this sum was approximately equal to I. In other words, the current flow to point A is equal to the current flowing away from it. This is an important law known as Kirchhoff's Current Law. You will see applications of it time and time again in your electronics career.

Instructions for Statement No. 17: For the Statement we will change the circuit in Fig. 17-1 by placing resistor R between the positive battery terminal and the junction of R_1 and R_2. The new circuit will be like Fig. 17-4. With the circuit changed, we will see if the currents flowing to point B add up to the current flowing away from this point.

By simply reconnecting the two jumpers used in Fig. 17-2, we can change the circuit to that of Fig. 17-4. Resistors R and R_1 become interchanged. That is, resistor R in Fig. 17-4 was R_1 in Fig. 17-2 and resistor R_1 in Fig. 17-4 was R in Fig.

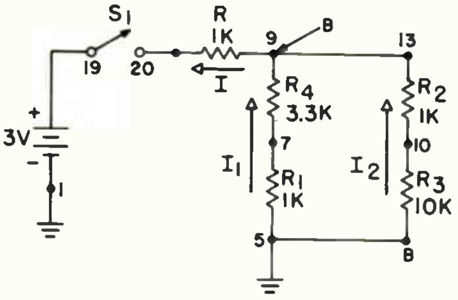

Fig. 17-4. Circuit for Statement 17.

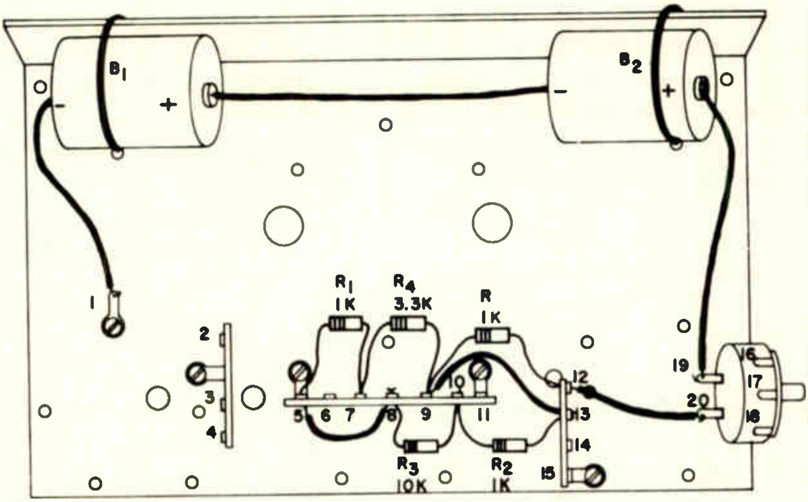

Fig. 17-5. Parts arrangement of Fig. 17-4.

17-2. Both resistors are 1K-ohm, so all is well.

To change the circuit, unsolder the jumper wire going to terminal 7 and resolder it to terminal 5. Unsolder the jumper lead going to terminal 12 and resolder it to terminal 9 as shown in Fig. 17-5. With the circuit changed, we will see if the currents flowing to point B add up to the current flowing away from this point.

Turn on S_1 and measure the current through R by connecting the meter clip to terminal 9 and the probe to terminal 12. Record your reading for I in Fig. 17-6. Now measure the current through R_1 by connecting the meter ground clip to the chassis and touching the probe to terminal 7. Record this reading as I_1 in Fig. 17-6. Finally, measure I_2 by connecting the meter ground clip to terminal 10 and the probe to terminal 13. Record your reading in Fig. 17-6. Add up the currents I_1 and I_2 and enter the sum in Fig. 17-6. Now you can answer the statement.

Turn S_1 off and unsolder and remove the resistors and jumper wires. Leave the battery connected to terminals 1 and 19.

Statement No. 17: **I found that the sum of I_1 and I_2 was:**

[✓ *(1) approximately equal to*]
(2) considerably greater than
(3) considerably less than

current I.

CURRENT MEASURED	YOUR READING
CURRENT I THROUGH R	.~~3~~725
CURRENT I_1 THROUGH R_1	.54
CURRENT I_2 THROUGH R_2	.22
CURRENT I_1+I_2	.76

Fig. 17-6. Record the readings for Statement No. 17 here.

Putting Your Ohmmeter Into Operation

The ohmmeter section of your tvom should be ready to operate. You assembled it and installed the battery when you constructed the unit. If your tvom has been operating properly up to this point, you should have no difficulty with the ohmmeter.

TRYING OUT THE OHMMETER

Turn on the tvom and set the function switch to dc, and the range switch to R X 1. Carefully adjust the zero set knob on the front panel. Look to see that the test leads from the meter are not touching, and rotate the function switch to the "ohms" position. The meter pointer should move upscale. If it moves downscale, you have the flashlight cell installed backwards.

Bring the meter pointer over the last mark on the right on the ohmmeter scale (the red scale on the meter) by adjusting the front panel ohms set knob.

If you cannot get it to the last mark, the flashlight cell voltage is too low, and you should install another cell. You should check the calibration adjustment of the voltmeter when the flashlight cell is replaced.

Turn the range knob through its various positions. The meter pointer should remain in approximately the same position for any position of the range switch. If there is much variation, the meter reading can be brought back to the last mark on the ohmmeter scale by means of the ohms set knob.

Turn the range switch to the R X 1 position and clip the ground lead to the probe tip. The meter will indicate a fraction of an ohm. This reading is normal and is due to the small resistance in the ground lead and the probe cable.

Turn the range switch to the R X 1M position. The meter pointer will swing to the left, coming to a stop approximately at zero on the ohms scale. This indicates there is zero resistance between the clip and the probe. The fraction of an ohm of resistance in the ground lead and cable is not indicated with high range switch settings. When you separate the clip and the probe, the meter pointer will swing all the way to the right to the last mark on the ohmmeter scale.

It is important that you know the meaning of these two marks. The one at the right means that the resistance between the test leads is too high to be read, and the zero mark at the left means that the resistance between the two probes is too low to be read.

Let us see how the ohmmeter works.

HOW YOUR OHMMETER WORKS

An ohmmeter does not measure the resistance of a part directly. It measures either the current flowing through the part or the voltage drop across the part. Your Model 212 and most commercial tvom's use the latter method.

As you already know from the discussion in Experiment 11, the bridge circuit in your tvom when balanced gives a zero reading on the meter scale. When a voltage is applied to the bridge, unbalancing it, there is a reading which depends upon the amount of the voltage.

A schematic diagram of your ohm-

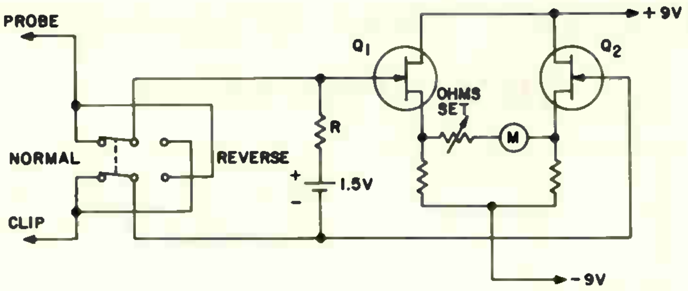

Fig. 14. Ohms circuit of TVOM.

meter circuit is shown in Fig. 14. When the ohmmeter is in use, the additional parts consist of the 1.5-volt cell, a resistor, and the ohms set rheostat in series with the meter. When the probes are separated, there is no voltage drop across the resistor, and the 1.5 volts is applied directly to the bridge circuit. When the ohmmeter is to be used, the ohms set is adjusted so the meter pointer moves all the way to the right. When the test probes are held together, no voltage is applied to the bridge circuit, and the meter pointer goes all the way to the left on the ohms scale.

If a resistor is connected between the ground clip and the probe, the 1.5-volt source voltage divides between the resistor built into the tvom and the external resistance under test. The voltage drop across the resistor being tested is applied to the bridge circuit. The meter is calibrated to give readings in ohms, corresponding to these voltage drops. Thus, the meter is actually measuring the voltage drop, but the scale is marked in ohms to give a direct resistance reading.

For each ohmmeter range position a definite resistor value is switched into the circuit. On the R X 1 range, we have a 10-ohm resistor; on the R X 10, a 100-ohm resistor; on the R X 100, a 1K-ohm resistor; on the R X 1K, a 10K-ohm resistor; on the R X 10K, a 100K-ohm resistor; on the R X 100K, a 1-meg resistor; and on the R X 1M, a 10-meg resistor. Since all of these ranges are multiples of 10, we can use the same ohmmeter scale for each range. On R X 1, the scale can be read directly. On the R X 10 range, we multiply the scale reading by 10. On the R X 100 range, we multiply the scale reading by 100. On the R X 1K range, we multiply the scale reading by 1000. On the R X 10K range, we multiply the scale reading by 10,000. On the R X 100K range, we multiply the scale reading by 100,000, and on the R X 1M range, we multiply the reading by 1,000,000. On this range we simply read the scale directly in terms of megohms (million ohms) rather than ohms.

The scale is arranged so that 10 falls in the center of the scale. If we measure a 10-ohm resistor on the R X 1 range, the resistance in the tvom and the external resistance will be equal, and the meter will read half-scale. The cell voltage divides equally between the resistance in the tvom and the external resistance. The meter will read half-scale on each range when the resistor under test equals the internal resistance of the ohmmeter. If a resistance higher than the internal resistance is measured, more of the voltage will be dropped across it and applied to the bridge circuit, and a higher value will be indicated. If a resistor lower than the one in the ohmmeter being tested, less of the voltage will be dropped across it, and a smaller voltage will be applied to the bridge circuit, giving a smaller deflection and a lower resistance reading.

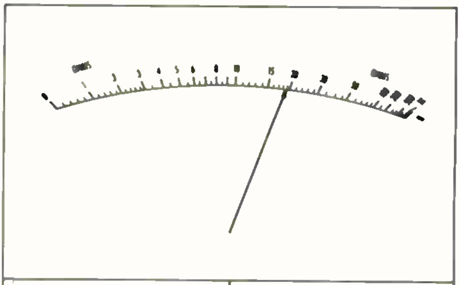
The values that can be read on any range are the ones included between the first mark on the ohmmeter scale to the right of zero and the 1K mark.

Thus, on the R X 1 scale, we can read values from .2 ohm to 1000 ohms. On the R X 10 scale, we can read values from 2 ohms to 10,000 ohms. On the R X 100 scale, we can read values from 20 ohms to 100K ohms. On the R X 1K range, we can read values between 200 ohms and 1 megohm. On the R X 10K range, we can read values between 2000 ohms and 10 megohms. On the R X 100K range, we can read values between 20,000 ohms and 100 megohms. On the R X 1M range, we can read values between 200,000 ohms and 1000 megohms.

These are the maximum extremes that can be measured on the various ranges. Actually, a range should be used that will give a deflection as near the center of the scale as possible. Avoid using a range that gives a reading on the extreme right.

READING THE METER SCALE

An expanded view of the meter scale is shown in Fig. 15 with the values of the in-between markings clearly illustrated. Study this and the scale on your meter until you are able to identify the values of the unmarked divisions quickly.



RANGE SETTING	VALUE INDICATED
R X I	19
RX10	190
RX100	1,900
R X IK	19,000
R X 10K	190,000
R X 100K	1,900,000
R X IM	19 MEG

Fig. 16. When the meter points to the first line before 20 on the ohms scale, the value indicated depends on the setting of the range switch.

For practice assume that the meter pointer rests at a certain position and then figure out what value this position would indicate on the various ranges.

Assume that the meter pointer points to the division just before 20. Write down the value this would indicate for each range of the ohmmeter. Then compare your reading to the ones in Fig. 16.

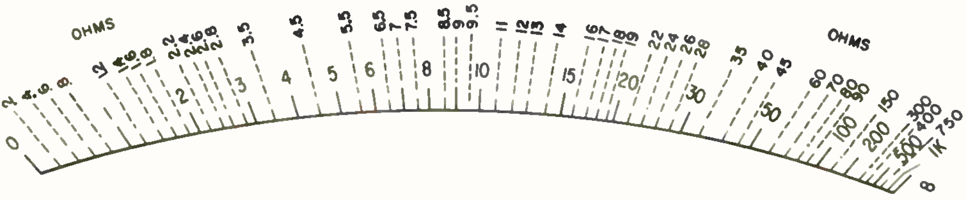


Fig. 15. An expanded view of the ohmmeter scale of the tvom.

Remember that the R X 1 scale is read directly in ohms, and the R X 1M scale is read directly in megohms.

Although, as we have said, your ohmmeter works by voltage division, you must remember that some current is drawn from the cell. With the range switch in the R X 1 position and the test leads shorted together, you have a 10-ohm resistor connected directly across the cell and considerable current is drawn from the cell. Do not leave the probes together for any length of time on the two lowest ohmmeter ranges. Make the readings quickly so you can disconnect the test probes and prolong the life of your flashlight cell. However, since replacement cells are inexpensive and are easy to install, you should take enough time to get satisfactory readings.

EXPERIMENT 18

Purpose: To show how practical measurements on individual resistors are made with an ohmmeter; and to show the precautions necessary for satisfactory results.

Introductory Discussion: In checking parts with an ohmmeter there are three important rules to bear in mind. These are:

1. Make sure the equipment in which the part under test is used is turned off. If it is supplied from the power line, turning the equipment power switch to the off position is usually sufficient. Many technicians, however, make it a rule to remove the power line plug of the equipment from the wall socket. Then there is no question that the power has been disconnected, and there is no chance of turning the switch on while checking the volume control, which may be part of the switch.

If the equipment is battery operated, all the batteries should be disconnected, because the on-off switch might disconnect only one battery terminal, leaving the other terminal connected to the circuits. In making tests with your ohmmeter, you might complete the battery circuit through your meter. If there is voltage across the part being tested, the resistance measurement is meaningless and if the voltage is high, the ohmmeter might be damaged. We will show what happens when voltage is present across a resistor being checked with an ohmmeter.

2. Use the correct range of the ohmmeter. As you will demonstrate, if you use the wrong range, the ohmmeter may indicate a good part is open or shorted.

3. Keep your fingers off the parts under test when measuring high resistances. The resistance of your body can affect the results of your measurements. On low resistances it does not matter. Do not touch the probes when checking iron-core devices, such as transformers or chokes, or you may receive a serious shock.

As you continue working with your ohmmeter, you will learn other valuable tricks of the trade that will enable you to get the greatest use from the ohmmeter section of your tvom.

Experimental Procedure: In this experiment you will need your tvom, the 3-volt battery, and the following parts:

1 10-megohm resistor
1 1-megohm resistor

1 100K-ohm resistor
1 22K-ohm resistor
1 18K-ohm resistor
1 10K-ohm resistor
1 3.3K-ohm resistor
3 1K-ohm resistors
1 Alligator clip

Turn the tvom on and turn the function switch to the dc position. Carefully adjust the zero set control. Now turn the function switch to the ohms position, and the range switch to the R X 1M position. Adjust the ohms set control so that the meter pointer is over the last division at the right on the ohms scale. Now hold the test leads together; the pointer should move to zero on the left of the scale. You are now ready to demonstrate the first step in the experiment. Slip the alligator clip over the tvom probe as you did in Experiment 14. This will make it easier to connect the ohmmeter to the circuits used in this experiment.

Step 1: To show the effect of touching the circuit under test when measuring large resistance values.

In this step you will first use the 10-meg resistor. With the resistor on your workbench, clip the ground lead of the tvom to one lead of the resistor and the probe to the other resistor lead. You will get a reading of approximately 10 megohms. Let us see how we read this. The meter pointer should point to about 10 on the ohms scale and this, of course, means 10 megohms on this range.

Now with the ground lead and the probe clipped to the 10-megohm resistor, grasp one test clip in each hand. This places your body in parallel with the 10-megohm resistor. Note the change in the meter reading. The large reduction in the reading shows that your body resistance is in parallel with that of the 10-megohm resistor. You might measure 2 megohms, 4 megohms, or 6 megohms, depending upon the moisture on the surface of your skin and the pressure you exert in touching the test leads. In any event, you can see that such a test of the resistor gives meaningless results.

Lay the 10-megohm resistor to one side, and set the range switch to the R X 10K position. Connect the ground clip to one lead of the 100K-ohm resistor, and the probe to the other end, and note the reading. Grasp one test clip in each hand, placing yourself across the resistor. Again note that there is a reduction in the resistance reading, although considerably less than in the case of the 10-megohm resistor. The reduction is less because the resistance of your body across the 100K-ohm resistor causes less of a change in the resistance between the ohmmeter leads.

Now disconnect the 100K-ohm resistor and lay it to one side. Place the range switch in the R X 1K position. Connect the ground clip to one lead of a 10K-ohm resistor, and the probe to the other end. Your reading will be somewhere near 10 on the ohms scale. Multiplying this by 1000 will give you the approximate value of the resistor. Now touch the ground clip with the fingers of one hand, and touch the probe with your other hand. Note that there is only a slight change in the resistance value.

This step showed you that touching the ohmmeter leads with your hands is not very important when measuring low resistances, but is extremely important when measuring high resistances. You should make it a habit to keep your hands off the circuit under test.

Step 2: To show that using the incorrect ohmmeter range may give misleading results.

Connect the ground clip to one lead of the 100K-ohm resistor, set the range switch to the R X 1 position, and touch the probe of the tvom to the free lead of the resistor. Note that there is no appreciable movement of the meter pointer, indicating, as far as this range is concerned, that the resistor is open. Now, remove the probe from the resistor, and switch the range switch to the R X 1M position. Again touch the probe against the free lead of the resistor. The pointer will move almost to zero, and you might conclude that the resistor was either completely or partially shorted. Now, remove the probe from the 100K-ohm resistor, and change the range switch to the R X 10K position. Touch the probe to the resistor again and you will find that the meter pointer swings to 10. Multiplying this by 10,000 gives us 100,000 for the value of the resistor.

From this demonstration you can see how important the choice of range is. Let us learn how to choose the right range.

Step 3: To show how to choose a suitable ohmmeter range.

A suitable ohmmeter range is one that is easily read. Before demonstrating this statement, examine Fig. 18-1. This chart lists the resistance values covered by each range. It also shows how many places to move the decimal point for each multiplying factor. For example, if the meter reads 10 when using the R X 10 range, move the decimal one place to the right, which gives you 100, the value of the resistor under test.

RANGE	COVERAGE	NO. OF PLACES TO RIGHT TO MOVE DECIMAL POINT
R X 1	.2 OHM TO 1K OHMS	0
R X 10	2 OHMS TO 10K OHMS	1
R X 100	20 OHMS TO 100K OHMS	2
R X 1K	200 OHMS TO 1 MEGOHM	3
R X 10K	2K OHMS TO 10 MEGOHMS	4
R X 100K	20K OHMS TO 100 MEGOHMS	5
R X 1M	200K OHMS TO 1000 MEGOHMS	6

Fig. 18-1. The resistance values covered by each range of the ohmmeter.

To find the ohmic value when the meter reads 30 using the R X 100K range, move the decimal point five places to the right, which gives 3,000,000 or 3 megohms.

When the readings fall on unmarked values to the left of 6, the meter value will end with a decimal. Thus the line between 5 and 6 is 5.5. On the R X 10 range, a meter reading of 5.5 is 55 ohms. Also notice that the long mark between 6 and 8 is not numbered and it represents 7. Likewise, the long mark between 8 and 10 is not numbered and it represents 9. The short marks between 6 and 7, 7 and 8 and 8 and 9 indicate a value ending in .5.

Suppose you are using the R X 10K range, and the meter pointer is on the third mark past zero. This is .6. To get the reading in ohms, multiply .6 by 10,000 or move the decimal point four places to the right. The answer is 6000 ohms.

With practice you will be able to read

values quickly and easily. Many times you can tell the range to use by reading what the value is supposed to be on the schematic diagram.

Let us see which range to use for your 18K-ohm resistor. First, put the range switch in the R X 1 position. Clip the ground lead to one lead of the resistor, and the probe to the other lead. Record your reading in Fig. 18-2. Now, move the range switch to each of the other positions, and watch the meter. Record your meter readings in the spaces marked "Reading" in Fig. 18-2. Figure out the value in ohms by multiplying each reading by the multiplying factor for each range setting. Write these under "Value" for each range.

When you use the R X 1 range, the pointer will be all the way over to the right, so you know the resistance is more than 1000 ohms, so you switch to the next range. On R X 10, the pointer still stays all the way over to the right, so again you switch to a higher range. On R X 100, the pointer should be between 150 and 200, so switch to a higher range. On R X 1K, the pointer should be at about 18; on R X 10K, it will be anywhere from 1.6 to 2; on R X 100K, it will move past the first scale division on the left, .2; and on the R X 1M range, there will be no perceptible reading.

From these, you know that the resistance you are measuring will be more than 1000 ohms, and less than 20,000 ohms. You could read it on the R X 100, the R X 1K or the R X 10K range. You will get a more accurate reading on the R X 1K range, because at that part of the scale, each division represents 1, and the reading is near the center of the scale. On the R X 100 range the reading is way over to the right, and each division represents 50 or 100. On the R X 10K range the reading is way over to the left, and each division represents 2.

The readings you obtain might be closer together or even farther apart than those shown in Fig. 18-2. Exact agreement is very unusual and, as you will learn, unnecessary. Since the readings are taken on different parts of the scale, the error introduced by the meter itself and by the resistors in the instrument may vary. For service and general electronic work such an error is unimportant.

Now check each of your resistors on

RANGE	R X 1		R X 10		R X 100		R X 1K		R X 10K		R X 100K	
	READING	VALUE	READING	VALUE	READING	VALUE	READING	VALUE	READING	VALUE	READING	VALUE
SAMPLE FIGURES	1K +	1K +	1K +	10K +	150 +	15K +	18	18 K	1.6 +	16 K +	LESS THAN .2	LESS THAN 20K
YOUR FIGURES	1K+	1K+	1K+	10K+	200+	20K+	16	16K	1.7	17K	.2 -	20K

Fig. 18-2. Record your reading for each range setting under the column headed "Reading". Record the value that reading indicates on each range under the heading "Value".

each range, recording your scale readings in Fig. 18-3, and the value this reading indicates. Clip the ground lead to either lead of the resistor being measured, and the probe to the other lead. Turn the range switch to the positions indicated on the top of the table, and enter the meter reading you obtain under the heading marked "Reading." Compute the ohmic value of the resistor, and enter it in the space marked "Value."

For the 1K-ohm reading, use any one of the 1K-ohm resistors. For the 330-ohm resistance you are to measure, connect the three 1K-ohm resistors in parallel. To do this, clip the tvom ground lead to one end of all three 1K-ohm resistors, and the probe to the other ends.

Practice working out the ohmic value of each reading you record in Fig. 18-3. If you find one range is as easy to read as another, it does not matter which range you use.

If you want the greatest accuracy, use the range that gives an indication nearest the center of the scale. For example, when you measure the 330-ohm resistance on the R X 1 range, the pointer will move between 200 and 300 at the right-hand side of the scale, but that is about as close as you can read it. On the R X 1K range, it will move between .2 and .4, so you know the value is between 200 and 400. However, on the R X 100 range, it will move to the first division past 3, so you know the value is between 300 and 350. This is the best scale to use for this particular resistance value.

Step 4: To show that power must not be applied to a circuit when ohmmeter tests are made.

Connect a 1K-ohm resistor, a 10K-ohm resistor and a 22K-ohm resistor in series. Connect the free lead of the 1K-ohm resistor to terminal 15 and connect the 22K-ohm resistor to terminal 20, as shown in Fig. 18-4. Make sure S_1 is off. To make the connections to the 10K-ohm resistor, simply twist the resistor leads together for this temporary connection. Note that the circuit is not completed,

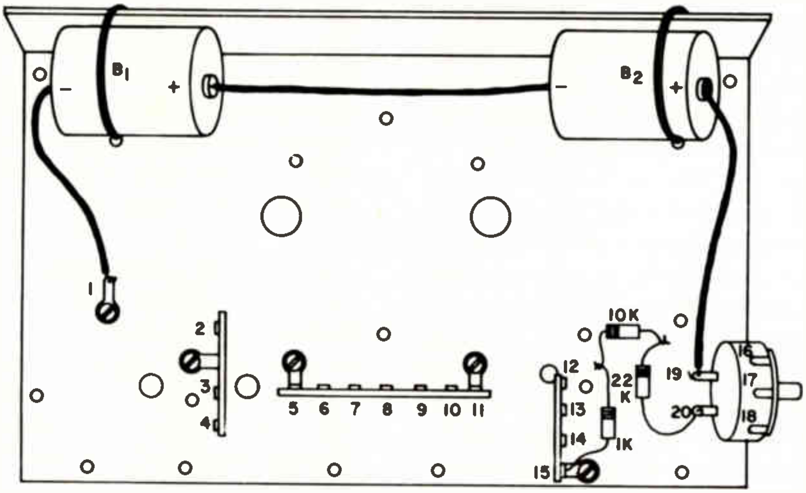

Fig. 18-4. Circuit for Step 4.

since S_1 is off and the 22K-ohm resistor is not connected to the positive terminal of the battery. Consequently, there will be no voltage drops across the resistors, and no current flow through the circuit.

Measure the resistance of the 1K-ohm resistor by clipping the ground lead to the chassis. Set the range switch of the tvom to the R X 1K position, and clip the probe to the junction of the 1K-ohm and 10K-ohm resistors. The meter needle will indicate approximately 1; multiplying this by 1000, you get 1000 ohms for the resistance of the resistor.

Clip the probe to the junction of the two resistors and turn on S_1. Note that there is a marked increase in the resistance reading, so much so, in fact, that you might suspect that the resistor was defective. Turn off S_1 but do not dismantle the circuit. You will use it again to answer the statement.

Discussion: In this experiment you have learned that you must choose a suitable ohmmeter range. The wrong range might indicate that a good resistor is open or that it is shorted. Also, you must choose a suitable range so that the value can be read easily and accurately.

You have seen that if power is applied to a circuit in which a resistance measurement is being made, the measurement will be so far off as to be meaningless.

You have found that the ohmmeter is not 100% accurate. However, in service work, this is unimportant. When making resistance measurements on equipment you have been called upon to repair, you are looking for an open, for a short, or for a radical change in resistance value. If a part has changed sufficiently in resistance so that the equipment operates improperly, the change will be large. You would not expect a change of 25% to cause trouble in most circuits. In general, the change, if that is what the trouble is, will be 50% or more. For example, you might find that the plate load resistor of an amplifier had changed from its normal value of 100,000 ohms to 20,000 ohms. This would cause a marked loss in gain, and cause excessively high plate voltage.

When a technician has improperly operating equipment, he does not check the value of each and every resistor with his ohmmeter. He localizes the trouble to a section and then to a stage. Then he decides whether to make ohmmeter measurements or other measurements according to the symptoms he discovers. You will be taught how to localize trouble to a stage, and from the symptoms, to decide what type of test should be made.

There are, of course, many uses for an ohmmeter besides just checking individual resistor values. We will describe other uses in later experiments.

Instructions for Statement No. 18: In Step 4, you saw that if voltage was applied to the resistor under test, the reading was incorrect. We are now going to see if the polarity of this voltage has any effect on the reading by reversing the ohmmeter connections.

Make sure the tvom polarity switch is set to normal. Connect the ground clip of your tvom to the junction of the 10K-ohm and 1K-ohm resistors. Set the range switch to R X 1K, and touch the probe to the chassis. You are again measuring the 1K-ohm resistor. While holding the probe against the chassis, turn on S_1. Note the new ohmmeter reading. You now have sufficient information to answer the statement. Take the circuit apart, but leave the batteries connected and in place on the chassis.

Statement No. 18: When I turned on S_1, the ohmmeter reading:

(1) increased.
[✓ *(2) decreased.*]
(3) remained unchanged.

EXPERIMENT 19

Purpose: To show how circuit continuity can be checked with an ohmmeter, and to show that the presence of continuity does not indicate the condition of all parts in the circuit.

Introductory Discussion: You have seen how circuit continuity can be checked with a voltmeter and that continuity indicates only that the circuit will carry current. Parts may be shorted or may have changed in value without affecting the ability of the circuit to carry current. If a circuit has continuity, it simply means that the circuit is not open.

Most technicians prefer the ohmmeter for continuity testing, since it can easily be shifted to various points in the circuit to measure their actual resistance. When making continuity tests, the ohmmeter is not used to measure the total resistance of the circuit, although it does show the approximate sum of the resistances. The true purpose is to show that the circuit is complete. In making continuity measurements, technicians seldom bother to determine the resistance of the circuit. They simply check to see if there is a reading showing continuity.

In this experiment, you will demonstrate that in a circuit containing large and small resistances, a small resistor could be shorted without materially affecting the resistance measurement. To find such a short, a check of the individual resistors would be required. This would be done only if the symptoms indicated that it was the cause of the difficulty.

Experimental Procedure: In this experiment, you will need your tvom, the dummy resistor you built in Experiment 16 and the following parts:

- 1 10-megohm resistor
- 1 1-megohm resistor
- 1 100K-ohm resistor
- 1 22K-ohm resistor
- 1 10K-ohm resistor
- 1 1K-ohm resistor

In this experiment, you will make up a voltage divider using five resistors in series, and check the continuity. You will not use the chassis for this experiment, simply solder the 10-megohm, the 1-megohm, the 100K-ohm, the 1K-ohm, and the 10K-ohm resistors together as shown in Fig. 19-1. You are now ready to conduct the first step in this experiment.

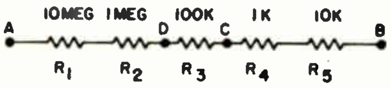

Fig. 19-1. Voltage divider you will use in Experiment 19.

Step 1: To determine accurately the resistance between terminals A and B of the voltage divider.

STEP	MEASUREMENT	VALUE
1	R_1	9.6 Meg
	R_2	1. Meg
	R_3	.96 K
	R_4	.900K
	R_5	8.8K
	TOTAL	10.7057 Meg
2	A TO B	11 Meg
3	R_4 AND R_5 SHORTED	11 Meg
4	R_4 = 22K	

Fig. 19-2. Record your readings for Experiment 19 here.

9.6 Meg
1.
.096
.0009
.0088
10.7053

Measure the value of each resistor in the divider, and record the resistance in ohms in the spaces provided in Fig. 19-2 for Step 1. Now add up the values of all five resistors and record this as the total resistance in the space provided.

Step 2: To measure the resistance between terminals A and B of the voltage divider.

Connect the ground clip to the end of the divider marked A in Fig. 19-1. Touch the probe to the end of the divider marked B, adjust the range switch to give a reasonable indication, and record the value in Fig. 19-2. Your reading should be approximately the same as the sum of your individual resistance measurements.

Step 3: To show the effect on the total resistance of shorting a relatively small resistance.

To simulate a short across resistors R_4 and R_5, solder a short piece of wire from point C to point B. Connect the ground clip to point A, and the probe to point B. Record your reading in the space provided in Fig. 19-2. The value should be almost the same as that obtained in Step 2, showing that the two resistors could be completely shorted without materially affecting the ohmmeter measurements.

Step 4: To show that an increase in a relatively small resistor in a circuit will have no noticeable effect on the total resistance of the circuit.

Remove the 1K-ohm resistor, R_4, from the circuit, and replace it with the 22K-ohm resistor. A change in resistance value from 1000 ohms to 22,000 ohms is perfectly apparent, if you check the individual resistors. Let us see how it affects the total resistance. Check the resistance from A to B, and record your result in Fig. 19-2.

Step 5: To show how lack of continuity is indicated in a resistance circuit.

Remove the 22K-ohm resistor, and in its place substitute the dummy resistor you made in an earlier experiment, between R_3 and R_5. Now measure the resistance between A and B. You will find that the circuit is either open, indicated by no movement of the meter needle from the open position at the extreme right, or that the resistance is extremely high. You might read a value such as 1K, which would mean 1000 megohms. This would be through the resistance of the insulation around the wires of the dummy resistor where they are wrapped together. A value of 1000 megohms, however, would be interpreted as an open in a circuit with an original total resistance of approximately 11 megohms.

Step 6: To find the open part in a circuit having no continuity.

To find the open in the voltage divider consisting of R_1, R_2, R_3, the dummy resistor, and R_5, connect the ground clip to point A. Now touch the probe to point B. Notice that there is no continuity. Move the probe to the junction of the dummy resistor and R_5. Again note that there is no continuity reading. Move the probe to point C, the junction of R_3 and R_4. Here there is continuity, showing that in making your measurements, you just passed over the defective part. You can check the part by connecting the ohmmeter test probes directly across it, proving that there is an open.

Discussion: In this experiment, you have seen that continuity can be checked with an ohmmeter. If the battery in the ohmmeter can force even an extremely small amount of current through the circuit, there will be an indication on the proper ohmmeter range. If there is no continuity, the meter needle will not move at all or will move only slightly, giving an extremely high resistance reading. By examining the diagram of the circuit whose continuity you wish to measure, you can, by adding the values of the resistors as marked on the diagram, determine what the approximate total resistance will be. This will show you what to expect and help you to choose an appropriate resistance range if you want to check the resistance. However, if you simply wish to check for continuity, you can use any range that gives a reasonable meter pointer movement.

You have seen that we can reduce the resistance of the divider in Fig. 19-1 by completely shorting out R_4 and R_5 without changing the measured total resistance.

Because of this fact, it is apparent that to check this condition of individual resistors in a circuit having a high resistance, you must connect the ohmmeter directly across each resistor in question. You have also seen that a radical increase in resistance of one of the low resistance parts will have no apparent effect on the total measured resistance. These are points to remember when troubleshooting electronic equipment. You make continu-measurements when you suspect a circuit is open. This does not show the value of the individual parts.

Instructions for Statement No. 19: In working with the voltage divider shown in Fig. 19-1, you saw that there was no change in the total resistance when resistors R_4 and R_5 were shorted. These, however, have a relatively low value. Now we will see what happens when R_3, R_4, and R_5 are shorted. First, remove the dummy resistor from the circuit, and reconnect the 1K-ohm resistor so that the circuit again is like that shown in Fig. 19-1. Recheck the resistance between A and B, and jot down your reading. Then, solder a piece of wire between point D and point B on the divider to simulate a short across R_3, R_4, and R_5. Again measure the resistance from A to B and note the reading. You now have sufficient information to answer the statement. Unsolder the resistors.

Statement No. 19: When measuring the divider resistance with R_3, R_4, and R_5 shorted, I found that this value was:

[✓ *(1) the same as*]
(2) noticeably more than
[✓ *(3) noticeably less than*]

the value measured between A and B with all of the resistors in the circuit.

EXPERIMENT 20

Purpose: To show how to find the combined resistance of resistors connected in parallel; and to show that the resistance of one cannot be measured without being disconnected from the others.

Introductory Discussion: You already know that parts connected in parallel have a combined resistance less than that of the smallest resistor in the group. However, the serviceman may want to know what the exact combined resistance should be so he can measure the combined resistance and decide if the parts are in good condition.

In Experiment 18, you connected three 1K-ohm resistors in parallel to get a resistance of approximately 330 ohms. When the parallel-connected parts have the same resistance, it is easy to decide what the combined resistance should be. The rule is as follows: The combined resistance of equal parts in parallel is equal to the resistance of one of the resistors divided by the number of resistors in the group.

Thus, if we connect three 1K-ohm resistors in parallel, the combined resistance is 1000 divided by 3, or 333 ohms. Three 3.3K-ohm resistors in parallel have a resistance of 1000 ohms; two 22K-ohm resistors in parallel have a combined resistance of 11,000 ohms.

Parallel-connected resistors are not necessarily equal in value. The combined resistance, R, can be found by using the formula,

$$R = \frac{R_1 \times R_2}{R_1 + R_2}$$

For example, if we have a 1K-ohm resistor and a 3.3K-ohm resistor in parallel,

$$R = \frac{1000 \times 3300}{1000 + 3300}$$

$$= \frac{3{,}300{,}000}{4300}$$

$$= 769 \text{ ohms}$$

It is not important for you to be able to do these computations, because as a busy technician you won't waste time on them. Instead, if you cannot tell the combined resistance at a glance, you will unsolder one end of each one of the resistors and check the resistors individually. If you have the time to spare, and find the computations easy to do, then you do not need to go to the trouble of unsoldering a component to find out whether or not the combined resistance is correct.

When resistors do not have any shunting (parallel connected) parts, the resistance value is checked without unsoldering the leads, by connecting the test probes directly across the resistor.

In this experiment you will connect resistors in parallel and check their measured combined resistance against their computed resistance to prove that the computed value is correct and to note the variations to be expected between the computed and measured values.

Experimental Procedure: In this experiment you will need your tvom and the following parts:

1 1K-ohm resistor
1 3.3K-ohm resistor
1 10K-ohm resistor
2 22K-ohm resistors
1 100K-ohm resistor
1 10-megohm resistor

In connecting the parts in parallel, it is not necessary to use your soldering iron. Hold the two resistors so two of their leads cross as shown in Fig. 20-1. Clip the ground lead directly to the point where the leads cross each other. Bend the free leads together and clip the probe to them.

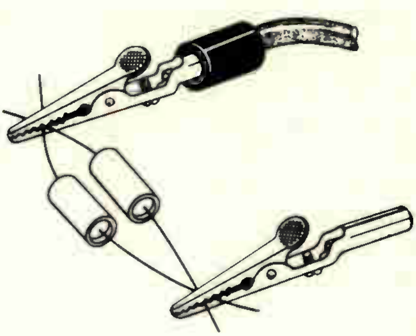

Fig. 20-1. How to measure two resistors in parallel.

You can then adjust the range selector switch for a reasonable reading.

Step 1: To find the combined resistance of a 1K-ohm and a 3.3K-ohm resistor in parallel.

As we have already shown, the computed resistance of a 1K-ohm and a 3.3K-ohm resistor in parallel is 769 ohms. To measure the combined resistance, connect the 1K-ohm and the 3.3K-ohm resistors in parallel. Clip one lead of your tvom to one end, and the other lead to the other end of the combination as shown in Fig. 20-1. Record the reading in the space in Fig. 20-2.

PARALLEL COMBINATION	COMPUTED VALUE	MEASURED VALUE
1K AND 3.3K	769 OHMS	
1K AND 10K	909 OHMS	780
10K AND 22K	6875 OHMS	6.9K
10MEG AND 100K	99K OHMS	97K
22K AND 22K	11K OHMS	11.5K

Fig. 20-2. Record your readings for Experiment 20 here.

Step 2: To find the combined resistance of a 1K-ohm and a 10K-ohm resistor in parallel.

Again we can compute the resistance of the combination from the formula:

$$R = \frac{R_1 \times R_2}{R_1 + R_2}$$

Substituting the values of the resistors, we have:

$$R = \frac{1000 \times 10{,}000}{1000 + 10{,}000} = 909 \text{ ohms}$$

Now let us measure the resistance of the combination. Clip the ground lead to one lead of each resistor, and the probe to the other end of each resistor. The correct way to do this is shown in Fig. 20-1. Record the reading in Fig. 20-2.

Step 3: To find the combined resistance of other parallel combinations of resistors.

Following the same procedure, measure the combined resistance of the other parallel combinations listed in Fig. 20-2. In each case, the computed value is given so that you can check your measured value with it.

Discussion: Now compare your measured values with the computed values given in the chart. They should be fairly close in most cases. However, because of the tolerances of the resistors, you may find that they differ quite a bit in some cases.

When two resistors are in parallel, and one is much larger than the other, the resistance of the larger cannot be checked unless it is disconnected. For example, when you measured the 10-megohm and the 100K-ohm resistors in parallel, their combined resistance should have been close to 100,000 ohms, the resistance of the smaller resistor. Even with the 10-megohm resistor completely removed, the resistance would still be close to the parallel value.

When there is only a slight difference in the values of the parallel resistors, if one is disconnected or is defective, there will be considerable change in measured value across the combination.

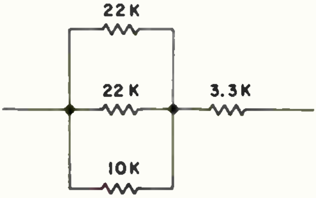

Fig. 20-3. Series-parallel circuit for Statement No. 20.

Instructions for Statement No. 20: To answer this statement, you are to build the series-parallel circuit shown in Fig. 20-3. You do not need to solder the resistor leads. Twisting them together is enough. Twist one end of a 10K-ohm resistor and two 22K-ohm resistors together. Twist the other ends and one end of a 3.3K-ohm resistor together as shown in Fig. 20-4.

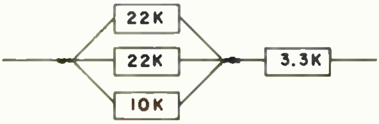

Fig. 20-4. How to arrange the parts for the circuit shown in Fig. 20-3.

Before you measure the combined resistance, examine the circuit carefully and see if you can decide in advance what the total resistance will be. As a matter of interest to yourself, jot down what you think it is on a separate sheet of paper. Now, connect the ground clip to one lead of the circuit and the probe to the other. Choose an appropriate range on your ohmmeter, and read the resistance value. Compare this with the value you chose by inspecting the circuit. You now have enough information to answer the statement. Separate the resistors.

Statement No. 20: When I measured the resistance of the circuit shown in Fig. 20-4, I found that the resistance was:

(1) *approximately 5500 ohms.*
[✓ (2)] *approximately 8500 ohms.*
(3) *approximately 13,000 ohms.*

LOOKING AHEAD

This completes the experiments in Kit 2T. When you have completed the second kit, remove the resistors and the potentiometer and clean the terminals. Leave the terminal strips, solder lugs, and battery connected. Make sure you have answered all the statements on the Report Sheet, fill in the top of the Report Sheet, and mail it to NRI for grading. While waiting for your graded answers to return, place your tvom in a safe place where it will not be damaged. Place all the left-over parts, listed in Table I, in a box and store them where they will not be lost. You can leave the two flashlight cells, the potentiometer and the terminal strips on the chassis plate. You may also leave the wires to the flashlight cells in place. Be sure to clean all excess solder from all of

1	Chassis plate

1	470,000-ohm resistor
1	1-megohm resistor
2	10-megohm resistors
2	1/4" X 4-40 machine screws
2	Silicon diodes
	Hookup wire
	Solder

Table I. Left-over parts to be stored for use later.

the terminals. The following parts are attached to the chassis plate:

2	Flashlight cells
1	3-lug terminal strip
1	4-lug terminal strip
1	7-lug terminal strip
1	Small solder lug
6	1/4" X 6-32 machine screws
6	6-32 hex nuts
1	Potentiometer mounting bracket
1	500K-ohm pot. with switch

While you are waiting to start on the next kit, clean the leads on the parts you have left over so you'll be ready to start your experiments when your graded answers are returned. Do not start the next kit until you have received a passing grade on the experiments in Kit 2.

In the next kit you will add parts to the circuit board of your tvom so you can measure ac. You will begin your study of ac circuits and see that many of the laws that you have verified for dc circuits can also be applied to ac circuits. You will also see how capacitors and coils act in ac circuits. Both audio signals and radio frequency signals are ac signals. Your next kit will be a big step forward for you. The experiments are designed to show how ac signals behave. The fundamentals you will study in Kit 3 will be used in later kits in your study of more complex circuits using vacuum tubes and transistors.

HEADING TOWARD SUCCESS

You have every reason to expect real success in your Electronics career. I base this statement on the following facts:

. . . you like Electronics and have much natural ability in this science.

. . . you are willing to work to increase your knowledge of Electronics, as proved by the progress you have made with your NRI course.

The above qualifications make for success, in the opinion of most experts. As Mark Sullivan once put it: "To find a career to which you are adapted by nature, and then to work hard at it, is about as near a formula for success and happiness as the world provides."

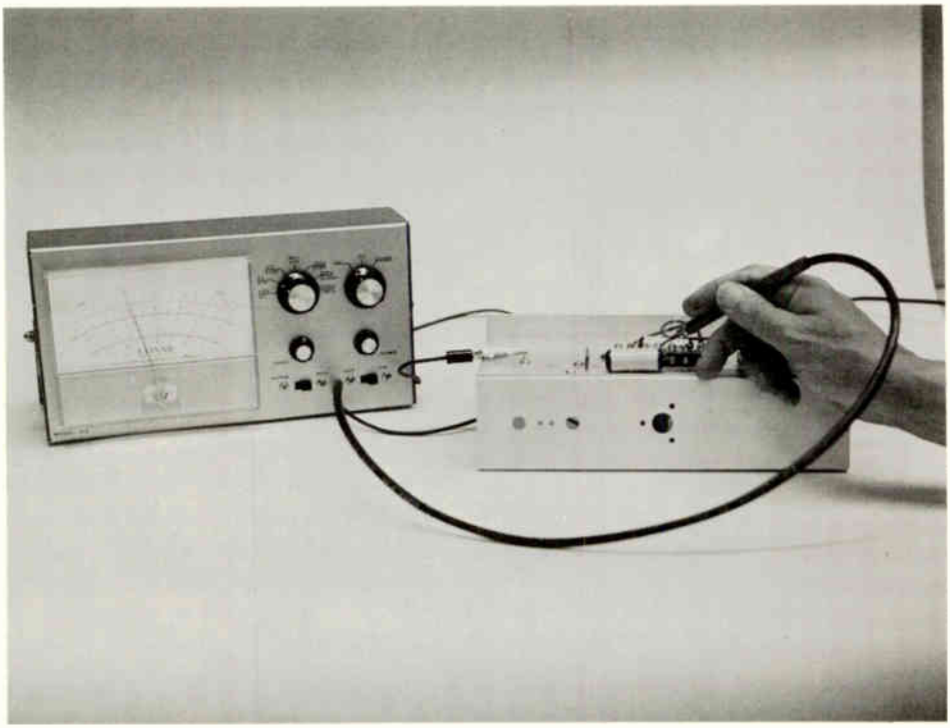
NATIONAL RADIO INSTITUTE • WASHINGTON, D. C.

TRAINING KIT MANUAL 3T

PRACTICAL DEMONSTRATIONS OF BASIC ELECTRONICS



The completed tvom being used to make ac measurements.

INDEX OF SECTIONS

JP2M1075 1975 EDITION Litho in U.S.A.

INSTRUCTIONS FOR PERFORMING EXPERIMENTS 21 THROUGH 30

Now that you have experimentally proved Ohm's Law, Kirchhoff's Voltage Law, and Kirchhoff's Current Law for dc circuits, you are ready to prove that the laws also hold for ac circuits. It is extremely important for you to become thoroughly familiar with ac circuits, because they are the ones through which all radio and television signals pass. These experiments, in which you will see for yourself how ac circuits work, are a very valuable part of your training.

To perform these experiments, you will have to measure ac voltages with your tvom. As you already know, your tvom is capable of measuring dc and resistance. You demonstrated this in the previous experiments. In the experiments you are about to perform, most of the measurements to be made are ac measurements.

You have probably been wondering why one of the test leads is very much heavier than the other. It is a special type of low capacity cable known as coaxial cable. It is so designed that a very low capacitance exists between the center conductor and the outer shield braid, which is covered by an insulated coating. With this low capacitance cable, it is possible to measure ac voltages with frequencies up to several thousand kilohertz. The outer braid shield is necessary when using your tvom on the low ac ranges to prevent stray capacitive pick-up.

CONTENTS OF THIS KIT

The parts included in this kit are illustrated in Figs. 1 and 2, and listed in the captions. Check the parts you received against this list to be sure that you have all of them.

If any part of this kit is obviously defective or is damaged in shipment, return it to NRI immediately for replacement, as directed on the packing slip accompanying this kit.

Gather the parts left over from the previous kits and put them in some convenient place. You will need them in your experiments.

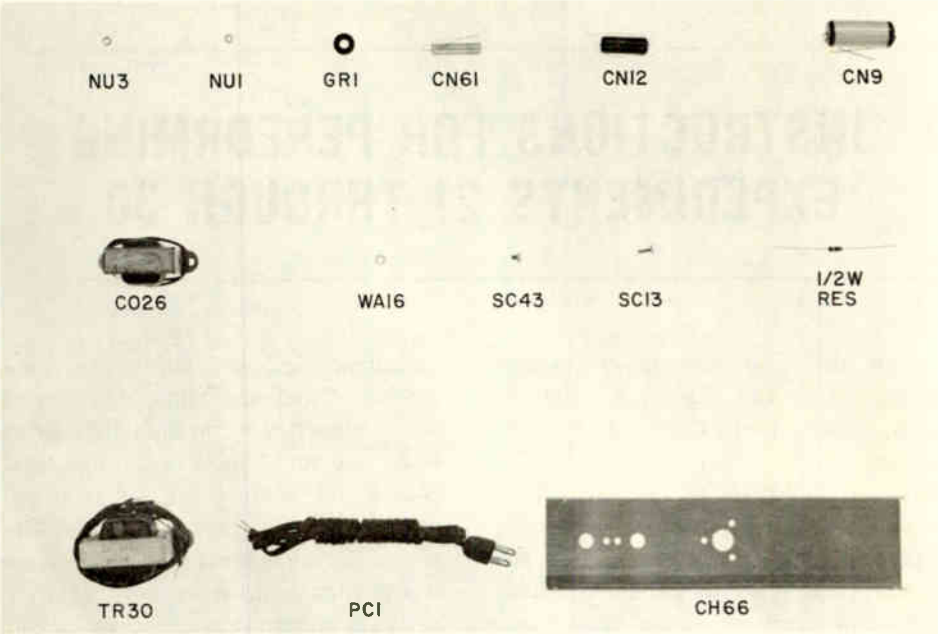


Fig. 1. The experimental parts for this training kit are shown above and listed below.

Quan.	Part No.	Description	Price Each
1	CH66	Chassis rail	.79
2	CN9	.25 mfd tubular cap.	.25
1	CN12	.1 mfd tubular cap.	.18
2	CN61	20 mfd, 150V elect. cap.	.65
1	CO26	Iron core choke coil	1.30
2	GR1	3/8" grommet	12/.25
1	NU1	6-32 hex nut	12/.15
4	NU3	8-32 hex nut	12/.15

Quan.	Part No.	Description	Price Each
1	PC1	Power cord	.40
1	RE27	220-ohm, 1/2W res.	.15
1	RE35	47K-ohm, 1/2W res.	.15
1	RE93	1.8 megohm, 1/2W res.	.15
1	RE102	3K-ohm, 1/2W res., 5%	.24
2	SC13	3/8" X 6-32 screw	12/.15
4	SC43	1/4" X 8-32 screw	12/.25
1	TR30	Power transformer	2.50
4	WA16	No. 8 lockwasher	12/.15

All resistors are 1/2-watt, 10% tolerance unless otherwise specified.

Before you begin your experiments in this Training Kit you will install components on the etched circuit board of your tvom to enable you to read ac voltages. You will also calibrate the ac portion of your tvom, recheck the dc calibration, and install the tvom in its cabinet.

ADDING THE AC FUNCTION TO YOUR TVOM

The parts needed to add the ac function to your tvom are shown in Fig. 2 and listed under the figure. Gather together those parts shown in Fig. 2.

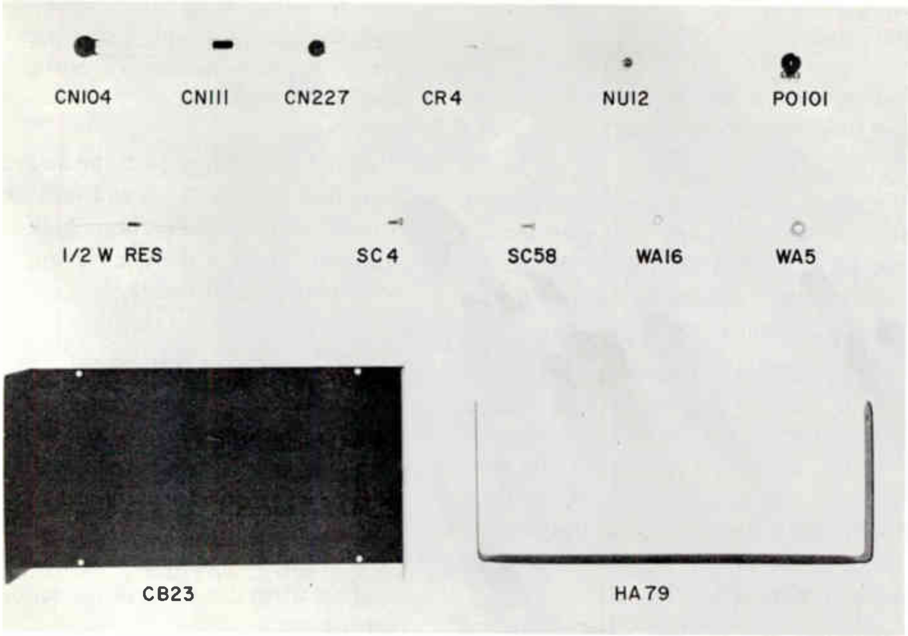

Fig. 2. The ac parts for your tvom are shown above and listed below.

Quan.	Part No.	Description	Price Each
1	CB23	Cabinet	2.95
1	CN104	.1 mfd disc cap.	.36
2	CN111	5 mfd elect. cap.	.35
1	CN227	120 pf disc cap.	.15
4	CR4	1N60 diode	.45
1	HA79	Handle	2.18
2	NU12	8-32 cap nut	12/.25
1	PO101	100K-ohm trimmer pot.	.23

Quan.	Part No.	Description	Price Each
1	RE39	1 megohm, 1/2W res.	.15
1	RE48	2.7K-ohm, 1/2W res.	.15
2	SC4	3/8" X 8-32 screw	12/.15
4	SC58	3/8" X 6-32 thread cutting screw	12/.25
2	WA5	No. 8 flat metal washer	12/.15
2	WA16	No. 8 lockwasher	12/.15

All resistors are 1/2 watt, 10% tolerance unless otherwise specified.

To add the parts to the circuit board, you must first remove the circuit board from its installation behind the panel. First, make sure the meter is "off," then remove the 9V battery and the battery connector . . . . ( )

Remove the two bar knobs from the Range and Function switches and the two round knobs from the Zero and Ohms Adjust controls . . . . ( )

Loosen the two nuts which secure the circuit board to the meter terminals. Be careful not to damage Q_1 and Q_2 . . . ( )

Remove the two nuts that secure the

Range switch and Function switches to the panel . . . . (✓)

Remove the two meter terminal nuts and the two washers . . . . (✓)

The etched circuit board is now free of the panel and may be carefully pulled to the rear of the panel. You may remove the 1.5V "C" cell from its holder to give a little more working room. You do ***not*** have to disconnect any of the wires (✓)

The assembly instructions are given in Fig. 3. The four glass diodes have colored bands at the cathode end and ***must*** be installed as shown in Fig. 3. Be very careful when you bend the diode leads not to bend them too close to the body of the diode or you may break the glass seal and ruin the diode.

Also, be sure to observe the polarity of the two electrolytic capacitors, as you did in the last kit.

When you are sure you know how to mount all the parts, proceed with the assembly instructions in Fig. 3.

After completing the assembly, reinstall the circuit board to the panel and meter. Replace the battery, battery connector and the knobs . . . . (✓)

Before proceeding with the ac calibration, turn the meter on and recheck the Balance and DC calibration. Follow the procedure given in the last training kit to perform these adjustments . . . . (✓)

AC CALIBRATION

After you have checked the dc calibration and balance, you will calibrate the ac portion of the tvom. You will use the voltage at your wall outlet to calibrate your tvom, so you must exercise extreme caution when carrying out the calibration procedures.

Commercial ac voltage, while nominally 117 volts, varies from one part of the country to another, and, indeed, from hour to hour at any given location. These variations are due to the varying demand

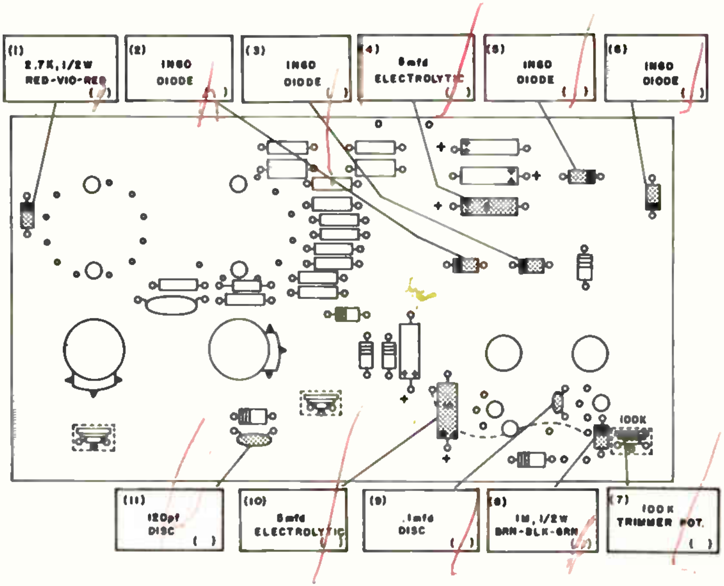

Fig. 3. Steps used for assembling your tvom.

on the power company generators. During high usage times the voltage may drop as low as 95 volts and at other times may rise to 125 volts. The high usage times are around mealtimes (morning, midday, and 6-7 p.m.) and during hot, humid days when many air conditioners are in use. It would be best to perform your calibration at some time ***other*** than these high usage times.

For purposes of calibrating your tvom you can assume the line voltage to be 120 volts and use this value as your calibration reference. To calibrate your tvom, place the meter face up so that you have access to the AC Calibrate trimmer potentiometer through the hole labeled "AC." Set the Range switch to "1200V", the Function switch to "AC", the Polarity switch to "Norm." and turn the meter "ON". Short the probe tip to the ground clip and zero the meter with the Zero adjust control.

With a thin bladed screwdriver, turn the AC Calibrate control fully clockwise (to the right). Now touch the ground clip to the screw head which holds the cover of a wall outlet in place, and insert the probe tip into one of the openings of the ac outlet. If you get no reading at all on your meter, try the probe in the other opening of the ac outlet. When you have found the "hot" opening, remove the probe and ground clip and switch the meter to the "300V" range. You can loosen the screw holding the cover of the ac outlet slightly so that you can clip the ground clip in place without having to hold it. With the ground clip in place, insert the probe tip into the "hot" ac opening and watch the meter. The pointer should move upscale. Adjust the AC Calibrate control until the meter reads 120 volts. (This is the second division after "10" on the 0 to 30 range.)

Remove the probe from the ac outlet and switch to the 120V range. Again insert the probe into the "hot" opening and adjust the AC Calibrate control for exactly full scale.

ASSEMBLING THE CABINET AND HANDLE

To assemble the handle to the cabinet, first place a No. 8 lockwasher over one of the 3/8" X 8–32 screws. Pass the screw through one of the holes in the center of one end of the cabinet from the ***inside*** to the ***outside***. While holding the screw head and lockwasher against the inside of the cabinet, place a No. 8 flat metal washer over the screw, then position the handle so that the screw can also pass through one of the holes in the handle. Secure this assembly temporarily with one of the cap nuts. Tighten only finger-tight for now.

Following exactly the same procedure just described, secure the other end of the handle to the cabinet with a 3/8" X 8–32 screw, No. 8 lockwasher, No. 8 flat washer and a cap nut.

With both ends of the handle fastened, tighten both screws as much as possible. This will secure the handle and yet allow you to move it around to serve as a stand for the completed tvom.

To fasten the cabinet and tvom together, lay the tvom face down on a clean, soft surface such as a tablecloth or bedspread. Put the cabinet into place, being sure that the four small holes in the back of the tvom panel line up with the holes in the cabinet. Now fasten the cabinet to the tvom with the four 3/8" X 6-32 thread-cutting screws. **DO NOT OVERTIGHTEN THESE SCREWS**. The tvom panel is aluminum, and if you overtighten the screws they will probably pull out of the aluminum.

Performing The Experiments

The experiments you are to do will demonstrate many of the basic facts you should know about resistance, inductance, and capacitance, and their effect in ac circuits. Do not skip any of the experiments; each of them is vitally important to your training. Follow the same procedure for carrying them out that you used in the previous manuals.

(1) Check the condition of the tip of your soldering iron. Clean it or retin it, if necessary.

(2) Read the experiment through completely, paying particular attention to the Introductory Discussion and the Experimental Procedure to get an idea of what is to be accomplished.

(3) At the beginning of each section describing the procedure to be followed, we will give you a list of the parts you will need. We will not, however, list the tools, solder, or hookup wire you will need. Just remember to keep them handy and to have your soldering iron ready.

We will not give the color code of the various resistors you will need. By this time you should be familiar enough with the resistor color code to select the correct ones. Gather the parts listed at the start of each experimental procedure from the parts you received in this kit and those left over from earlier kits.

(4) With the parts at hand, and with your soldering iron hot and ready for use, read the experiment again, this time carrying out the instructions exactly as given and in the order listed. Record all data in the tables provided, make the necessary computations, and prepare any graphs that are required.

(5) Read the Discussion of the experiment. If your experimental results don't seem to be right, repeat the experiment.

IMPORTANT: If you cannot do an experiment successfully, don't just give up and go on to the next one. Reread the experiment carefully to be sure you are performing it correctly. Look for loose solder joints, incorrect connections, or wrong parts. If you cannot find the trouble, write to us on the special consultation blank you received with this kit.

Give an accurate and complete description of the action that takes place and include the results of any measurements you have made that have a direct bearing on the problem. Be sure to tell us exactly which experiment you are working on and the step or steps in the experiment that you can't carry out successfully so that we can help you as quickly as possible.

(6) Read the instructions for each Statement carefully. Carry out any experimental procedures required. Read the Statement carefully, and put a circle around the choice that best completes the Statement according to your findings. Then, on the Report Sheet, write the statement number and your choice(s) for the Statement. When you have finished all the Statements, fill in the rest of the spaces as instructed on the Report Sheet, and send in the Report Sheet to NRI for grading.

At this point, you should have a solder lug, three terminal strips, a 500K-ohm potentiometer with on-off switch, and two series-connected flashlight cells mounted on your chassis (Fig. 4).

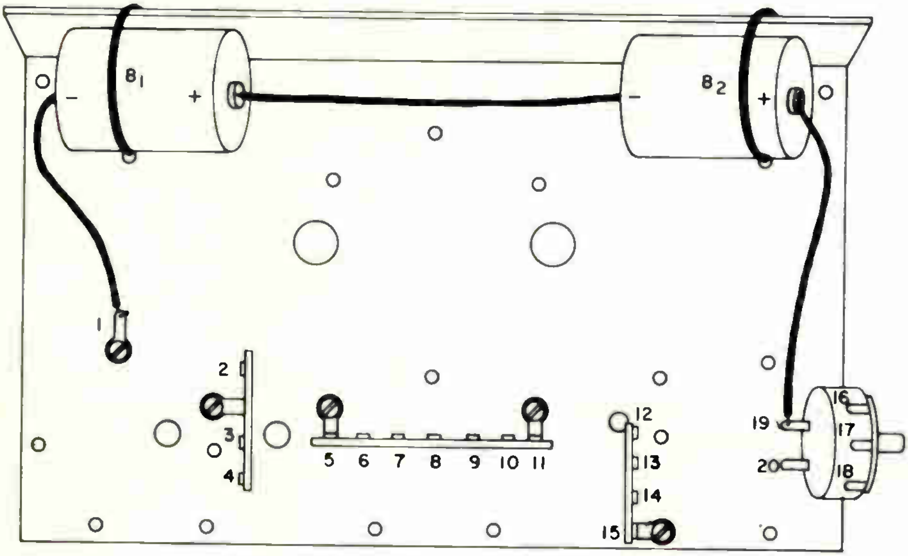

Fig. 4. Chassis before Experiment 21.

EXPERIMENT 21

Purpose: To show that the period of time required to charge or discharge a capacitor through a resistance depends upon the values of the resistance and the capacitance.

Introductory Discussion: As you learned in your regular lessons, a momentary surge of current takes place when the terminals of a charged capacitor are connected together. The period of time that this current flows is usually too brief to have any practical value, except when high currents over short periods of time are required, as in some forms of electric welding. However, if the rate of charge and discharge can be controlled, the practical applications are almost unlimited. The operation of the sweep circuits that move the electron beam in the picture tube of a TV receiver is a practical example of the charging and discharging of a capacitor.

In this experiment, we will show that the rate at which a capacitor charges or discharges depends upon the amount of resistance in the circuit as well as on the capacitance. Thus, with any given capacitor value, we can control the rate of charge and discharge by changing the resistance in the circuit. The time in seconds required for a capacitor to charge up to 63% of the applied voltage, or discharge to 37% of the applied voltage, is equal to the product of the resistance in megohms and the capacitance in microfarads. This is known as the "time-constant" of the combination.

In this experiment, you will show the effect on the time-constant of changing the resistance in the circuit.

Experimental Procedure: To perform this experiment, in addition to your experimental chassis and your tvom, you will need the following parts.

2 .25-mfd paper capacitors
1 1.8-megohm resistor

Step 1. To charge a .5-mfd capacitor through a 12-megohm resistance.

The circuit we will use is shown in Fig. 21-1. The 12-megohm resistance is the internal resistance of your tvom. For the 3-volt source, you will use the series-connected flashlight cells.

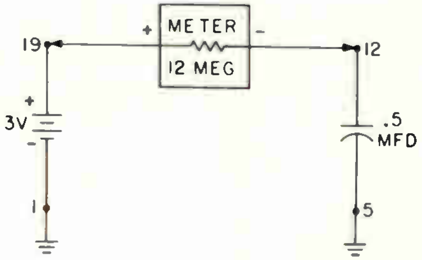

Fig. 21-1. Charging a capacitor through a resistance.

To get the .5-mfd capacitance, we will use two .25-mfd capacitors. As you have learned in your regular lessons, when two capacitors are connected in parallel, the total capacitance is the sum of the capacitance of the individual capacitors. Therefore, two .25-mfd capacitors in parallel will give us .5 mfd.

First, connect the two .25-mfd capacitors in parallel from terminal 5 to terminal 12, as shown in Fig. 21-2. Solder both connections.

Arrange the capacitors so their leads do not touch the chassis. Then short-circuit their leads for a few moments with a screwdriver to be sure they are fully

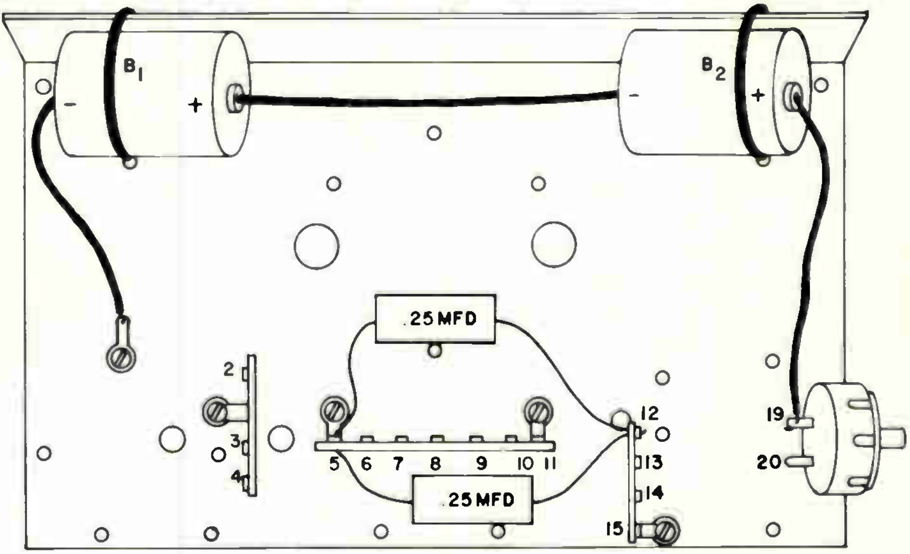

Fig. 21-2. Record results for Experiment 21 here.

discharged. Touch the screwdriver blade to terminal 12 and the chassis at the same time. Do not touch the capacitor leads while doing this experiment or the resistance of your body will affect your reading.

Now, be sure you still have the flashlight cells connected in series with the negative terminal grounded to terminal 1, and the positive lead connected to terminal 19 of the ON-OFF switch, as shown in Fig. 21-2. The battery connects to the capacitor leads at terminal 5 through the chassis ground.

Turn your tvom on to dc; turn the range switch to 3V, and set the polarity switch to normal. Then clip the ground lead to terminal 12, and touch the probe to the positive battery terminal (or terminal 19), and watch the meter pointer.

The meter pointer will move rapidly to the extreme right-hand end of the 3V scale, and then move gradually back toward 0.

To find the time-constant, you will count the number of seconds it takes for the capacitor to reach 63% (approximately two-thirds) of full charge. Since the full voltage is 3 volts, two-thirds will be 2 volts.

Here, the meter is actually indicating the voltage across the 12-megohm input resistance of the tvom. As you have learned, the sum of the voltage drops in a series circuit is equal to the source voltage. Therefore, when you first connect the circuit, the voltage across the resistance of the tvom will be the full 3 volts, making the meter pointer swing all the way over to the right. Then, as the capacitor charges, the voltage across the resistance gradually decreases. When the voltage across the resistance is 1 volt, you know there must be 2 volts across the capacitor, so you count the number of seconds it takes for the meter pointer to move from 3 to 1 on the 3-volt scale.

STEP	MEASUREMENT	YOUR TIME IN SECONDS	COMPUTED TIME IN SECONDS
1	CHARGING .5 MFD THROUGH 12 MEGOHMS	6	6
2	DISCHARGING .5 MFD THROUGH 12 MEGOHMS	5	6
3	CHARGING .5 MFD THROUGH 1.5 MEGOHMS	1	.75
4	DISCHARGING .5 MFD THROUGH 1.5 MEGOHMS	1	.75

Fig. 21-3. Record results of Experiment 21 here.

You can estimate the time in seconds by counting at a normal speaking rate as follows: "one hundred and one," "one hundred and two," etc. The length of time it takes to speak the words will be very close to one second. If you practice counting while watching the second hand of a watch or clock, you can do this very accurately. Record in Fig. 21-3 the number of seconds it takes the meter pointer to move from 3 to 1.

We can compute the time-constant mathematically by multiplying the resistance in megohms by the capacitance in microfarads. This would be 12 X .5, or 6 seconds. Compare the time you estimated with this computed time.

Step 2. To discharge the .5-mfd capacitance through the 12-megohm resistance.

Leave the circuit as it was in Step 1, and hold the meter probe on terminal 19 until the meter pointer swings all

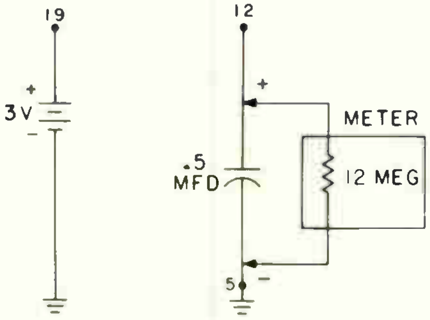

Fig. 21-4. Measuring the voltage across the capacitors as they discharge through the meter resistance.

the way to zero. At that point the capacitors will be fully charged.

Remove the probe from terminal 19. Switch the polarity switch on your tvom to reverse and touch the probe to the chassis ground. You should have the circuit shown in Fig. 21-4.

With the meter connected this way, you are measuring the voltage across the capacitors. As they discharge, the meter pointer will move from 3 down to 0. You want to know how long it takes for the capacitors to discharge to 37% of full charge. This is approximately two-thirds, so you count the number of seconds it takes for the pointer to reach 1 on the 3-volt dc scale. Record your reading in Fig. 21-3.

Step 3. To charge the .5-mfd capacitance through a lower resistance.

We will use the circuit shown in Fig. 21-5, in which we have a 1.8-megohm resistor in parallel with the resistance of the meter. As you have learned, when two resistors are connected in parallel, the combined resistance is less than that of the smaller resistor. In this case, the total resistance will be approximately 1.5 megohms. (You can place an alligator clip on your tvom probe for convenience in making the measurements.)

Connect the positive tvom lead to terminal 20. Set the polarity switch to normal. Connect and solder the 1.8-megohm resistor from terminal 12 to terminal 20. (See Fig. 21-2.) Then, clip the negative test lead of your tvom to terminal 12.

Turn the switch on by rotating the 500K-ohm potentiometer shaft clockwise and watch the meter. As in Step 1, the meter pointer will swing over to 3, and then move back toward 0. This time notice that the meter pointer moves from 3 to 1 so rapidly that it is difficult to estimate the time.

To compute the time-constant, we multiply 1.5 megohms times .5 microfarad, which gives us .75, or less than one second for the time-constant. Estimate the time-constant of the combination you have, and record your result in Fig. 21-3.

Step 4. To discharge the .5-mfd capacitor through the 1.5-megohm resistance.

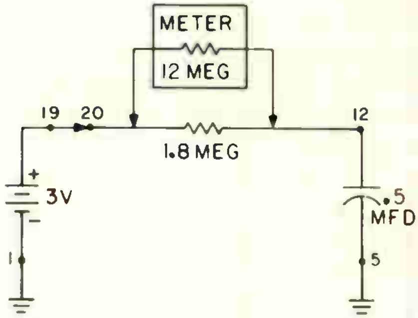

Fig. 21-5. Charging the capacitor through a lower resistance.

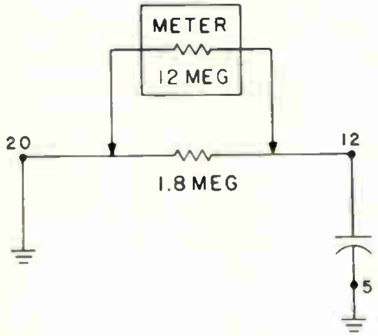

Fig. 21-6. Circuit for discharging the capacitor through a lower resistance.

With the circuit as in Fig. 21-5, leave the switch on until the capacitors are fully charged (until the meter pointer moves all the way to 0). Then, turn the switch off and set the polarity switch on your tvom to reverse. The circuit for this step is shown in Fig. 21-6. To see how long it takes the capacitors to discharge to one-third, short terminal 20 to the chassis with a screwdriver to complete the circuit shown in Fig. 21-6 and count the time it takes the pointer to move from 3 to 1. Again, record the time in Fig. 21-3. It should be the same as the time for Step 3 – less than one second.

Discussion: In Steps 1 and 2 of this experiment you saw that for a given capacitance and resistance in a circuit, the time it takes the capacitor to charge to 63% of full charge is the same as the time it takes it to discharge to 37% of full charge. This time, in seconds, is called the time-constant. It can be computed by multiplying the capacitance in microfarads and the resistance in megohms.

In Steps 3 and 4, you demonstrated that decreasing the resistance in the circuit caused the time-constant to decrease. If you had increased the resistance, the time-constant would have increased.

Instructions for Report Statement No. 21: In this experiment you showed that decreasing the resistance in the discharging circuit of a capacitor reduces the time-constant of the circuit. It can also be shown that decreasing the capacitance of the capacitor without changing the resistance reduces the time-constant.

For the Statement you will prove this by reducing the capacitance to .125 mfd by connecting the two .25-mfd capacitors in series. When two capacitors having the same value are connected in series, the combined capacitance is equal to half the capacitance of one alone.

Unsolder and lay aside the 1.8-megohm resistor and unsolder one end of one capacitor from terminal 5, but leave the other capacitor lead connected to terminal 12. Solder the free lead to terminal 20.

Set the polarity switch on your tvom to normal, and clip the negative test lead to terminal 5. Clip the probe of your meter to terminal 20. Turn the switch on to complete the circuit shown in Fig. 21-7. When the meter pointer goes all the way to 3, the capacitors are fully charged.

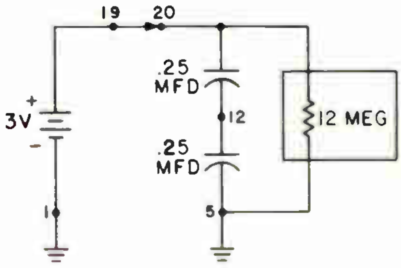

Fig. 21-7. Circuit for connecting capacitors in series.

Turn the switch off, but leave the probe clipped to the capacitor lead. Count the time it takes for the meter pointer to move from 3 down to 1. Then, answer the Statement below and on the Report Sheet.

Turn off the tvom, and unsolder and remove the capacitors from your chassis and store them for future use.

Statement No. 21: When I discharged the .125-mfd capacitance through the 12-megohm input resistance of the tvom, I estimated that the meter pointer dropped from 3 volts to 1 volt:

(1) instantly.
[✓ *(2) in about two seconds.*]
(3) in about ten seconds.

EXPERIMENT 22

Purpose: To show that when a dc voltage is applied to an electrolytic capacitor, the connections must be made with the proper polarity to prevent excessive leakage.

Introductory Discussion: As you learned in your lesson on capacitors, an electrolytic capacitor is quite different in many respects from paper or mica capacitors. One very important difference is that the dielectric in an electrolytic is a very thin film of aluminum oxide that has been formed on the anode by electrochemical action during manufacture. The insulating properties of this oxide depend on the amount of voltage used to form it initially, the amount of voltage applied to the capacitor in use, the temperature, the type of material used for the electrodes, and the kind of electrolyte used.

At best, the dielectric in an electrolytic capacitor is not a perfect insulator, so there will always be some current flow through the dielectric whenever voltage is applied to the capacitor. In a good capacitor, this current flow will be small if the voltage is applied with the proper polarity (the negative terminal of the voltage source connected to the negative terminal of the capacitor and the positive terminal of the source connected to the positive terminal of the capacitor). If the voltage is applied with the wrong polarity, the oxide film will break down. The unit will then cease to act as a capacitor and will instead act as a very low resistance. Pure ac voltage is constantly changing in polarity. Therefore, it should never be applied to an electrolytic capacitor.

The oxide film will also be destroyed if too high a voltage is applied to an electrolytic capacitor, even if the polarity of the voltage is correct. An electrolytic capacitor always has a dc working voltage rating that shows the maximum voltage that can be continuously applied to the capacitor without causing it to break down. Whenever you find it necessary to replace such a capacitor, make sure that the voltage rating of the replacement is at least as high as that of the original.

In this experiment, you will prove that an electrolytic capacitor passes direct current, and that the amount of current passed depends on the polarity of the applied voltage. Because the dc source voltage you have available is low, the current may be rather small when the voltage is applied with the correct polarity. In fact, the current may be too low to be detected with the equipment you have. The characteristics of your particular electrolytic will also affect the amount of current. Some capacitors have higher leakage currents than others, even though they are normal in all other respects. What we want you to observe in this experiment is that reversing the polarity of the source voltage changes the current through the capacitor.

Each of the electrolytic capacitors sent to you in this kit is made in dry form (that is, it contains a paste electrolyte). Its schematic symbol is the same as the symbol for any other capacitor except that it has a + sign near the positive lead.

Experimental Procedure: For this experiment, you will need your experimental chassis, tvom, and the following parts:

2 20-mfd electrolytic capacitors
1 47K-ohm resistor

Fig. 22-1. Schematic showing an electrolytic capacitor in series with a resistor and a battery.

Turn your tvom on; set the polarity, range and function switches to measure +3V dc.

It is desirable to make as many measurements as possible in any given experiment on the same range of your test instrument to avoid errors due to differences between ranges. For example, a dc source may produce exactly full-scale deflection on the 3V range, but a meter

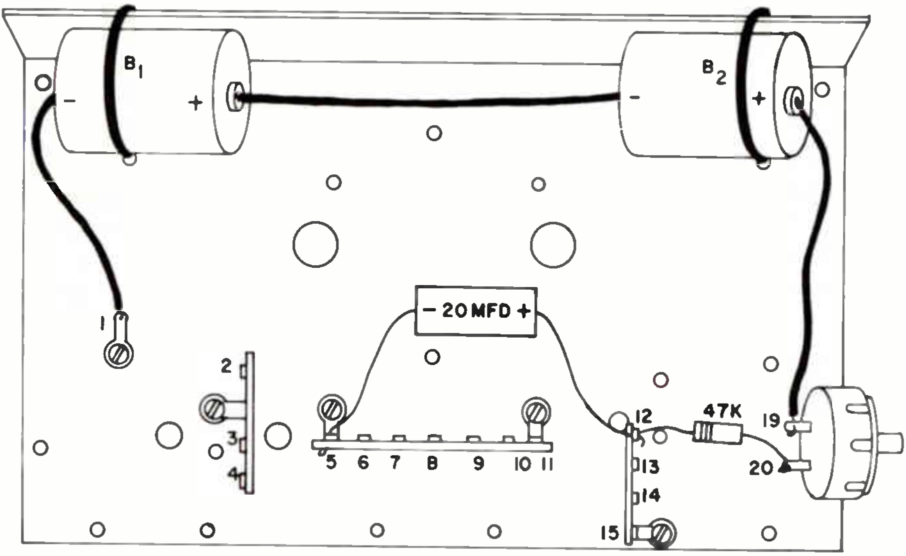

Fig. 22-2. Pictorial of the circuit in Fig. 22-1.

reading of 2.5 to 3.5 volts on the 12V range. Such variations are well within normal tolerances, and for ordinary purposes could be overlooked. However, they may prove troublesome when you are performing experiments that require accurate readings. Remember, the maximum tolerance of the meter movement alone is about 2 or 3 percent of the full-scale value. Also, the resistors in the voltage divider network of the tvom have a 1% tolerance, so a slight difference in reading on two ranges could occur even with everything normal. Using a single range whenever possible removes this cause of error.

The capacitor leads are identified by a + sign or by both + and – markings on the body of the capacitors. Solder the negative lead of one electrolytic capacitor lead to terminal 5. Connect the positive capacitor lead to terminal 12. Connect a 47K-ohm resistor from terminal 12 to terminal 20. Solder the connections.

The circuit for this step is shown in Fig. 22-1. The wiring is shown in the pictorial diagram in Fig. 22-2.

Step 1. To determine how much current flows through the electrolytic capacitor when it is connected with the correct polarity. To do this, you will measure the voltage drop across the 47K-ohm resistor.

Connect the probe of your tvom to terminal 20. Connect the ground clip to terminal 12. Turn the switch on and observe the meter. When the pointer becomes stationary, read the meter. Enter the voltage measured on the top line in Fig. 22-3. Turn off the switch.

Step 2. To determine how much current flows through the electrolytic capacitor when it is connected with the reverse polarity.

STEP	CIRCUIT USED	VOLTAGE
1	+ CAPACITOR LEAD TO + BATTERY TERMINAL	.8V ✓
2	+ CAPACITOR LEAD TO – BATTERY TERMINAL	1.3V

Fig. 22-3. Results of Experiment 22.

Reverse the capacitor connections by unsoldering and interchanging them, so that the positive lead of the capacitor goes to terminal 5 and the negative lead is connected to the 47K-ohm resistor at terminal 12.

Again, turn the switch on and measure the voltage drop across the 47K-ohm resistor. Leave the tvom connected to terminal 12 and to terminal 20 as in the previous step. Enter the voltage reading on the second line of Fig. 22-3. Turn the switch off to open the circuit.

Discussion: The voltage drop across the resistor is produced by the current flowing through the capacitor and the resistor. The amount of current can be found by dividing the measured voltage by 47,000. The current is very small.

Do not conclude from this experiment that the direct current passed by an electrolytic capacitor is negligible, however. Remember, you have a source voltage that is far less than the voltage that is usually applied to a capacitor in a practical circuit. With the normal circuit voltage applied to the capacitor, you could measure the current directly with a milliammeter, instead of using the indirect method you have followed here.

The amount of voltage drop across the resistor in Step 1 will vary with different capacitors. Some of the capacitors that we tried in the NRI laboratory had so little leakage that we were unable to measure any voltage drop at all across the resistor. Do not be concerned, therefore, if your voltage reading for Step 1 is 0.

You should, however, find a definite voltage drop across the resistor after you have reversed the capacitor connections to carry out Step 2. Here again the exact voltage depends on the characteristics of your capacitor, but the voltage should be greater than that measured in Step 1. This increase in voltage represents a corresponding increase in the current in the circuit; therefore, you have shown that the amount of current through the capacitor depends upon the polarity of the capacitor.

Because of this characteristic of electrolytic capacitors, be sure that you connect them with the proper polarity (positive terminal of the capacitor to positive terminal of the voltage source) when you install them in a circuit. Furthermore, you must not apply an ac voltage to an electrolytic capacitor unless the ac is superimposed on a larger dc voltage so that the total voltage applied to the capacitor never reverses itself.

Instructions for Statement No. 22: In the experiment for this Statement, you are to find out whether or not the capacitance of an electrolytic capacitor has any effect on the leakage current produced by connecting the capacitor with the wrong polarity.

Connect the two 20-mfd electrolytic capacitors in parallel. Solder the positive leads of both capacitors to terminal 5. Then, solder the negative capacitor leads to terminal 12. This puts the two capacitors in parallel, giving a capacitance of about 40 mfd. The circuit for this statement is shown in Fig. 22-4.

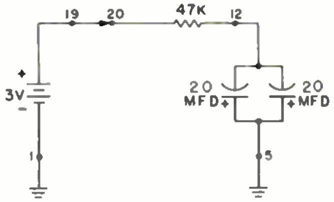

Fig. 22-4. The two capacitors are connected in parallel and placed in series with the resistor.

To measure the voltage drop across the 47K-ohm resistor, connect the probe of your tvom to terminal 20, and the ground clip to terminal 12. Turn the switch on and take a voltage reading. Compare this reading with the voltage for Step 2. 1.5V Choose the answer to the Statement below, and also on the Report Sheet that most nearly corresponds to the results of your comparison. Turn the switch off and disconnect the tvom leads.

Unsolder and remove the 47K-ohm resistor and the electrolytic capacitors. Leave the flashlight cells in place, but unsolder the positive lead from terminal 19.

Statement No. 22: When I connected the two capacitors in parallel, the leakage current (as indicated by the voltage drop across the resistor):

(1) remained unchanged.
[✓ *(2) increased.*]
(3) decreased.

Building An AC Voltage Divider

To do the rest of the experiments in this kit, you must have a source of ac voltage with some way of adjusting the output. You will use the 117 volts supplied by the ac power line and a transformer to produce about 12 volts across a potentiometer. By adjusting the potentiometer, you will be able to get the exact voltage needed for the experiments.

To build this assembly, you will need:

1	Power transformer (TR30)
1	Chassis rail (CH66)
1	1K-ohm potentiometer (PO7 from Kit 1)
2	3/8" rubber grommets (GR1)
2	1/4" X 8-32 screws (SC43)
2	3/8" X 6-32 screws (SC13)
2	8-32 hex nuts (NU3)
1	6-32 hex nut (NU1)
2	No. 8 lockwashers (WA16)
1	5' power cord (PC1)

The transformer and potentiometer will be mounted on the chassis. The transformer will be mounted in its permanent location on the underside of the chassis plate. Fig. 5 shows where to mount the parts. Fig. 11 of your IT Manual shows the hole locations. The power transformer is represented by the broken lines.

Install the rubber grommets in holes E and J, which are the large holes near the middle of your chassis plate. Squeeze one of the grommets into an oblong shape and push it into one of the holes so that the hole in the chassis fits into the groove in the grommet. Install the second grommet in the same manner.

Place the power transformer on your worktable with its mounting feet up. Push the two green leads and the green/yellow lead of the transformer through the grommet (shown in Fig. 5) in hole J

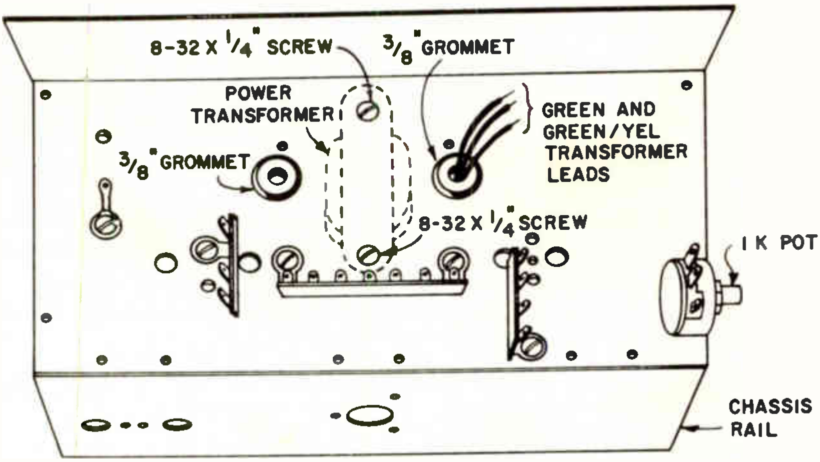

Fig. 5. Mounting the parts.

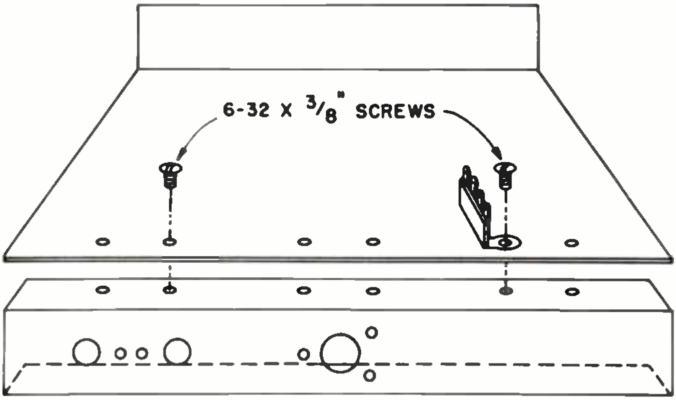

Fig. 6. Mounting the chassis rail.

from the underside of the chassis. Line up the mounting holes in the chassis, holes G and H, over the mounting feet in the transformer. Attach the transformer to the chassis with two 1/4" X 8-32 screws, two No. 8 lockwashers and two 8-32 hex nuts.

Remove the 500K-ohm potentiometer with On-Off switch and replace it with the 1K-ohm potentiometer (PO7).

Position the 1K-ohm potentiometer so that its terminals are pointing upward, and tighten the mounting nut.

Mount the chassis rail along the front edge of the chassis. Turn the rail so that the lip having six holes in it is up. These six holes mate with the six holes in the edge of the chassis, as shown in Fig. 6. Remove the screw holding the 4-lug terminal strip and replace it with the 3/8" X 6-32 screw. Pass the screw through the mounting foot in the terminal strip, the hole in the chassis and the mating hole in the chassis rail. Attach a nut and tighten.

Pass a 3/8" X 6-32 screw through the second hole from the left side of the chassis and the mating hole in the chassis rail. Attach a nut and tighten.

During the remainder of this kit, the chassis will be supported by the chassis rail and the power transformer.

WIRING THE AC CIRCUIT

Connect the power cord to the **BLACK** power transformer leads. Separate the two conductors at the end of the power cord. Connect each conductor to a black transformer lead. Solder both connections and wrap them with electrical tape.

Carefully wrap the bare ends of the two red and the red/yellow power transformer leads with tape. Do not connect these leads together. Coil them up near the chassis as these leads will not be used in this kit.

On the top of the chassis, make the following temporary connections which are shown in Fig. 7. Connect and solder one green power transformer lead to terminal 11. Connect the other green transformer lead to terminal 12. Connect and solder the green/yellow transformer lead to terminal 9.

Cut a 3" length of hookup wire and

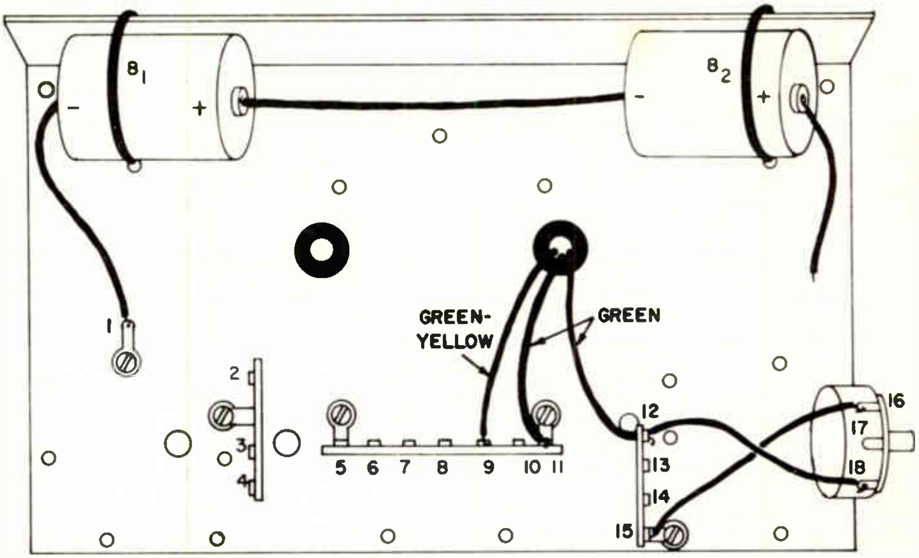

Fig. 7. Wiring the ac voltage divider.

remove 1/4" of insulation from each end. Using temporary connections, connect this wire from terminal 12 to terminal 18 on the 1K-ohm potentiometer.

Prepare a 4" length of hookup wire. Connect it from terminal 15 to terminal 16. Solder both connections. Check to see that your circuit is wired according to Fig. 7.

The schematic of the circuit you have wired is shown in Fig. 8.

Caution: It is extremely important that you perform all ac experiments on an insulated work surface. An ordinary wooden table, either bare or covered with linoleum or oilcloth, is ideal. A porcelain-top table is unsatisfactory, because the porcelain is applied over a metal base. For safety's sake, you should perform all experiments where you will not be able to touch any grounded object, such as a radiator, a water pipe, or a damp concrete basement floor. If you must carry out your experiments in the basement, be sure that you always stand on a dry board while working on the ac supply.

Be sure to disconnect the plug from the ac line before making changes in your circuit or before moving the meter lead clipped to a terminal or lead.

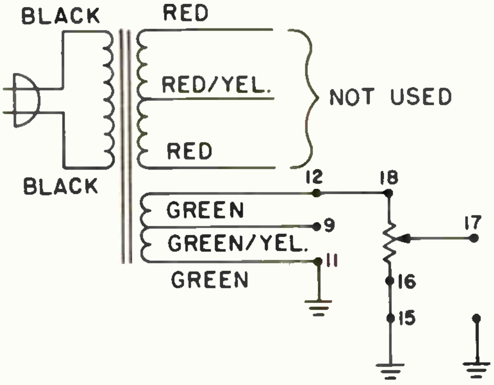

Fig. 8. Schematic diagram of the ac voltage divider circuit.

EXPERIMENT 23

Purpose: To show that a capacitor will block dc but will pass ac.

Introductory Discussion: A capacitor is a device for storing electrical energy. It cannot do this, however, unless the dielectric used to separate the plates has certain characteristics, the most important of which is that it must electrically insulate the plates from each other.

It might seem that insulating the plates so that there is no conductive path between them would block the flow of an electric current completely. However, as you have learned from your course, this is not true. Although a capacitor does block direct current, it passes ac in the circuit. You are going to demonstrate these capacitor actions experimentally.

To demonstrate the insulating properties of a capacitor with a solid dielectric, you will measure the current through the capacitor for each type of voltage. Your tvom will not measure current directly. You must determine the current in a circuit indirectly by measuring the voltage across a resistor in the circuit, and then dividing the measured voltage by the resistance across which you measured the voltage. The result will be the current in amperes. This is the same method you used to determine the current in the last experiment.

You learned that pure ac should not be applied to an electrolytic capacitor. The reversing ac voltage will either put a positive potential on the negative plate of the capacitor or a negative potential on the positive plate of the capacitor. When this wrong polarity is applied to the oxide film dielectric of an electrolytic capacitor, the dielectric breaks down, causing leakage between the capacitor plates. However, an electrolytic capacitor can be safely used to pass ac if we also apply a dc potential of the correct polarity to the capacitor. By doing this, we no longer have pure ac. Instead, we have dc with an ac component superimposed on the dc. The voltage across the capacitor plates does not reverse polarity and the dielectric does not break down.

To demonstrate a circuit condition having ac superimposed on dc, you will connect the 3-volt battery into a circuit with the electrolytic capacitor and measure the dc and ac voltages.

You will determine the peak-to-peak value of the ac voltage applied to the capacitor. Knowing the peak-to-peak amplitude of the ac waveform enables you to compare the ac component with the dc component. From your studies in the regular lessons, you know that the ac scales on your tvom indicate the effective or rms value of the ac waveform.

To refresh your memory, examine the ac waveform shown in Fig. 23-1A. It shows one cycle of an ac voltage having an effective value of 1 volt. Notice that the waveform rises to a peak value of 1.4 volts above zero on the positive half-cycle and to -1.4 volts on the negative half-cycle. The total height of the waveform from the negative peak to the positive peak is twice the peak value, or 2.8 volts peak-to-peak.

Now let's superimpose this ac waveform on a dc voltage as shown in Fig. 23-1B. The figure shows +2 volts dc with a 1 volt ac waveform varying above and below the 2 volt level. Notice that with 1 volt ac superimposed on 2 volts dc, the resultant voltage never goes to zero. When

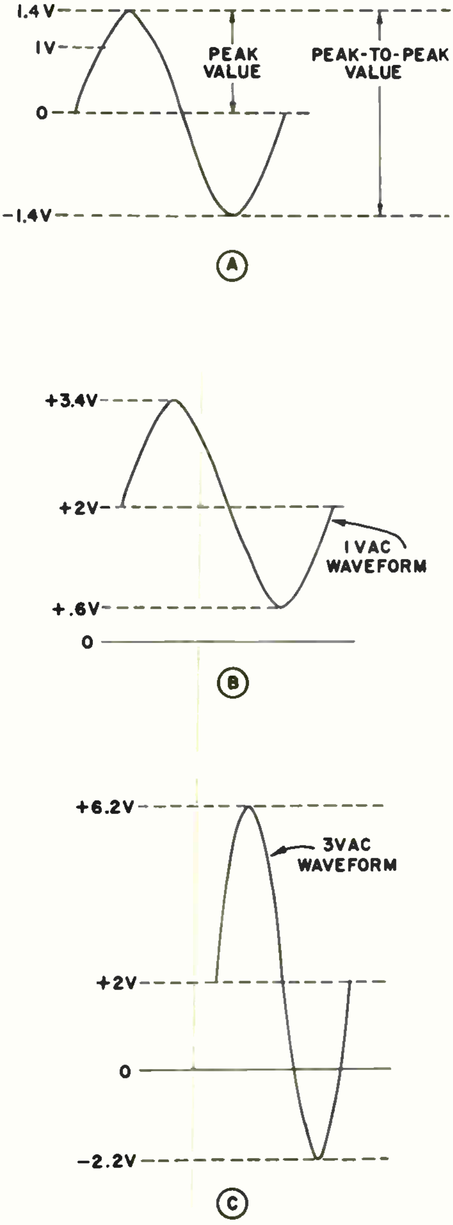

Fig. 23-1. Waveform of 1 volt (effective) with peak value and peak-to-peak value indicated (A); 1 volt ac superimposed on +2 volts dc (B); 3 volts ac superimposed on +2 volts dc (C).

the 1 volt ac waveform is zero, the resultant voltage is 2 volts, or the value of the dc voltage alone. When the ac waveform rises to a peak of 1.4 volts, the resultant voltage is 3.4 volts, or the su of the peak voltage plus the dc value. When the waveform falls to its lowest value, the resultant voltage is the difference between the peak value and the dc value, or 2 – 1.4 = 0.6 volt. From this you can see that the voltage never goes to a negative value.

A large ac waveform superimposed on a dc voltage can cause the voltage to reverse if the peak of the ac value is greater than the dc voltage. Fig. 23-1C shows a 3-volt ac waveform superimposed on +2 volts dc. Again the instantaneous values of the ac voltage combine with the dc voltage to produce the resultant voltage. The peak value (one-half the peak-to-peak value) of a 3-volt ac waveform is 4.2 volts. When the ac waveform reaches its maximum negative peak, the resultant voltage goes to a negative value, or -2.2 volts. Thus, the resultant voltage reverses its polarity for a small portion of the ac cycle.

From this discussion you can see that if we apply a dc potential of the proper polarity to the plates of the electrolytic capacitor we can prevent an ac voltage from reversing the polarity on the plates of the capacitor. Also you can see that we know what value of dc will be needed to prevent a given ac waveform from reversing the polarity on the capacitor plates.

In these experiments, we have placed resistors in the circuits where current values must be determined. However, in actual service work, if there is no suitable resistance in the circuit, one can be inserted. If you do this, you must be careful to choose a suitable value. Too low a resistance will not develop a measurable voltage when a small current flows through it, and too high a resistance will change the total impedance of the circuit enough to cause a significant decrease in the amount of current.

Experimental Procedure: For this experiment, you need your experimental chassis, your tvom, and:

1 18K-ohm resistor
1 .25-mfd capacitor
1 1K-ohm resistor
1 20-mfd electrolytic capacitor

Wire the circuit shown in Fig. 23-2. The chassis layout is shown in Fig. 23-3. Connect the 18K-ohm resistor from terminal 11 to terminal 14 and connect a .25 mfd capacitor from terminal 14 to terminal 13. Solder all three connections.

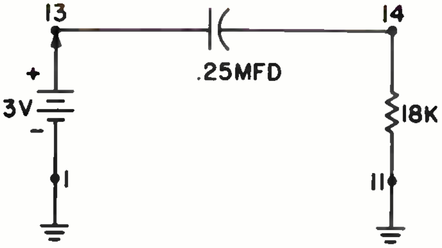

Fig. 23-2. Schematic of circuit used to measure current through the capacitor.

Step 1. To measure the dc voltage drop across the 18K-ohm resistor.

First set up your tvom for use as a dc voltmeter. Set the function switch to dc, the range switch to 3V and set the polarity switch to normal. Connect the

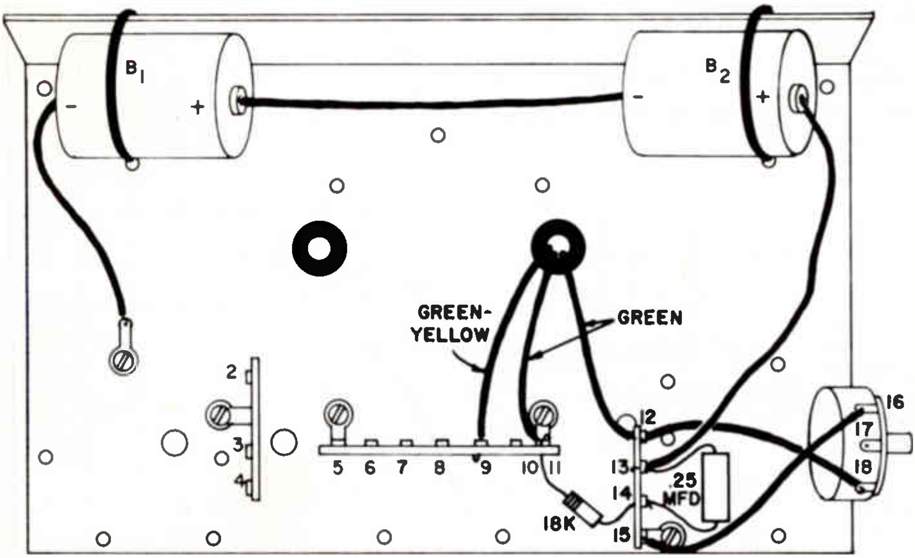

Fig. 23-3. Circuit wired for Step 1.

VOLTAGE ACROSS RESISTOR	
STEP 1 DC	0
STEP 3 AC	2.55V

Fig. 23-4. Results of Steps 1 and 3.

ground clip of your tvom to the chassis and clip the probe to terminal 14. Touch the positive battery lead to terminal 13 and read the voltage. The reading will depend upon the characteristics of your particular capacitor. Ideally, it should be zero, but an imperfect dielectric or leakage along the outside of the capacitor case may allow enough current through the circuit to give you some small reading. Record your reading on the top line of Fig. 23-4.

Remove the positive battery lead from terminal 13 and disconnect your tvom from terminal 14.

Step 2. To apply an ac voltage to the resistor-capacitor network that you used in Step 1.

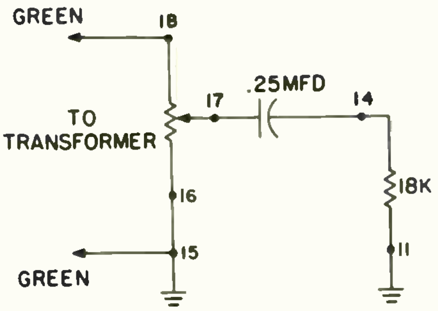

Fig. 23-5. Schematic of the circuit in Fig. 23-4.

Unsolder and disconnect the lead of the .25-mfd capacitor from terminal 13. Solder the capacitor lead to terminal 17, which is the center terminal of the 1K-ohm potentiometer.

Position the resistor and the capacitor so that their leads cannot touch any of the exposed terminals or the metal chassis. The circuit is shown in schematic form in Fig. 23-5.

Now, prepare your tvom for making ac measurements. Set the function switch to ac and the range switch to 12V. When measuring ac or dc voltages on this range, read the meter scale that is numbered from 0 to 12. The reading is given directly in volts.

Clip the ground lead of your tvom to the chassis. Plug the power cord from your experimental chassis into an ac receptacle.

Hold the probe by the insulated handle so as not to touch the metal tip. Touch the meter probe to the center terminal (terminal 17) of the potentiometer, and rotate the control shaft of the potentiometer with your fingers until the meter pointer indicates less than 3 volts. Now turn the range switch on the tvom to the 3V position, and carefully adjust the potentiometer to give you a reading of exactly 3 volts.

Your voltage divider will now have an output voltage that is equivalent to the dc voltage you used in Step 1 of this experiment.

Step 3. To measure the voltage across the 18K-ohm resistor.

Leave the ground clip of the tvom clipped to the chassis. Touch the probe to terminal 14, and read the 3-volt scale of the meter. Record the meter reading in Fig. 23-4 as the voltage across the resistor in Step 3.

Remove the plug from the ac outlet. Disconnect the tvom test probes from the circuit. Unsolder and remove the .25-mfd capacitor. Unsolder and remove the lead of the 18K-ohm resistor from terminal 11 and connect this lead to terminal 8.

Step 4. To apply both ac and dc to a circuit containing the electrolytic capacitor.

You will use the circuit shown in Fig. 23-6. Solder the negative lead of the 20-mfd electrolytic capacitor to terminal 17 of the ac voltage divider. Solder the positive lead of the electrolytic capacitor to terminal 14 and the lead of the 18K-ohm resistor.

Solder the positive battery lead to terminal 8. If necessary, splice a piece of hookup wire to the lead. Check your work against Fig. 23-6.

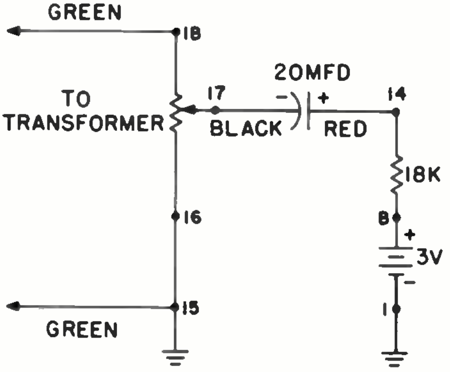

Fig. 23-6. Schematic of the circuit for Step 4.

	DC	AC	PEAK TO PEAK
BATTERY VOLTAGE	3V	☒	☒
VOLTAGE ACROSS 18K-OHM RESISTOR	0	1	2.8
VOLTAGE ACROSS CAPACITOR	3V	0	[illegible]0

Fig. 23-7. Record the values measured in Step 4.

Clip the ground lead of the tvom to the chassis. Set the function switch to dc and the range switch to 3V. Touch the probe to the positive terminal of the battery. Record the voltage in the space provided in Fig. 23-7. Move the ground clip to terminal 14. Touch the probe to the other lead of the 18K-ohm resistor at terminal 8. Record the reading in the space provided in the dc column in Fig. 23-7. This reading should be very nearly zero and indicates the amount of leakage through the electrolytic capacitor.

Clip the ground lead of your tvom to terminal 17 of the ac voltage divider. Touch the probe to the junction of the capacitor lead and the 18K-ohm resistor at terminal 14. Record your reading in the dc column of Fig. 23-7 for the voltage across the capacitor.

Set the function switch to ac and the range switch to 12V. Plug the power cord into the ac receptacle. Touch the probe to the chassis. Adjust the potentiometer until the meter indicates less than 2 volts on the 12V scale. Switch the range switch to 3V and adjust the potentiometer for exactly 1V. Move the probe to terminal 14. Read the meter and record the voltage across the capacitor in the ac column of Fig. 23-7. Compute the peak-to-peak value by multiplying the meter reading by 2.8. Record this in the peak-to-peak column.

Next, measure the ac voltage across the resistor. Unplug the power cord and clip the ground lead of the tvom to terminal 8. Plug the power cord in and touch the probe to terminal 14. Read the ac voltage across the 18K-ohm resistor. Record the reading in the space provided in Fig. 23-7. Compute the peak-to-peak value of the ac voltage across the resistor. Put the value also in Fig. 23-7. Unplug the power cord and disconnect your meter leads. Also unsolder the positive battery lead from terminal 8.

Discussion: The voltage you measured across the series resistor in Step 1 depends on the quality of the dielectric and the amount of leakage along the outside of the capacitor case. You probably will not measure any voltage drop across the resistor. If you had more sensitive measuring equipment and the dc voltage had been considerably higher, you would have measured a voltage drop across the resistor as the result of a dc flow through the dielectric of the capacitor, because no dielectric is a perfect insulator.

Of course, if we exceed the voltage rating of a dielectric, it will break down, and we no longer have a capacitor. A capacitor having a solid dielectric will block the flow of dc only if the applied voltage is kept below the rated working voltage of the capacitor.

In practical radio and TV circuits we also have to consider the effects of leakage along the outside of a capacitor. Moisture, dirt, and grease form conductive paths and decrease the effectiveness of the capacitor. It is essential, therefore, to keep equipment clean and dry.

In Step 2 you obtained some valuable experience using your tvom. Notice we first set the instrument on the 12-volt range, adjusted the potentiometer to less than 3 volts, and then switched to the 3-volt range. When you measure an unknown voltage, you should always begin by turning the range switch to one of the higher ranges. Then, when you are sure it is safe to do so, switch to a lower range to get more accurate readings.

The voltage you measured across the resistor in Step 3 with ac applied to the test circuit is clear evidence that a capacitor with a solid dielectric will pass ac. As we pointed out in your regular lesson on capacitors, the electrons do not actually pass through the dielectric of a capacitor; instead, they move to and from the capacitor plates, thus permitting a back and forth or ac flow in the circuit connected to the capacitor. As far as the rest of the circuit is concerned, the effect of this back and forth movement is the same as if the current actually passed through the dielectric of a capacitor.

You can consider that the readings you obtain in Steps 1, 2 and 3 are correct if you find that the voltage across the resistor is greater when ac is applied to the circuit than when dc is applied.

In Step 4 you worked with a circuit having both ac and dc voltages applied to the capacitor. The nearly 0 volt dc reading across the 18K-ohm resistor shows that the electrolytic capacitor blocks the dc current. This is to be expected because the dc voltage is applied with the correct polarity to the plates of the capacitor. The 3-volt dc reading across the capacitor shows that in this circuit the battery potential appears across the plates of the capacitor. When the ac voltage is applied to the circuit, the capacitor couples the ac voltage through the capacitor and almost the entire applied ac voltage appears across the 18K-ohm resistor. The large 20-mfd electrolytic capacitor offers almost no opposition to the flow of alternating current at a frequency of 60 Hertz. Therefore, the ac voltage reading across the capacitor is nearly zero. You will often find electrolytic capacitors used as coupling capacitors in transistor circuits. The value of these electrolytic coupling capacitors is frequently 5 mfd or greater.

At low audio frequencies, a sizable ac voltage develops across a capacitor of this size. You will find that the capacitors are connected in the circuit in such a way that a dc bias potential is placed on the capacitor. The dc potential has the correct polarity to prevent the voltage on the capacitor plates from reversing when an ac signal is applied to it.

Instructions for Statement No. 23: For the Statement in this experiment, you are to determine the opposition offered by your .25-mfd capacitor to the flow of 60 Hertz ac.

When we speak of opposition to ac, we actually mean impedance. However, if the ac resistance of the capacitor is very low, as it is in a capacitor with a good solid dielectric, the impedance is practically the same as the reactance of the capacitor. Therefore, although you will really determine the impedance of your capacitor for 60 Hertz ac in this experiment, you can consider your result to be its reactance at that frequency also.

To get the information you need to calculate the impedance of the capacitor, disconnect and remove the 20-mfd capacitor and the 18K-ohm resistor. Solder one lead of a 1K-ohm resistor to terminal 17 of the 1K-ohm potentiometer. Connect the other lead to terminal 14. Solder a .25-mfd capacitor from terminal 14 to terminal 5. See Fig. 23-8.

Connect the ground clip of your tvom to terminal 14 and plug the power cord into an ac receptacle. With your tvom on the 3-volt ac range, touch the probe to terminal 17, and adjust the potentiometer to give you a voltage of less than 1.2V across the 1K-ohm resistor. Switch to the 1.2V range and adjust for .5V. The current in the circuit will now be .5 milliampere or .0005 ampere.

Turn the range switch on your tvom to the 12V position, and touch the probe to the chassis. The reading on your tvom is the voltage across the capacitor with an alternating current of .0005 ampere flowing through it. Remember to read your tvom on the 12V scale when you measure this voltage.

To determine the impedance of the capacitor, all you need do is apply Ohm's Law. Divide the voltage that you mea-

$X_c = \frac{1}{2\pi F C}$

sured across the capacitor by the current (.0005 ampere), and you will have the impedance. Perform this computation and answer the Statement. Disconnect your power cord from the power line. Do not disconnect the 1K-ohm resistor and the .25-mfd capacitor. You will use them in the following experiment.

Statement No. 23: I found that the impedance of my .25-mfd capacitor was:

(1) approximately 3,000 ohms.
[✓ *(2) approximately 10,000 ohms.*]
(3) approximately 30,000 ohms.

EXPERIMENT 24

Purpose: To show that when capacitors are connected in parallel, their combined capacitance is equal to the sum of their individual capacitances; and to show that when capacitors are connected in series, their combined capacitance is less than that of the smallest capacitor.

Introductory Discussion: The capacitance of a capacitor depends upon four things: (1) the area of the plates, (2) the number of plates, (3) the distance between adjacent plates, and (4) the kind of dielectric or plate separator material used. If any one or any combination of these four things is varied, the capacitance changes.

As you have learned in your lessons, when capacitors are connected in parallel, the plate area is effectively increased. Therefore, the capacitance should increase. In this experiment, you will show that the capacitance increases, and that it is equal to the sum of the capacitance of the individual capacitors.

Capacitors can also be connected in series. As you learned in your lessons, connecting capacitors in series is electrically equivalent to increasing the thickness of the dielectric material between the plates. This should decrease the capacitance. You will show that this is actually what does take place.

To show exactly how much the capacitance changes, you will use the same procedure you used in the Statement of the preceding experiment to determine the impedance of the combination of capacitors.

The capacitance of a capacitor can be calculated by rearranging the formula for capacitive reactance, if you know the reactance and the frequency. For all practical purposes, the reactance of the capacitor at that frequency is equal to its impedance. Thus, since we know the impedance we can find the capacitance by using the formula

$$X_C = \frac{1}{6.28fC}$$

If we rearrange this formula, we can write it in the form

$$C = \frac{1}{6.28fX_C}$$

By substituting the impedance value you determine for X_C and 60 for f, you can get the capacitance in farads. You can convert this to microfarads by multiplying by 1,000,000.

As a serviceman, you will not have to make this type of calculation. Therefore, we have prepared a graph that you can use to determine the capacitance once you have the impedance. The graph is a plot of reactance in ohms at 60 Hertz plotted against capacitance in mfd. If you know the value of the capacitor, you can find its reactance in ohms at 60 Hertz. Or if you know the reactance in ohms at 60 Hertz, you can find the capacitance in mfds. You get the same information from the graph that you would get by working out the reactance formula.

The important thing for you to watch in this experiment is what happens to the total capacity when you put capacitors in parallel or in series.

Your first set of measurements will be made with two capacitors connected in parallel. The capacitance you compute should be nearly equal to the sum of the rated capacitances. Because of manufacturing tolerances, the actual capacitance will probably not be the same as the rated capacitance, so the calculated capacitance will probably be somewhat different from the sum of the rated values.

After making measurements and computations for capacitors connected in parallel, you will connect the same two capacitors in series and repeat the measurements. This time you should find that your computed capacitance is less that that of the rated value of the smallest capacitor in the combination.

Experimental Procedure: For this experiment, you need the circuit from the preceding experiment and:

1 10K-ohm resistor
1 .1-mfd capacitor (CN12)
1 .25-mfd capacitor

From now on, we will not give you step-by-step instructions for using your tvom in making all the measurements required in your experiments. We will occasionally tell you how to connect the test leads, but for the most part we will merely tell you to make the measurements and leave it up to you to set up the tvom properly from them. Of course, we will give you help when you use the instrument on a range that you have not used before in the experiments.

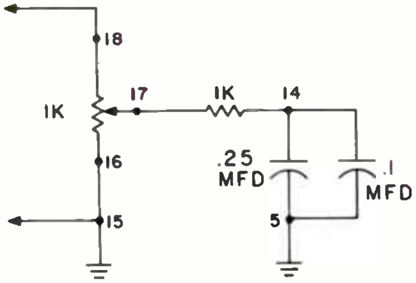

Fig. 24-1. Schematic showing capacitors in parallel across the potentiometer.

To connect the capacitors in parallel, set up the circuit shown in the schematic diagram in Fig. 24-1 and the pictorial diagram in Fig. 24-2. Since you already have the 1K-ohm resistor and the .25-mfd capacitor in place, all you need to do is connect the .1-mfd capacitor in parallel with the .25-mfd capacitor from terminal 5 to terminal 14.

Step 1. To adjust the voltage across the resistor to a fixed value.

Connect the tvom across the 1K-ohm resistor and set the range switch to 12V. Apply ac power to the voltage divider, and adjust the potentiometer to produce a meter reading of less than 1 volt on the 12V scale. Now switch to the 1.2-volt range and adjust the potentiometer to give you a voltage of .5 volt across the

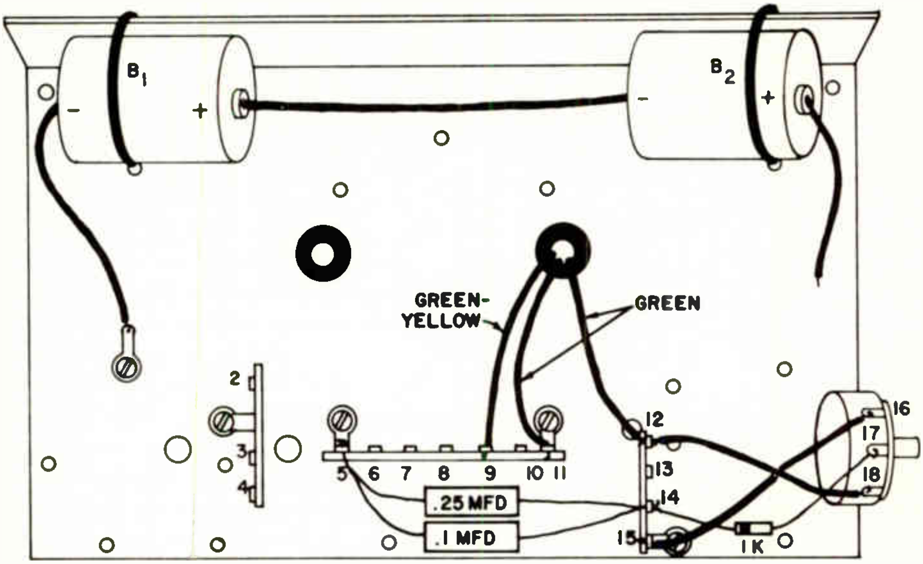

Fig. 24-2. Chassis layout for Step 1.

1K-ohm resistor. You now have a current of .5 milliampere flowing in the circuit. Adjust this voltage as accurately as you can. A small error here will cause a considerable error in your computed capacitance value. Unplug the power cord.

Step 2. To measure the ac voltage drop across the capacitors.

Switch the tvom to the 12V range and connect it across the parallel-connected capacitors. Plug the power cord into the ac outlet. Record the measured voltage in Fig. 24-3. Unplug the power cord.

Step 3. To determine the impedance of the parallel-connected capacitors.

You know the current in the circuit is .5 milliampere. To calculate the impedance, divide this current value into the voltage value you measured across the capacitors. An easy way to do this is to multiply the voltage by 10,000 and then simply divide by 5.

When we carried out this experiment in the laboratory, we had a voltage of 3.5 volts across the combination. Multiplying this by 10,000 gave us 35,000, and dividing this by 5 we got 7000 ohms as

CAPACITOR GROUPING	VOLTAGE ACROSS CAPACITORS	CURRENT IN AMPS	REACTANCE IN OHMS	CAPACITANCE IN MFD
PARALLEL	3.6V	.0005	7.2K	.35
SERIES	4V	.0001	40K	

Fig. 24-3. Results of Experiment 24.

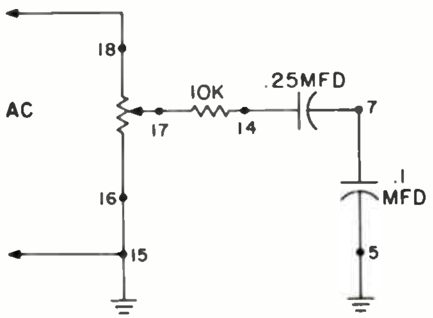

Fig. 24-4. The capacitors are connected in series.

the impedance of the combination. Your value should be reasonably close to this figure. Record the impedance you calculated in Fig. 24-3 in the column headed "Reactance in Ohms."

Connect the capacitors in series, as shown in Fig. 24-4. Unsolder the lead of the .1-mfd capacitor from terminal 14 and connect it to terminal 7. Unsolder the lead of the .25-mfd capacitor from terminal 5 and solder it to terminal 7. Unsolder and remove the 1K-ohm resistor and replace it with the 10K-ohm resistor from terminal 14 to terminal 17 of the potentiometer.

Step 4. To adjust the voltage across the resistor to 1 volt, and measure the voltage across the series-connected capacitors.

Connect the tvom across the 10K-ohm resistor. With the range switch in the 12-volt position, energize your circuit and adjust the potentiometer to give you a voltage less than 3 volts. Then switch to the 3V range, and adjust the potentiometer to give you a voltage of 1 volt.

Unplug the power cord to the voltage divider, switch the range switch to the 12V position, and connect the tvom across the two capacitors connected in series from the chassis to terminal 14. Plug in the power cord to the voltage divider and read the meter. Be sure to switch to the 3V range if the voltage is less than about 2.5 volts. Record your reading in Fig. 24-3. Disconnect the ac power.

Step 5. To determine the impedance of the series-connected capacitors.

You can easily determine the value of the current in the circuit. Since you have one volt across a 10K-ohm resistor, the current must be 1 ÷ 10,000, which is .0001 ampere. To determine the impedance, you must divide the voltage across the two capacitors by this current. Again, an easy way to do this is to multiply the voltage by 10,000. Do this and enter your value in Fig. 24-3.

Step 6. To find the net capacitance of the two capacitors connected in parallel.

Use the graph shown in Fig. 24-5. Notice the dark vertical lines. Each one of these lines represents 5000 ohms. The lines representing 30,000 and 60,000 ohms are marked. In the example we gave, where we had an impedance of 7000 ohms, we would find the vertical line representing 7000 ohms. This is the seventh line from the left. The first dark line to the right of the zero line is 5000 ohms; the second light line to the right of the 5000-ohm line is the 7000-ohm line. Now follow this line up until it crosses the curve on the graph, and then follow the nearest horizontal line to the left side of the graph.

In our example, the vertical 7000-ohm

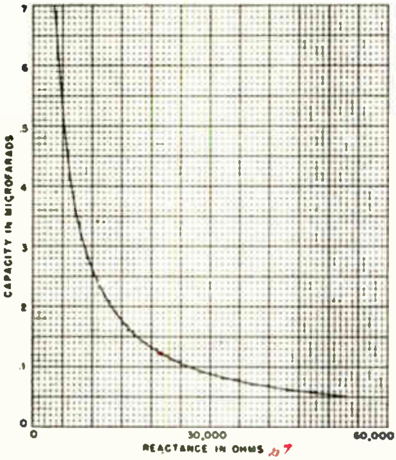

Fig. 24-5. Graphic plot of reactance in ohms at 60 cycles plotted against capacitance in mfd. You will use this graph in Steps 6 and 7.

line intersects the curve about 2 lines above the dark horizontal line, midway between .3 and .4. This dark line represents .35 mfd, and since there are five lines between it and .4 mfd, the second line above .35 represents .37-mfd. This means the parallel capacitance is .37-mfd, which is close to the value we obtain by adding .25-mfd and .1-mfd. Now, determine the capacitance of your parallel combination using Fig. 24-5.

Step 7. To determine the net capacitance of the capacitors when they are connected in series.

Use the value of reactance in ohms that you obtained in Step 5 when the capacitors were connected in series. Enter this value of reactance in the graph in Fig. 24-5 and find the value of capacitance. You should find that the total capacitance of the two in series is about .07-mfd.

Discussion: The actual value of your capacitors may be quite different from the capacitance marked on them. Most capacitors of this type have tolerances of +20% and -10%. Thus, the actual capacitance of your .25-mfd capacitor may be anything between .225-mfd and .3-mfd, and the actual capacitance of your .1-mfd capacitor may be any value between .09 and .12 mfd. Therefore, the sum of their actual capacitance may be anywhere from .32-mfd to .42-mfd, even though the sum of their rated capacitance is .35-mfd. However, as far as any of the experiments in your practical training course are concerned, you can find the capacitance of a group of capacitors accurately enough for all practical purposes by using the rated capacitance of the individual capacitors in your computations.

This experiment has proved that the capacitance of a group of capacitors connected in parallel is larger than that of any of the individual capacitors, and that the capacitance of a group connected in series is less than that of the smallest of the group. We can find the capacitance of a group of capacitors connected in parallel by adding the value of the individual capacitors. To find the capacitance of two capacitors connected in series, you can use the formula:

$$C = \frac{C_1 \times C_2}{C_1 + C_2}$$

If there are more than two in the series group, work with just two at a time, and find the net capacitance by applying the formula as many times as necessary.

Instructions for Statement No. 24: Remove the .1-mfd capacitor from the circuit and connect a .25-mfd capacitor in its place between terminals 5 and 7. You should now have two .25-mfd capacitors in series with the ac voltage source and the 10K-ohm resistor. Connect your tvom across the 10K-ohm resistor, and apply power to the voltage divider. Adjust the potentiometer for a voltage of 1 volt across the 10K-ohm resistor. Next, measure the voltage across the two .25-mfd capacitors in series. Unplug the power cord, compute the impedance, and then determine the net capacitance of the combination from the graph in Fig. 24-5. Use exactly the same procedure you followed in the experiment.

Compare the net capacitance you have computed with the capacitance of one of the two capacitors. Then, choose the answer in the Statement below and on the Report Sheet that most nearly represents the results of your comparison.

When you have done this, disconnect the 10K-ohm resistor and put it aside. Do not remove the two .25-mfd capacitors from the circuit, however. They will be used in the following experiment.

Statement No. 24: When I connected two capacitors of equal capacitance in series, the net capacitance was approximately: .12 mfd.

[✓ *(1) one-half*]
(2) four times
(3) the same as
(4) twice

that of one capacitor alone.

EXPERIMENT 25

Purpose: To show that when ac is applied to two or more capacitors connected in series, the sum of the voltage drops across the capacitors equals the source voltage; and

To show that the capacitor with the lowest capacitance will have the most voltage across it.

Introductory Discussion: In this experiment, you will show that voltage applied to several series-connected capacitors divides among them in accordance with their individual reactances. You will do so by connecting three capacitors in series, and measuring the ac voltage drop across each. You will remember that you performed a similar experiment to show that in a dc circuit the sum of the voltage drops is equal to the source voltage. This is Kirchhoff's Voltage Law. You have seen that it works for dc; you will now prove that it is also true in ac circuits.

Experimental Procedure: In addition to your chassis and tvom, the parts you need for this experiment are:

1 .1-mfd capacitor
1 47K-ohm resistor
1 18K-ohm resistor

Set up the circuit shown in Fig. 25-1 as follows:

You should have two .25-mfd capaci-

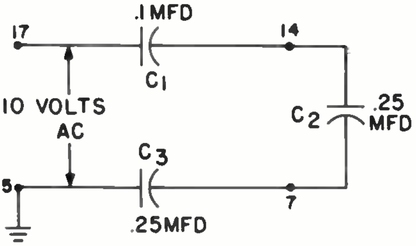

Fig. 25-1. Schematic of the circuit for Exp. 25.

$\frac{2.2V}{.0001A} = 22K\Omega$

tors connected in series, one from terminal 5 to terminal 7 and the other from terminal 7 to terminal 14. Connect one lead of a .1-mfd capacitor to terminal 14. Solder the connection. Solder the other lead of the .1-mfd capacitor to terminal 17 of the potentiometer. The chassis should now appear as shown in Fig. 25-2.

Now connect the ground clip of the tvom to the chassis. Touch the probe to terminal 17 of the potentiometer. Switch your tvom to the 12V range, apply power to the circuit, and adjust the voltage until the meter indicates exactly 10 volts.

Step 1. To measure the ac voltage across one of the .25-mfd capacitors.

You already have the ground lead of your tvom connected to the chassis ground. To measure the voltage across capacitor C_3, touch the meter probe to terminal 7. Record your reading on the first line in Fig. 25-3.

Step 2. To measure the ac voltage across the second .25-mfd capacitor.

Remove the power cord. You must do this, because it is not good practice to change the connections of the tvom while the circuit is energized. The safest procedure, both for yourself and for the tvom, is to unplug the power cord of the circuit you are working on before changing the connections of the tvom test leads. Do not plug the power cord in again until you have the tvom connected for the next measurement.

Transfer the ground clip of the tvom to terminal 7, which is the junction point of the two .25-mfd capacitors. Apply the ac power, and touch the tvom probe to terminal 14. Read the meter carefully,

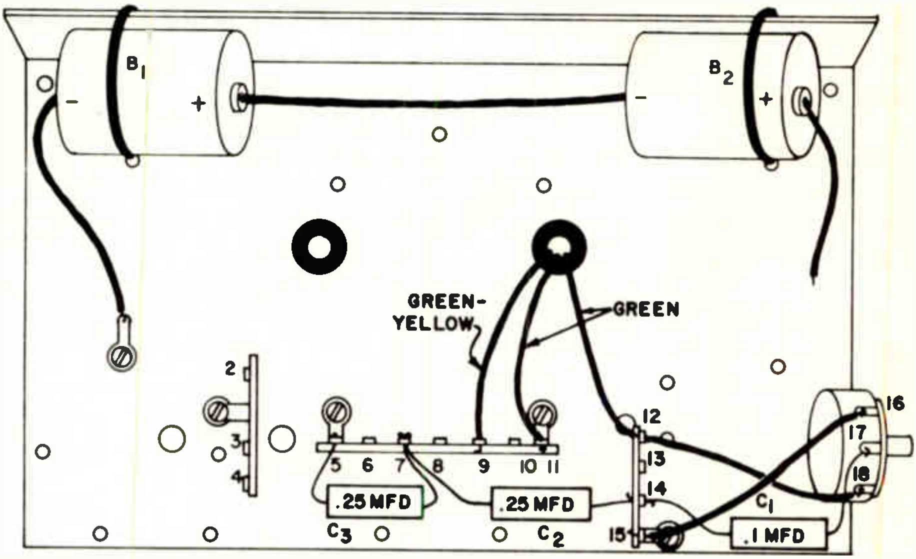

Fig. 25-2. The wiring for Step 1.

	YOUR READING
STEP 1	2.2V
STEP 2	2.15V
STEP 3	5.4V
TOTAL	9.75V

Fig. 25-3. Results of Experiment 25.

and record your reading on the second line in Fig. 25-3.

Step 3. To measure the voltage across the .1-mfd capacitor.

Unplug the power cord from the ac source, and move the ground clip to the junction of the .1-mfd capacitor and the .25-mfd capacitor at terminal 14. Then, reapply the power, touch the probe to terminal 17 of the potentiometer, and read the meter carefully. Record your voltage measurement on line 3 of Fig. 25-3.

Unplug the circuit and unsolder and remove all three capacitors from the circuit. Keep them handy for use in the Statement of this experiment.

Discussion: The voltages you recorded in the table in Fig. 25-3 should show you two things. First, the sum of the individual drops should be approximately equal to the source voltage. Add the voltages you measured in Steps 1, 2 and 3, and record the total in the space provided in Fig. 25-3. Since it is difficult to read small voltages accurately, the sum of your voltage may not be exactly 10 volts. You should, however, come close enough to be able to say that the sum of the voltage drops equals the source voltage within the limits of accuracy of your experimental measurements.

From the readings, you should also notice that the greatest voltage drop is across the smallest capacitance. Since it is the smallest capacitance that has the highest reactance at any given frequency, your measurements prove that the greatest voltage drop is across the highest reactance. The voltage drops across the two .25-mfd capacitors should be approximately equal. If you were to compute the reactance of each capacitor, you would see that the voltage drops were proportional to the individual reactances.

If you want to do this, find the reactance by using the formula

$$X_C = \frac{159{,}000}{fC}$$

in which f is the frequency in Hertz of the applied voltage and C is the capacitance in microfarads.

For example, to find the reactance of the .1-mfd capacitor, multiply 60 (the power-supply frequency) by .1. This answer is 6. Dividing this into 159,000, you get the value 26,500, which is the reactance in ohms of the capacitor at 60 Hertz. You can compute the reactance of the .25-mfd capacitors in exactly the same way.

Instructions for Statement No. 25: For your report on this experiment, you are going to determine what happens when a coupling capacitor has leakage.

A very common radio and TV circuit uses a capacitor to pass the ac signal from the plate circuit of one stage to the grid circuit of the next stage. We can simulate

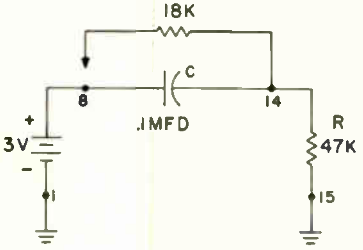

Fig. 25-4. Circuit used for Statement 25.

such a circuit as shown in Fig. 25-4. The 3-volt battery represents the plate supply, capacitor C acts as the coupling capacitor, and resistor R represents the grid resistor of the next stage. We know that ac passes through the capacitor, but should there be a dc voltage across R? Will there be if C is leaking? To find out, we will use the 18K-ohm resistor to simulate leakage in the capacitor. Wire the circuit shown in Fig. 25-4. Notice that one lead of the 18K-ohm resistor is not connected as yet.

Use your tvom as a dc voltmeter and measure the dc voltage across the 47K-ohm resistor. Make a note of your reading in the margin of this page.

0V

Next, simulate leakage in the .1-mfd capacitor by connecting the 18K-ohm resistor in parallel with it. To do this, solder the free lead of this resistor to terminal 8. Again measure the dc voltage across the 47K-ohm resistor R. Make a note of your reading in the margin.

1.6V

Unsolder and remove the capacitor and the two resistors. Leave the battery and the ac voltage divider. Complete the Statement below and on the Report Sheet.

Statement No. 25: When I simulated leakage by connecting the 18K-ohm resistor across the capacitor, I found that the dc voltage across resistor R was:

(1) the same as
[✓ *(2) greater than*]
(3) less than

it was before the leakage resistor was connected.

Using Vectors To Combine AC Quantities

In a circuit in which the resistance is the only device that opposes the flow of alternating current, the voltage drop across each resistor is in phase with the current. By this we mean that during each cycle, the voltage and current maximums and minimums occur at the same instant.

In other words, at the instant when the ac voltage is zero, the current also is zero; and at the instant the voltage is at its peak value, the current is at its peak value. Consequently, the sum of the individual voltage drops in the circuit is equal to the source voltage.

When the circuit contains reactance as well as resistance, however, the resulting phase shifts make it impossible to simply add the voltage drops, because the voltages do not reach their peaks at the same time. Complex mathematics can be used to combine ac values, but there is a much simpler graphical method. This is in the use of vectors. Vectors are important because they help you see exactly what is happening in an ac circuit. You will also use them later, particularly when you study color television.

A vector is a line whose length is proportional to the magnitude of a voltage or current, and whose position with respect to other vectors or to a reference position indicates phase relationship. In other words, both the length of the vector and its position convey information.

Fig. 9. A simple vector.

A simple vector is shown in Fig. 9. If the line OA is a voltage vector, the length of the line indicates an amount of voltage. For example, if a scale in which 1 inch equals 1 volt is being used, a line 5 inches long would represent a voltage of 5 volts. If line OA is a current vector, its length represents an amount of current, depending on the scale used.

The reference or starting position for vectors is along a line drawn to the right of the point of origin, O.

A vector is considered to rotate in a counterclockwise direction only. If it forms an angle with the reference vector and is pointing upward, it is considered to be ahead of, or leading, the reference vector. If it is pointing downward, it is considered to be lagging behind the reference vector.

For example, in Fig. 10, vector OB is said to be 90° ahead of OA, and vector OC is said to be 90° behind OA. A complete cycle is 360°. Therefore, we

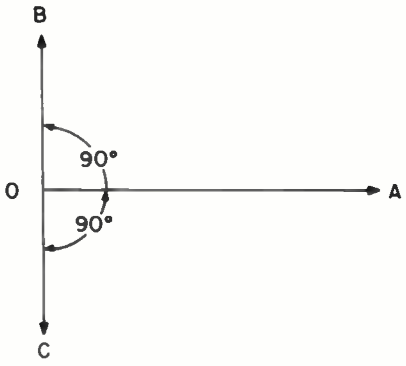

Fig. 10. Vectors show magnitude and phase.

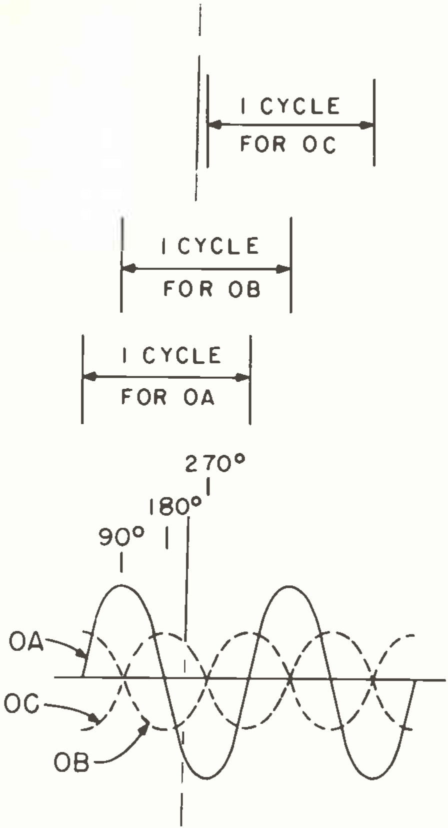

Fig. 11. Another way of showing Fig. 10 values.

could consider OC to be 270° ahead of OA; but if one cycle of OC is 270° ahead of one cycle of OA, that same cycle is 90° behind the next cycle of OA. Thus, it is customary to say that OC lags behind OA by 90° rather than leads it by 270°. This is illustrated in Fig. 11, in which each voltage is represented by a sine wave.

When two or more voltages or currents are to be compared, one vector is drawn for each. One is usually placed in the reference position and the others are drawn at an angle from the same point of origin. This angle represents the phase difference between the vectors. For example, vectors OA and OB, shown in Fig. 12A, represent two voltages. The voltage represented by OA is twice as great as the one represented by OB, and they are 90° out-of-phase. The phase difference between them is represented by the angle θ (the Greek letter theta is used to indicate a phase angle). Since the direction of rotation of vectors is always counterclockwise, we know vector OB leads vector OA by 90°. When voltage OB is one-quarter of the way through its cycle, OA is starting its cycle. The phase of two voltages or currents can be compared vectorially only if they have the same frequency so that one cycle of each frequency takes the same length of time.
